NFPA storage standards are based on full-scale fire tests and past loss experience. The standards address storage situations in which test data are available or in which conclusions could be drawn from the extrapolation of available data, judgment, or experience. Not all recognized protection technologies are equal. The NFPA standards identify the minimum acceptable level of protection for storage facilities. Operational planning or type of construction may limit the use of some recognized technologies. For this reason it is very important to understand certain protection scheme limitations before selecting a design method. For storage situations beyond the scope of a specific NFPA document, engineering judgment and other sources may be used but only with care and by professionals with an in-depth knowledge of fire protection science and practice. NFPA

James E. Golinveaux is the senior vice-president of research and development for Tyco Fire Products in Cranston, Rhode Island. He is a member of NFPA's Technical Committees on Automatic Sprinkler Systems, Parking Structures, and the Industrial Storage and Miscellaneous Occupancies.

storage documents and this chapter outline basic fire protection concepts for storage operations and can provide guidance where specific standards are not available.

To effectively prepare a fire protection plan for a storage occupancy, the following steps should be followed:

- Determine the commodity classification.
- Identify the storage arrangement.
- Establish the storage height and clearance from the top of storage to sprinklers.
- Develop a protection scheme (automatic sprinkler system).

In addition to the basic steps just outlined consideration also is needed for the following:

- Water supply
- Special commodities
- Special storage facilities
- Supplemental means of fire protection
- Construction

Changes to any one of the above, whether daily, weekly, seasonally, or over the life of the building can seriously impact the adequacy of protection. For this reason, it is very important to consider all of the storage variables that are known to exist or are expected to exist due to normal operations.

COMMODITY CLASSIFICATION

Proper design of sprinkler systems requires that the commodities to be stored are identified and categorized according to their burning characteristics. Categorizing commodities is a difficult task because a wide variety of products can be found within stored commodities. Some storage facilities are designed to support seasonal changes in commodity types and packaging. This has to be taken into consideration in selecting the worst case commodity classification. Additionally and probably the most difficult is to consider possible planned commodity changes, such as replacing steel parts with plastic. Although these changes can be handled through system upgrades in the future, it is much more cost-effective to address the known variables during the initial system design.

The classification of a commodity is based on a unit of storage of the commodity. For the most typical commodities, the unit of storage is the pallet load and includes the pallet, the packaging of the commodity, and the commodity itself. Commodity classification does not take into account mixed storage of commodities. For example, a storage area containing pallet loads of paper products, which are Class III commodities, mixed with pallet loads of Group A plastic commodities cannot be classified as Class IV storage based on the relative number of pallet loads of each commodity. The most challenging commodity (highest class number) determines protection for everything in an undivided, unseparated area. The paper products must be protected as a plastic commodity, unless the commodities are separated and each is properly protected.

The reason for this is quite simple. The fire tests on which NFPA 13 is based involve no more than a 200 ft^2 (18.6 m^2) fire area. Fires that were not confined to that size by sprinklers were typically not controlled. So the severity of a fire in mixed commodity storage is dictated by where the fire starts, not the overall mix of commodities. And, since any point of origin is possible, the most challenging point—near the most challenging commodities—sets the need for protection of the entire space.

Classifications reflect the burning rate and heat release rate of a commodity, as well as the effect of water (from sprinklers) on the commodity. For this reason, small-scale tests, which measure heat of combustion or relative horizontal burning rates, are of little use in determining commodity classification.

Full-scale fire tests can be used to determine commodity classification, but full-scale tests can be quite expensive. Intermediate-scale test methods (such as the fire products collector commodity classification method developed by Factory Mutual Research and used by FM Global and Underwriters Laboratories) provide a more economical means to accurately determine commodity classification.

NFPA Categories

NFPA 13 provides an approach that categorizes materials into one of seven major categories—Classes I through IV and Groups A, B, and C plastics. (NFPA 13 contains a comprehensive list of commodities and their classifications.) The definitions of the various commodity classifications are as follows:

- *Class I.* Class I commodities are noncombustible products in corrugated containers with or without single-thickness cardboard dividers, stored on wood pallets. The standard Class I test commodity is glass jars in compartmented cardboard cartons on wood pallets.
- *Class II.* Class II commodities are Class I products with slightly increased amounts of combustible packaging (such as multiple-layer cartons) or trim (such as plastic knobs). The standard Class II test commodity is a metal-lined double triwall corrugated carton on a wood pallet (Figure 16.5.1).
- *Class III.* Class III commodities include ordinary combustibles (wood, paper, natural fiber cloth) in cardboard cartons on wood pallets. The standard Class III test commodity is paper cups in compartmented cardboard cartons on wood pallets.
- *Class IV.* Class IV commodities are Class I, II, or III products containing limited amounts of Group A plastics in corrugated cartons and Class I, II, and III products in ordinary corrugated cartons, with limited amounts of expanded Group A plastic packaging on wood pallets. Limited amounts of Group A plastics are considered to be 5 to 15 percent by weight and 5 to 25 percent by volume. The standard Class IV test commodity is a mixture of paper and plastic cups (15 percent plastic by weight) on wood pallets.

Classification of Class I through IV commodities is based on the assumption that they are stored on wood pallets. When *unreinforced* polypropylene or high-density polyethylene plastic pallets are used, the classification of the commodity unit is increased one class (e.g., Class III will become Class IV, and Class IV will become cartoned unexpanded Group A plastics). When *reinforced* polypropylene or high-density polyethylene plastic pallets are used, the classification of the commodity unit is increased two classes, except for Class IV commodity, which will be increased to a cartoned unexpanded Group A plastic

FIGURE 16.5.1 Standard Class II Test Commodity (Source: Underwriters Laboratories)

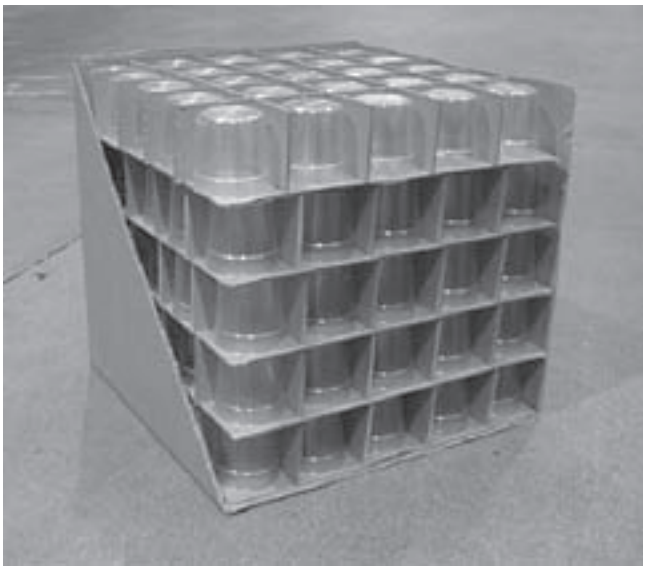

FIGURE 16.5.2 Nonexpanded Group A Test Commodity—16 oz (473 mL) Polystyrene Plastic Jars Individually Separated by Cardboard (Source: Underwriters Laboratories)

commodity (e.g., Class II will become Class IV and Class III and IV will become a cartoned unexpanded Group A plastic commodity). Plastic pallets are assumed to be reinforced if no permanent marking or manufacturer's certification of nonreinforcement is provided. This can complicate the decision to convert from wood pallets to plastic pallets in storage areas, as the existing sprinkler protection probably will no longer be adequate and will require modification. However, there now exist listed plastic pallets that can be treated as standard wood pallets for determining the commodity type.

Plastics

Plastics present a greater fire protection challenge because their combustion can produce about 1½ to 3 times as much heat per unit of weight as wood or paper. In addition, plastics can burn at a much faster rate, resulting in a very challenging, high heat release rate fire.

Plastic materials are categorized in NFPA standards into one of three groups: A, B, or C. Group A plastics present the most severe hazard (Figure 16.5.2), whereas Group C plastics present the least severe. Group B plastics behave similarly to Class IV commodities, and Group C plastics behave similarly to Class III commodities.

The following list identifies a number of plastics according to their potential fire severity. The list contains unmodified plastic materials. Although fire-retardant modifiers and other additives can inhibit ignition, once ignited, heat release is usually the same as for unmodified plastic. Intermediate or full-scale testing is the best means to determine a modified material's classification. The plastics are categorized as follows:

Group A

- ABS (acrylonitrile-butadiene-styrene copolymer)
- Acrylic (polymethyl methacrylate)
- Acetal (polyformaldehyde)
- Butyl rubber
- EPDM (ethylene-propylene rubber)
- FRP (fiberglass-reinforced polyester)
- Natural rubber (if expanded)
- Nitrile rubber (acrylonitrile-butadiene rubber)
- Polybutadiene
- Polycarbonate
- Polyester elastomer
- Polyethylene
- Polypropylene
- Polystyrene
- Polyurethane
- PVC (polyvinyl chloride—highly plasticized—e.g., coated fabric, unsupported film)
- SAN (styrene acrylonitrile)
- SBR (styrene-butadiene rubber)

Group B

- Cellulosics (cellulose acetate, cellulose acetate butyrate, ethyl cellulose)
- Chloroprene rubber
- Fluoroplastics (ECTFE—ethylene-chlorotrifluorethylene copolymer, ETFE—ethylene-tetrafluoroethylene copolymer, FEP—fluorinated ethylene-propylene copolymer)
- Natural rubber (not expanded)
- Nylon (nylon 6, nylon 6/6)
- PET (thermoplastic polyester)
- Silicone rubber

Group C

- Fluoroplastics (PCTFE—polychlorotrifluoroethylene, PTFE—polytetrafluoroethylene)

- Melamine (melamine formaldehyde)
- Phenolic
- PVC (polyvinyl chloride—rigid or lightly plasticized—e.g., pipe, pipe fittings)
- PVDC (polyvinylidene chloride)
- PVF (polyvinyl fluoride)
- PVDF (polyvinylidene fluoride)
- Urea (urea formaldehyde)

In determining the classification of a commodity that is a mixture of different materials, the amount of the most hazardous material and its effect on a fire must be considered. If the most hazardous material dominates the behavior of the burning commodity, then the product must be classified the same as the most hazardous material. For instance, thick, expanded Group A plastic packing material surrounding a Class IV commodity in a corrugated carton will completely dominate fire behavior in the early stages of the fire, when the protection battle is won or lost. So the commodity must be classified as an expanded Group A plastic.

STORAGE ARRANGEMENT

Storage configuration has a major impact on how a fire burns. Therefore, a commodity's storage arrangement must be considered when preparing the fire protection plan. Materials are most commonly arranged as bulk storage, solid pile, palletized pile, or rack storage. Bins and narrow shelves also are used, more commonly in smaller stockrooms holding moderate quantities of product. Most warehouses combine these various storage arrangements.

The most critical factor among the various storage arrangements that affect fire behavior and the difficulty of controlling a fire is the presence of flue spaces. Storage configurations create these horizontal and vertical air spaces. Air passes through flue spaces, oxidizing the fire. Although flue spaces are not desirable, they should not be obstructed when present. Obstructed flue spaces can prevent heat and combustion products from reaching a fire detector or sprinkler and also can prevent water or other fire protection media from reaching the fire.

Bulk Storage

Bulk storage consists of piles of loose, free-flowing materials, including powder, granules, pellets, or flakes, and agricultural items, such as peanuts. The materials are typically stored in silos, bins, tanks, or in large piles on the floor. Flue spaces are typically not present. Fires in large piles tend to burrow down into the pile, making them difficult to extinguish. This type of fire requires prolonged soaking to reach the seat of the fire. Bulk storage arrangements are also subject to spontaneous ignition. Fires starting inside the piles are difficult to locate, unless heat sensors immersed in the pile continually monitor internal heating.

Material handling equipment, such as belt conveyors, air-fluidizing ducts, and bucket conveyors ("legs") are often employed to transfer the material to and from its storage location. This moving process agitates and disturbs material. Airborne combustible material presents an explosion hazard. This concern is significant, especially in grain storage facilities. In addition, conveyor belts and other components can be combustible and can burn together with the commodity in inaccessible places high above the floor, in tunnels, and in housings around conveying equipment.

Solid Pile Storage

Solid piling consists of cartons, boxes, bales, bags, and so on in direct contact with each other. Air spaces, or flues, exist only where contact is imperfect, or where a pile is close to, but not touching, another pile. Because pallets are not typically used, stacking is done by hand or by lift trucks using side clamps or prongs, which are pried between packages or bales without damaging the product.

Figure 16.5.3 illustrates a type of solid piling in which spaces left between cartons accommodate lift-truck prongs. Wide aisles give the lift truck plenty of room to maneuver. The dark pipes at the ceiling are sprinkler lines.

Relative to palletized and rack storage arrangements, solid piling gives fire the least opportunity to develop and spread due to restricted air access for burning, resulting in a fire challenge less than that for palletized or rack storage. Still, high piling presents a significant fire hazard, especially where the pile's surface consists of a material susceptible to rapid flame spread properties. Also, the higher the pile, the more difficult it is to break up and separate during a fire.

Palletized Pile Storage

Palletized storage consists of unit loads placed on pallets that are then stacked on top of one another. A pallet load usually takes the form of a cube, with sides of about 4 to 5 ft (1.22 to 1.52 m), consisting of a single package or multiple packages. The top surface of the pallet load must adequately support other pallet loads so that the commodity is not crushed or so that the pile does not become unstable. Due to these considerations, the maximum height of palletized storage usually does not exceed 30 ft (9.1 m).

FIGURE 16.5.3 Example of Solid Pile Storage

Pallets contain open horizontal spaces for forklift trucks. These horizontal spaces make this storage arrangement functional, but they increase the fire hazard. Air spaces usually continue in one direction along the entire width of a pile. Like vertical flue spaces, horizontal spaces let air easily pass to the fire. In addition, their configuration lets a fire burn in the space while shielding it from the water from an overhead sprinkler system.

Early fire collapse can be a positive factor in protection of solid pile and palletized storage, but the key word is early. In order for early pile collapse to be a positive factor for fire protection, it must occur within 2 to 3 minutes of the time the first sprinkler operates. Almost any commodity in solid pile storage will ultimately collapse, but credit can be given only if it can be assured that early pile collapse will occur. In general, the great majority of stored commodities will not qualify for credit for pile collapse.

Rack Storage

A storage rack is a structural framework in which a commodity is placed, usually as a pallet load. The design of rack storage systems maximizes vertical storage capability. The ceiling height or the vertical reach of materials-handling equipment limits storage heights. Some rack storage arrangements are over 100 ft (9.3 m) high.

The most common racking configurations are single-row and double-row racks. Single-row racks include racks up to 6 ft (1.83 m) wide, separated from other storage by at least 3.5 ft (1.07 m) aisles. Double-row racks consist of two single-row racks placed back-to-back, with a combined width up to 12 ft (3.66 m) and aisles at least 3.5 ft (1.05 m) wide on each side (Figures 16.5.4 and 16.5.5). Multiple-row racks, which can use a flow-through or drive-in configuration, are also becoming more widely used. They consist of racks greater than 12 ft (3.66 m) wide, or single- or double-row racks separated by aisles less than 3.5 ft (1.07 m) wide whose overall width exceeds 12 ft (3.66 m) (Figures 16.5.6 and 16.5.7). Note that with the multiple-row, drive-in storage racks pictured in Figure 16.5.7, forklift trucks drive into the rack to deposit and withdraw loads in the depth of the rack.

FIGURE 16.5.5 Double-Row Rack Holding Pallet Loads

Bin Box Storage. Bin box storage is a variation of rack storage in which substantial (wood or metal) vertical dividers create five-sided storage bins where the only open side faces an aisle. There are no gaps between the top, bottom, sides, and the back of the bin. Bins are usually no more than 3 ft (0.91 m) wide, 3 ft (0.91 m) high, and 3 ft (0.91 m) deep, and the stored commodity does not extend into the aisle beyond the face of the bin. Storage height is usually less than 20 ft (6.1 m). This storage arrangement creates the equivalent of solid five-sided storage

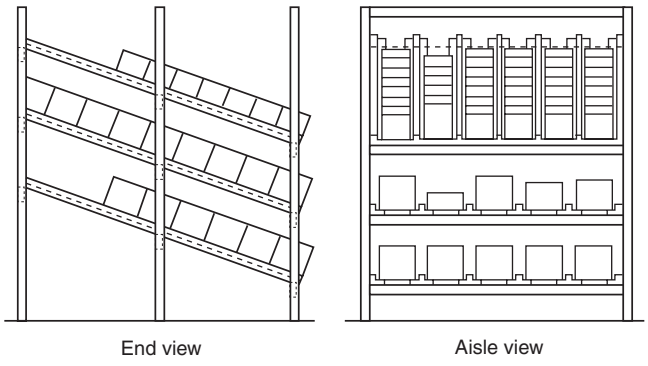

FIGURE 16.5.6 Multiple-Row Flow-Through Rack

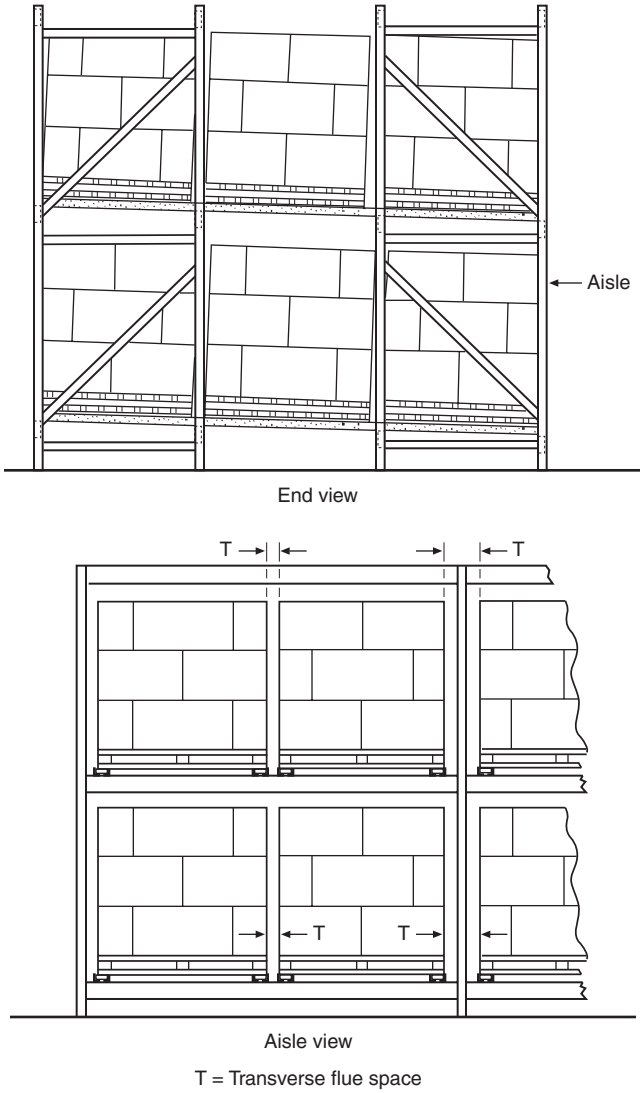

FIGURE 16.5.7 Multiple-Row, Drive-In Storage Rack, Two or More Pallets Deep

containers that limit vertical and horizontal fire spread. As a result, although the storage resembles rack storage, it can be protected as if it were solid-piled or palletized storage.

Shelf Storage. Shelf storage is another variation of rack storage, where the shelves are solid but narrow, measuring 30 in. (0.76 m) or less, and the racks are arranged in single rows, so that there is a maximum dimension of 30 in. (0.76 m) between aisles. Aisles are usually 24 in. (0.61 m) to 36 in. (0.91 m) wide. Shelves are typically less than 2 ft (0.61 m) apart vertically. And storage height is usually not greater than 15 ft (4.57 m). This storage can be protected as if it were solid-piled or palletized storage, so long as the shelf width (as measured from aisle to aisle) does not exceed 30 in. (0.76 m).

Other Types of Storage Racks. Other types of storage racks are also used. These include cantilever racks in which arms that extend horizontally from columns support the load. The load can rest on the arms or on shelves the arms support (Figure 16.5.8). Movable racks are connected to fixed rails or guides. They can be moved back and forth only on a horizontal, two-dimensional plane. A moving aisle is created as abutting racks are loaded or unloaded and then moved across the aisle to abut other racks (Figure 16.5.9). Portable racks are also used. They are not fixed in place and can be arranged in a number of configurations, as shown in Figure 16.5.10. A combination of rack and palletized storage can also be used (Figure 16.5.11).

Depending on the height and type of the rack structure, various types of materials-handling equipment can be used. These include manual and automated devices, as shown in Figures 16.5.12 through 16.5.14. Note that with the high storage racks pictured in Figure 16.5.13, stacker machines ride on floor rail, guided from the top.

Rack structures inherently create flue spaces within the storage arrangement allowing air to reach the fire. Racks also provide stability during a fire so that the burning commodity cannot collapse upon itself. As a result, fires in rack storage configurations can be the most difficult to control and extinguish.

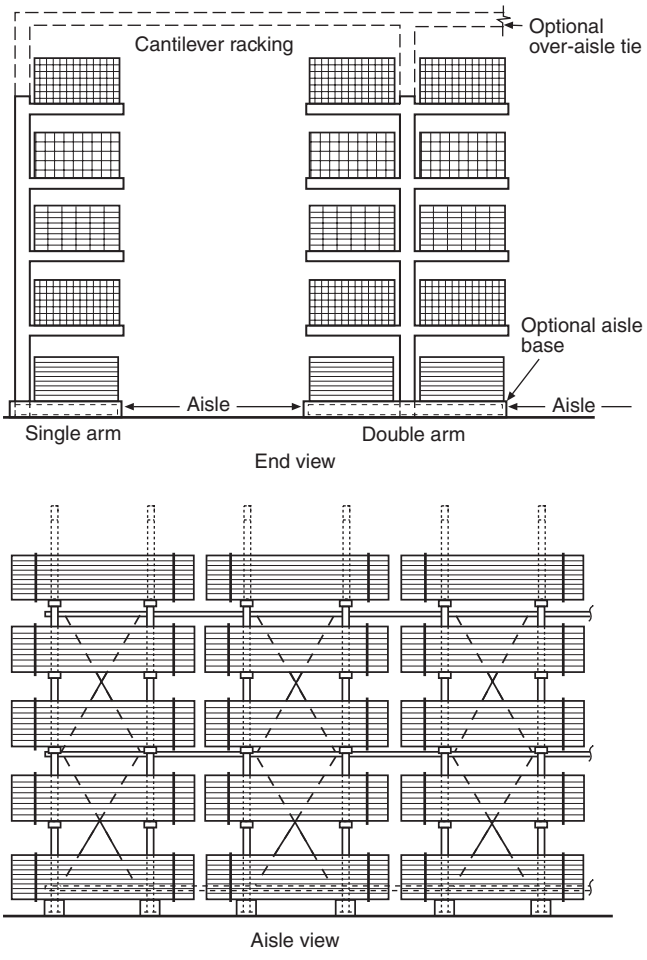

FIGURE 16.5.8 Cantilever Storage Rack

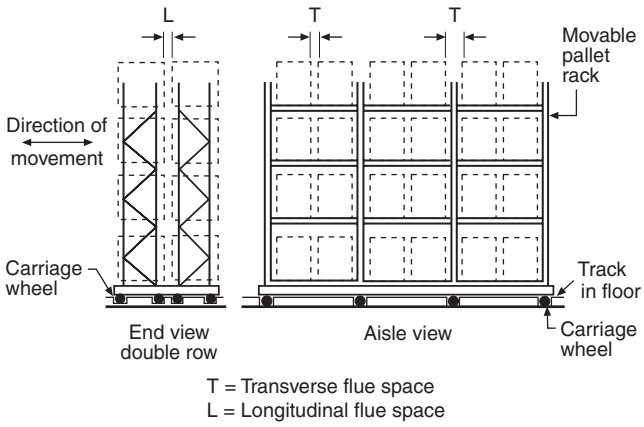

FIGURE 16.5.9 Movable Racks

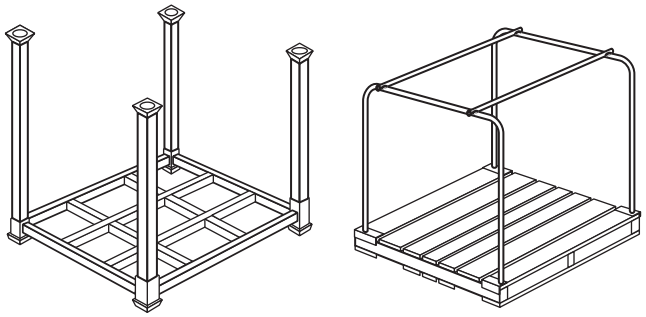

FIGURE 16.5.10 Portable Racks

Fires in racks typically burn up through flue spaces while consuming products on the racks. However, flue spaces should be kept unobstructed because they let heat from the fire reach and activate sprinklers. Flue spaces also provide a means for sprinkler discharge to penetrate the rack structure, prewet uninvolved material, and reach the fire.

Even if content damage is not severe in high-rack storage fires, heat from the fire can make the rack structure vulnerable to distortion and warping. This adversely affects materials-handling equipment because it must be accurately aligned to function properly. Such damage can impair the entire warehouse operation. Fortunately, storage racks are usually permanent structures that can support in-rack sprinklers. In-rack sprinklers are designed to contain fire to a small, localized area by reducing the horizontal and vertical spread of fire. Without in-rack sprinklers, fires in high-rack configurations can pose an impossible situation for a conventional sprinkler system installed at the ceiling. (Refer to the discussion of in-rack sprinklers later in this chapter.)

Aisle Width. Aisle spaces between stored materials let water from the ceiling sprinklers reach the fire and mitigate its spread from one storage pile or rack to another. The wider the aisle, the more advantageous it is to fire protection. In addition, aisles provide access for fire-fighting and salvage operations. Aisle widths are also a key factor in determining whether the rack arrangement is single, double, or multiple row.

For rack storage up to 25 ft (7.6 m) high, aisle widths significantly impact sprinkler system requirements. NFPA 13 provides sprinkler criteria for single- and double-row racks with 4 ft (1.22 m) and 8 ft (2.44 m) aisles as indicated in Figure 16.5.15. Interpolation is required for aisle widths between 4 ft (1.22 m) and 8 ft (2.44 m).

Racks incorporating 4 ft (1.22 m) aisles require greater sprinkler protection than those using 8 ft (2.44 m) aisles. Aisles wider than 8 ft (2.44 m) provide no more benefit than an 8-ft (2.44-m) wide aisle and, therefore, no reduction in sprinkler criteria is provided. If aisles are narrower than 3.5 ft (1.07 m), then

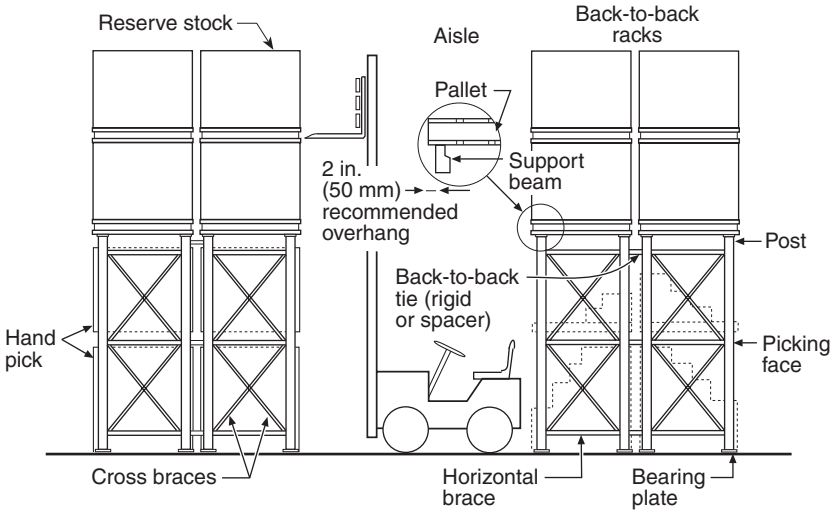

FIGURE 16.5.11 Common Arrangement of Double-Row Storage Racks with Palletized Storage Atop (Source: Unarco Material Handling, Inc.)

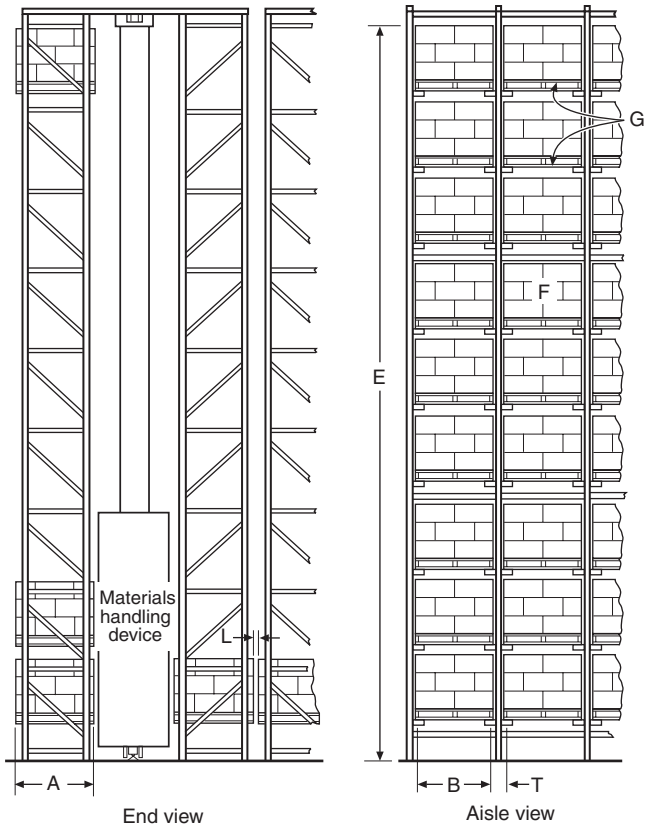
FIGURE 16.5.12 Unusual Storage Racks with Three Pallets Between Uprights—Three Transverse Flues (Source: Clark Material Handling Company)

FIGURE 16.5.13 High Storage Racks (53 ft [16 m]) with Narrow Aisle (Source: Unarco Material Handling, Inc.)

the rack arrangement is considered multiple row. Multiple-row racks demand a more powerful sprinkler system than double-row racks: the narrower aisles increase the likelihood of a fire spreading from rack to rack.



Legend

A = Load depth
B = Load width

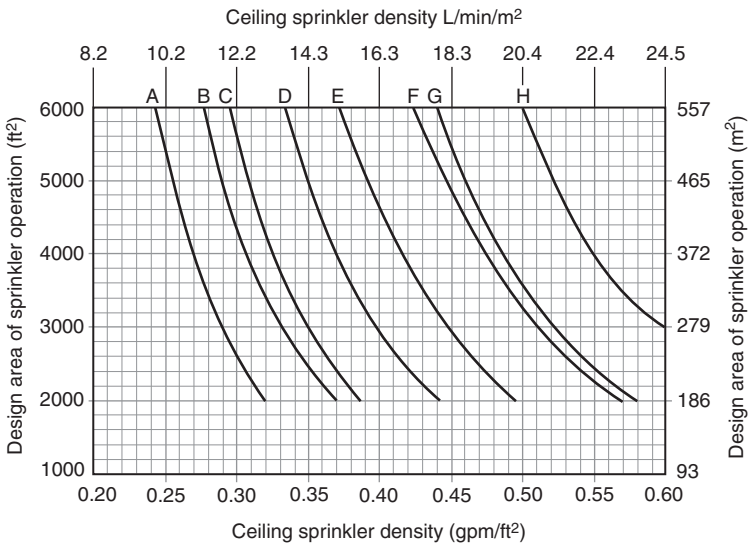
FIGURE 16.5.14 Automatic Storage-Type Rack

Aisles between palletized storage piles should not be more than 50 ft (15.2 m) wide. This lets streams from small hose lines penetrate 25 ft (7.6 m) into the center of the pile. Although NFPA 13 does not specially consider wide or frequent aisles, it assumes the presence of aisles. The aisles should be at least 8 ft (2.4 m) wide. This requirement is not unreasonable, considering that aisles are necessary for materials-handling operations and 8 ft (2.4 m) are typically needed to maneuver a lift truck. When judging the adequacy of existing sprinkler protection, aisle spacing and frequency need consideration.

STORAGE HEIGHT AND CLEARANCE

After commodity classification and storage arrangement, probably no other factor more profoundly influences a fire and its controllability than does storage height and clearance from the top of storage to sprinklers. As expected, the higher the storage arrangement, the more challenging the fire is. This is because an increase in storage height results in a larger fire size (heat release rate) at the time sprinklers operate, which in turn requires increased sprinkler performance to control.



Legend

A = Single- or double-row racks with 8 ft (2.44 m) aisles with 286°F (141°C) ceiling sprinklers and 165°F (74°C) in-rack sprinklers.

FIGURE 16.5.15 Sprinkler System Design Curves for 20-ft (6.1-m) High Rack Storage of Class IV Unencapsulated Commodities Using Conventional Pallets

Clearance also produces a significant effect on fire challenge. Increasing clearance from the top of storage to sprinklers increases the time required for sprinklers to operate in a fire of a given commodity and storage height, resulting in a larger fire size at the time sprinklers operate. Increased clearance also results in a larger fire plume above the top of storage, which reduces the ability of water from sprinklers to reach the seat of a fire.

In designing protection for a storage facility, the protection scheme must properly account for both storage height and clearance. The storage height used for design should be the maximum height expected. What may not be as obvious is that the clearance used for design should also be the maximum anticipated clearance.

NFPA 13 requires that, when ceiling heights exceed 30 ft (9.14 m) and the distance between the ceiling height and top of storage exceeds 20 ft (6.1 m), protection be provided for the storage height that would result in a 20 ft (6.1 m) distance between the ceiling height and top of storage. The clearance between the storage and the roof/ceiling is an important factor for control-mode density/area protection. Implicit in storage protection requirements is that protection for a given storage height in a building of a given height must also be adequate to protect any lesser storage height in that building. This requirement becomes necessary because warehouses are never completely full, and storage heights can fluctuate widely over both the short and long term. Clearances greater than 20 ft (6.1 m) are beyond the scope of testing used to develop the protection requirements for control-mode density/area sprinklers. Therefore, protection adequate for a storage height that results in a clearance of less than 20 ft (6.1 m) will be adequate for lesser storage heights, despite the fact that clearance exceeds 20 ft (6.1 m).

Warehouses are highly transient facilities, with the amounts of products varying widely from morning to night, week to week, and season to season. A sprinkler design cannot take advantage of low clearance (i.e., design area reductions for clearance from ceiling to top of storage less than 4½ ft [1.37 m]) unless the clearance will never be greater than that used in determining the sprinkler system design.

The minimum clearance of 18 in. (0.46 m) required below ceiling sprinkler deflectors is the minimum that will allow the proper spray pattern to develop. When early-suppression fast-response (ESFR) or specific-application control-mode sprinklers are used, the minimum clearance required is 36 in. (0.91 m).

AUTOMATIC SPRINKLER PROTECTION

Automatic sprinkler protection supplemented by manual fire-fighting operations and sound storage and housekeeping practices is the most effective and practical means of fire protection. Properly designed, installed, and maintained systems will perform their intended tasks. However, a fire protection plan incorporating an inadequate, impaired, or partial sprinkler system cannot be expected to produce good results.

Recent advances in sprinkler technology provide three basic approaches for sprinkler protection of storage operations. These include the use of (1) control-mode density-area sprinklers, (2) control-mode specific-application sprinklers, and (3) suppression-mode (ESFR) sprinklers. Each of the three approaches is associated with varying sprinkler types, sizes, and installation arrangements, thus providing a number of possible alternatives for sprinkler system design for most storage situations. There is no single "best" method for protecting a given storage arrangement, as each design must take into consideration the overall effectiveness, flexibility, and cost in relation to the design goals. Any of the protection alternatives specified in NFPA 13 for storage facilities will meet the basic goals of fire control. However, certain alternatives more effectively minimize property damage, maximize flexibility in relation to future changes in storage arrangement, or minimize cost.

The most common design approach is to determine the design that satisfies the minimum requirements of NFPA 13 at the least initial cost. Implicit in this approach is the assumption that any design that satisfies the requirements of NFPA 13 is equivalent to any other, and that the initial cost of installation is the only factor of consequence. In actual fact, minimizing the original cost of installation often doesn't even minimize the true cost of the sprinkler system over its useful life, much less maximize its overall cost effectiveness. The best approach, therefore, is to establish a comprehensive design that takes into consideration in a rational way clearly identified long-term operational and fire protection goals. This requires, in addition to an understanding of the requirements of NFPA 13 and sprinkler systems, in-depth knowledge of the strengths and limitations of the wide variety of sprinkler hardware and designs currently available and an understanding of the associated fire hazards.

Miscellaneous Storage

Most every occupancy outside of storage occupancies have some type/amount of storage. It is not the intent of the NFPA standards to trigger stringent storage rules every time incidental storage occurs in occupancy hazards. Storage protection per NFPA 13 can occur in occupancy hazards such as ordinary and extra hazards without changing the occupancy classification if the storage is incidental to the occupancy and meets the following definition:

> Storage that does not exceed 12 ft (3.66 m) in height and is incidental to another occupancy use group. Such storage will not constitute more than 10 percent of the building area or 4000 ft^2 (372 m^2) of the sprinklered area, whichever is greater. Such storage will not exceed 1000 ft^2 (93 m^2) in one pile or area, and each such pile or area will be separated from other storage areas by at least 25 ft (7.62 m).

Meeting this definition will result in an occupancy (ordinary or extra hazard) method of protection rather than a storage method of protection.

Control-Mode Density-Area Sprinklers

Control-mode density-area sprinklers are the oldest technology used to protect current storage methods. One key indicator of a control-mode density-area sprinkler is the description of the design area by a density, such as 0.3 gpm (12.2 mm/min), over an area of 2000 ft^2 (186 m^2). Control-mode density-area sprinklers are the only sprinklers that can change their minimum operating pressure by changing the spacing. The area of protection for each sprinkler dictates the minimum operating pressure, unlike control-mode specific-application and ESFR sprinklers that have a minimum operating pressure regardless of sprinkler spacing. The control-mode density-area category includes sprinklers with K-factors ranging from 5.6 (80.6) to 25.2 (362.9) in which discharge densities operating over a certain size area are selected from NFPA 13. The performance of these sprinklers in the protection of storage is characterized by the fact that the first sprinklers that operate work to contain or rather control the fire. Through a combination of prewetting of combustibles surrounding the initial fire area and cooling at roof/ceiling level, the fire is confined to a relatively small area until it is manually extinguished or burns itself out. Recent full-scale fire tests have shown that larger K-factor sprinklers have a distinct performance advantage.[1] That fact, coupled with the fact that the larger K-factor sprinklers require less pressure to achieve a specified discharge density, means that the minimum K-factor for sprinklers used to protect storage should be no less than 8.0 (115.2) and preferably 11.2 (161.4) or greater for certain applications.

NFPA 13 specifies both ceiling-only and ceiling-plus-in-rack sprinkler designs for protection of certain rack storage configurations using control-mode density-area sprinklers. Although there are a number of negative aspects associated with in-rack sprinkler protection (chief among which are installation cost and the potential for leakage due to mechanical damage), it remains the most effective and reliable method for protecting rack storage.

Control-Mode Specific-Application Sprinklers

Control-mode specific-application sprinklers are control-mode sprinklers whose performance characteristics have been enhanced through the use of orifice/deflector designs that produce larger water droplets that better penetrate a fire plume. This enhanced performance provides certain advantages over traditional control-mode density-area sprinklers. The discharge criterion for this type of sprinkler is specified as a number of sprinklers operating at a minimum pressure rather than a minimum density and design area.

The first control-mode specific-application sprinkler was the large-drop sprinkler. More recently, control-mode specific-application sprinklers with larger K-factors have been developed. The design requirements and applications of various types of control-mode specific-application sprinklers can differ and are based on fire testing. It cannot be assumed that, because one type of control-mode specific-application sprinkler is permitted by standards for protection of a type of storage, other types of control-mode specific-application sprinklers may be used.

Suppression-Mode Sprinklers

Suppression-mode, or ESFR, sprinklers are a radical departure from control-mode sprinkler technology and come with their own unique set of strengths and limitations. The fundamental premise of suppression-mode sprinkler protection is that a sensitive sprinkler capable of producing an optimized high-volume, high-momentum discharge can actually suppress (rather than simply control) a fire in storage. The primary advantage of suppression-mode sprinklers is their ability to protect many rack storage arrangements without the need for in-rack sprinklers. Although they are much more effective in protecting such storage than ceiling-only control-mode sprinklers, they are no more effective than a ceiling/in-rack sprinkler design using control-mode sprinklers. They also have their own quite complex and sensitive installation rules.

Comparison of Types of Sprinkler Protection

Looking at the design requirements for 20-ft (6.1-m) high storage of Class I to IV storage protection provided by the previously referenced technologies will help to develop an understanding of the different protection options available. Tables 16.5.1 through 16.5.7 show the design requirements for the protection of 20-ft (6.1-m) high storage of Class I to IV storage using the three types of sprinkler protection. Notice the effect of storage arrangements and encapsulation on control-mode density-area sprinklers, whereas there is little effect on control-mode specific-application sprinklers and no effect on suppression-mode sprinklers. Although there are many other commodities and storage heights, these simple comparisons will give the user a better understanding of the different protection methods available for a single commodity class.

Control-Mode Density-Area Sprinklers. The effect of the storage arrangement is shown for control-mode density-area sprinklers by interpreting the design density curves in NFPA 13 for 20-ft (6.1-m) high Class IV storage. Tables 16.5.1, 16.5.2, and 16.5.3 show the design densities required at a 2000 ft² (186 m²) hydraulically remote area (unless noted otherwise) for palletized/solid-piled, single-/double-row rack, and multiple-row rack, respectively. Minimum operating pressure changes with spacing. Density is applied based on the actual floor coverage area. Although clearance or ceiling height limitation are not in the protection table for control-mode density-area sprinklers, the clearance is limited to a 20 ft (6.1 m) maximum (see the previous discussion in Storage Height and Clearance).

Control-Mode Specific-Application Sprinklers. Spacing of control-mode specific-application sprinklers (from their

minimum to maximum allowable spacing) does not affect the minimum operating pressure required in the tables. Notice the addition of ceiling/roof height to Tables 16.5.4 and 16.5.5, which is important to the system design.

Suppression-Mode Early-Suppression Fast-Response (ESFR) Sprinklers. Notice that the ceiling/roof height is now the primary factor in determining the appropriate design criteria (see Tables 16.5.6 and 16.5.7). Unlike control-mode technology, the ESFR is not affected by clearance between the top of the storage and the sprinkler at the ceiling. It is one of the first technologies providing protection for the full height of the building and will not be affected by changes in storage heights. Spacing of ESFR sprinklers (from their minimum to maximum allowable spacing) does not affect the minimum operating pressure required in the tables.

In-Rack Sprinklers

Rack structures inherently create obstructions to rising heat and combustion products from a fire and to water discharge from a ceiling sprinkler system. As a result, a fire in racks can become very challenging, quickly overpowering most ceiling sprinkler systems. This phenomenon becomes more pronounced when storage heights increase and when both horizontal and structural flue spaces become obstructed. Sprinklers installed in racks alleviate this concern.

In-rack sprinklers work to contain a fire in a small, localized area. Once activated, they discharge water on or near the fire's source, without the delay associated with conventional ceiling sprinklers. In-rack sprinklers also prewet the area directly near the fire, thus reducing horizontal and vertical fire spread. In-rack sprinklers also minimize the potential water damage to stock because water is only applied to the localized area of the fire, usually eliminating the activation of the ceiling sprinkler system. Using in-rack sprinkler systems also reduces the demand on the ceiling sprinkler system and uses water supply more efficiently.

In-rack sprinklers are installed in the longitudinal flue spaces of the rack structure. As rack height increases, additional in-rack sprinklers may also be needed in the transverse flue spaces within 18 in. (0.49 m) of the aisle. Such in-rack sprinklers, referred to as "face sprinklers," protect against fire spread over the rack's vertical face and help prevent a fire from jump-

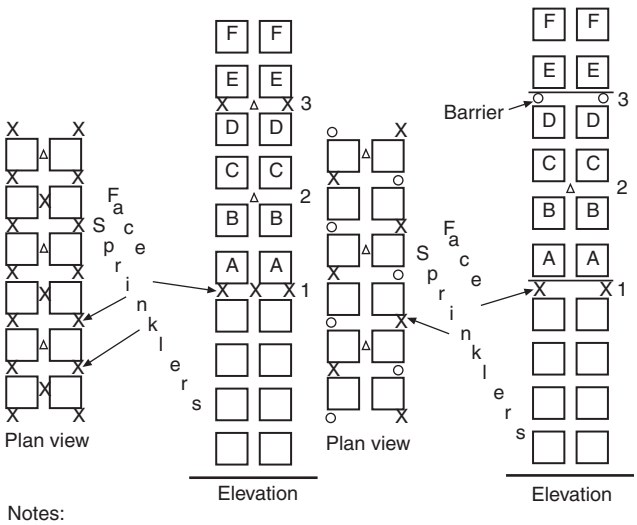
ing across the aisle to an adjacent rack. In some cases solid horizontal barriers covering the rack's entire length and width are also used with in-rack sprinklers. These barriers help activate the in-rack sprinklers and reduce the number of in-rack sprinklers needed. Figure 16.5.16 illustrates these concepts. Note in Figure 16.5.16 how horizontal barriers within the racks (right) reduce the number of in-rack sprinklers required (left). The symbols O, Δ, and X indicate sprinklers installed in a vertical or horizontal alternating or staggered arrangement on the sprinkler piping.

Sprinklers installed in racks can be standard or fast-response type with standard or large orifices. Ordinary-temperature-rated sprinklers should be used. However, intermediate-temperature- and high-temperature-rated sprinklers are required near heat sources. Water shields are required to guard against cooling or cold soldering of unactivated sprinklers by the water spray from in-rack sprinklers located higher in the rack. Figure 16.5.17 illustrates typical in-rack sprinklers. The upright standard-response sprinkler is shown on the left and the upright fast-response sprinkler is shown on the right. Pendent sprinklers can be field-equipped with water shields. The fast-response type is appropriate for protection under open-girded catwalks between racks, shelves, or bins.

The need for in-rack sprinklers depends on a number of factors, including the condition and type of ceiling sprinkler system, commodity type, and storage height. Generally, when spray sprinklers are used, in-rack sprinklers are required for rack storage over 25 ft (7.6 m), regardless of the commodity. For storage up to 25 ft (7.6 m), the need for in-rack sprinklers varies. When ESFR sprinklers are used, in-rack sprinklers are



Notes:
1. Sprinklers labeled 1 required where loads labeled A or B represent top of storage.
2. Sprinklers labeled 1 and 2 required where loads labeled C or D represent top of storage.
3. Sprinklers labeled 1 and 3 required where loads labeled E or F represent top of storage.
4. For storage higher than represented by loads labeled F, the cycle defined by Notes 2 and 3 is repeated.
5. Symbols O, Δ, and X indicate sprinklers on vertical or horizontal stagger.
6. Each square in the figure represents a storage cube measuring 4 to 5 ft (1.25 to 1.56 m) on a side.

FIGURE 16.5.16 In-Rack Sprinkler Arrangement for Class I, II, or III Commodities, with Storage Heights over 25 ft (7.6 m)

FIGURE 16.5.17 Typical In-Rack Sprinklers (Source: Grinnell Fire Protection Systems Co., Inc.)

not required in most cases. (See the discussion of sprinkler response time later in this chapter.)

NFPA 13 provides criteria to determine if in-rack sprinklers are necessary, their number, and arrangement. Various combinations of in-rack sprinkler installations have been found effective, so several design options are available.

Sprinkler Spacing

NFPA 13 provides the minimum and maximum spacing for the different types of sprinklers. It is just as important to recognize the minimum spacing requirements as the maximum spacing requirements to prevent the cold solder and skipping of adjacent rings of sprinklers in the event of a fire. The maximum spacing for most sprinklers is 100 ft^2 (9.3 m^2), whereas extended coverage sprinklers may be spaced at 196 ft^2 (59.7 m^2) for storage applications.

Temperature Rating of Ceiling Sprinklers

In control-mode sprinkler protection, the temperature rating of a sprinkler can exert a significant effect on the number of sprinklers that operate. Due to the comparatively weak performance of smaller-orifice sprinklers, ceiling gas temperatures can be high, even though control is achieved. This means that sprinklers further away from a fire can operate, and that fact must be taken into consideration in design. For larger-orifice control-mode and ESFR sprinklers, this effect is minimized and lower-temperature-rated sprinklers do not pose as great a concern.

Sprinkler Response Time

With the exception of ESFR sprinklers, testing has shown[2] that quick-response sprinklers offer neither significant advantages nor disadvantages in the protection of storage. However, NFPA 13 specifies the use of standard-response sprinklers unless quick-response sprinklers listed for storage applications are to be used. The same design requirements apply equally to both types.

Protection System Types

Dry Pipe Versus Wet Pipe Sprinkler Systems. In a wet pipe sprinkler system, the piping attached to the automatic sprinklers contains water under pressure at all times. In a dry pipe system, the piping contains air or nitrogen under pressure. When a sprinkler operates in a dry pipe system, air pressure is reduced, a dry pipe valve opens, water enters the piping, and after a short delay flows out the open sprinklers. Dry pipe systems should only be used in areas subject to freezing temperatures. Refer to Section 16, Chapter 3, "Automatic Sprinkler Systems," for discussions of various types of sprinkler systems.

Where dry pipe systems are used, the time delay associated with water delivery lets a fire grow and spread heat that in turn can activate more sprinklers beyond the immediate fire area. To compensate, the required design area of sprinkler operation usually increases by 30 percent for dry pipe systems. Density should be selected so that, after the 30 percent increase, the design area does not exceed the maximum allowable design area of sprinkler operation.

High-Expansion Foam. Although automatic high-expansion foam extinguishing systems can independently suppress a fire, some are reluctant to use them as the sole means of automatic fire control in certain cases. They are usually more expensive and more complicated than sprinkler systems, do not protect the roof structure until foam reaches it, involve the entire contents of a protected area regardless of the fire's size, and leave foam residue on unburned materials. However, they can be desirable when used with automatic sprinklers for certain high-challenge storage occupancies. A high-expansion foam system uses a series of foam-makers at ceiling level. When activated by the fire detection system throughout the area, the foam system sprays

water mixed with special foam concentrate in each foam-maker and strikes a screen while a fan blows through it. The system produces many uniformly sized bubbles, which cascade down into and gradually fill the warehouse area. The foam's expansion ratio is up to 1000:1. It flashes to steam on contact with burning material and engulfs other material, keeping it from burning. Building doors should automatically close when the system activates.

When high-expansion foam systems combine with ceiling sprinkler systems, the ceiling sprinkler discharge density may be reduced to one-half the density otherwise required. However, the density cannot be less than the following:

- 0.15 gpm/ft^2 (6.1 L/min/m^2) for Class I through IV solid-piled or palletized commodities, including idle pallets or plastics
- 0.24 gpm/ft^2 (9.8 L/min/m^2) for rubber tire storage
- 0.25 gpm/ft^2 (10.2 L/min/m^2) for roll paper storage

In-rack sprinklers are not required for rack storage when high-expansion foam is installed. In addition, ceiling density can be reduced to 0.2 gpm/ft^2 (8.1 L/min/m^2) for Class I, II, and III commodities, and to 0.25 gpm/ft^2 (10.2 L/min/m^2) for Class IV commodities.

WATER SUPPLY

The water supply must adequately supply the demands of the ceiling sprinklers, in-rack sprinklers if used, and hose streams. NFPA 13 outlines hydraulic calculations for determining the demand of the sprinkler system, including in-rack sprinklers. Sprinkler demand is expressed as a flow rate, such as gal/min (L/min), at a corresponding minimum residual pressure. Typically 500 gpm (1894 L/min) is added to the sprinkler demand for large and small hose streams. Hose streams are intended to operate concurrently with the sprinkler system, so the residual pressure demand for the sprinklers is typically used.

The sprinkler system piping design (i.e., pipe size, fittings, and material), affects the residual pressure. In general, at least 30 to 50 psi (207 to 345 kPa) pressure is needed at the ceiling-level distribution point or top of the riser. When greater pressure is available, more economic system design is possible. However, exposing the most remote conventional sprinkler to pressures over 60 psi (414 kPa) is undesirable. High pressures may create very fine, but not very effective, spray patterns.

The water supply needs to be available long enough for the sprinklers to control the fire, manual fire fighting, and mop-up operations. Two hours are typically required. However, if a central station monitors the fire alarms, this period can be reduced to 90 minutes.

The reliability of available water supplies also needs consideration, especially for high-value locations. A multiple-supply arrangement (e.g., a fire pump connected to a suction tank in conjunction with an adequate public supply) might be advantageous. Such redundancy is based on engineering judgment. For example, a $100 million warehouse may be connected to a single city water main. Although the supply may be adequate, it is possible that supply could be out of service for some time or deteriorate.

The layout of yard mains, tanks, pump houses, power supply to pumps, hydrants, and valves warrants qualified fire protection engineering attention in the planning stage. To correct a water supply deficiency, alternate methods can be considered. The factors discussed earlier offer such alternatives. Adding a booster fire pump may be an economical alternative for a sprinkler system requiring high pressure. On the other hand, it may be more economical to do one of the following:

- Upgrade the piping layout only in that system
- Replace ceiling sprinklers for that system with ones of a different temperature rating
- Install in-rack sprinklers in that area
- Lower pile heights in that area (not a good long-range solution)
- Combine methods

SPECIAL COMMODITIES

Many commodities have been studied separately because of the fire properties associated with their physical form, method of storage, and difficulty of fire control. The following describes some of the unique characteristics of special commodities.

Idle Pallets

Pallets used as storage aids are considered part of the commodity classification. Pallets are approximately 4 in. (102 mm) high and usually composed of wood or plastic, although some are metal or cardboard. A pallet's main purpose is to aid storage practices by allowing products to be moved easily by forklift trucks and to provide stability. The commodity classification does not include idle pallets because of their unique combustion characteristics. When stored outdoors, all types of pallets should be located away from a building at the distances indicated in Table 16.5.8.

Wood Pallets. Stockpiling idle pallets indoors or outdoors presents a very severe fire hazard. Wooden pallets tend to dry out so their edges become frayed and splintered. In this condition, a relatively small ignition source can ignite them. Their dried-out condition, high rate of heat release, and overall arrangement result in a quickly developing fire. The undersides of the slats or planks, shielded from the discharge of automatic sprinklers, make controlling or extinguishing a fire difficult. Figure 16.5.18 shows a conventional wooden pallet.

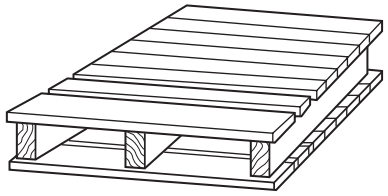


FIGURE 16.5.18 Conventional Wooden Pallet

TABLE 16.5.8 Recommended Clearances Between Outside Idle Pallet Storage and Building

Wall Construction		Minimum Distance (ft [m]) of Wall from Storage Of		
Wall Type	*Openings*	*Under 50 Pallets*	*50 to 200 Pallets*	*Over 200 Pallets*
Masonry	None	0	0	0
	Wired glass with outside sprinklers 1 hour doors	0	10 (3.0)	20 (6.1)
	Wired or plain glass with outside sprinklers ¾ hour doors	10 (3.0)	20 (6.1)	30 (9.1)
Wood or metal with outside sprinklers		10 (3.0)	20 (6.1)	30 (9.1)
Wood, metal, or other		20 (6.1)	30 (9.1)	50 (15.2)

The fire hazard idle pallets present can be mitigated by strictly limiting storage arrangements and employing an appropriate sprinkler system or by moving idle pallets outside and away from the building. Tables 16.5.9, 16.5.10, and 16.5.11 list protection criteria found to be effective for pallets stored indoors. However, the provisions of these tables need not be applied if the idle pallets meet any of the following conditions:

- Stacked no higher than 6 ft (1.8 m)
- Stored in piles not exceeding four stacks
- Stored in piles separated by a distance of 8 ft (2.4 m) from one another or by 25 ft (7.62 m) of commodity

Plastic Pallets. Plastic pallets other than nonexpanded polyethylene solid-deck pallets present an even greater fire hazard. Additional precautions must be taken. Refer to NFPA 13 for details.

Rubber Tires

Fires in rubber tires are very hot, smoky, and difficult to control and extinguish. High sprinkler densities are needed to control the fire and protect the building. (See NFPA 13.)

Tires are stored in piled form, in compact portable racks referred to as pallets, and in racks. They may be arranged on tread,

on side, or in a laced configuration (Figure 16.5.19). Because tires are not packaged, they contribute their own circular air space to the storage, forming considerable horizontal or vertical flues. Interiors of tire carcasses can flame vigorously, mostly beyond the reach of water from sprinklers. Final extinguishment involves laboriously applying water to individual tires, usually after removing them from the building.

Combined with sprinklers, high-expansion foam is very effective on rubber tires and causes minimal water damage or contamination. To fully penetrate the inner reaches of the tires, an additional hour of foam soaking is advised after the sprinklers are shut off to maintain the foam level.

Roll Paper

Roll paper is stored on its side or, more commonly, on end. One might assume that the latter arrangement permits easier paths for sprinkler water to penetrate the vertical air spaces and slow the fire, but experience with roll paper shows otherwise. In storage on end, peeling or exfoliation during a fire is a major concern. This phenomenon can be abated somewhat by metal banding, tightly applying steel baling wire by hand, covering ends as well as sides with fire-retardant-treated tight paper wrappers or closely spacing the columns of rolls. In effective close spacing, stacks or columns are less than 4 in. (101 mm) apart.

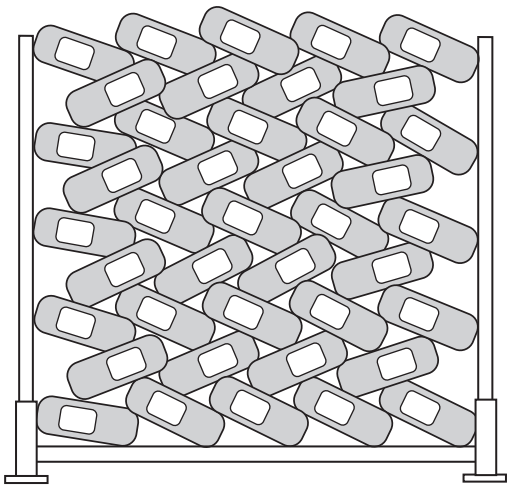

FIGURE 16.5.19 Laced Tire Configuration

NFPA 13 prescribes sprinkler density-area requirements according to the rolls' arrangement, whether they are banded or unbanded, the piles' height, and the paper's weight (i.e., heavy, medium, light, or tissue). Because rolled paper tends to absorb water from a discharging sprinkler and swells in size, it should be stored with sufficient clearance from walls.

Carpet Storage

Rugs or carpeting in rolls are generally stored in racks that accommodate 12- to 15-ft (3.7- to 4.6-m) long rolls. Therefore, racks are at least that deep and sometimes placed back-to-back, forming a total width of 24 to 30 ft (7.3 to 9.1 m) between aisles. Of course, small carpet pieces and rolls may be placed in cartons and stored in regular solid or palletized piles or conventional racks.

Long carpet rolls will deflect if their length is not supported, so solid or slatted shelves are used in wide racks, or in some cases, rolls of carpet are stored in paperboard tubes. A strict application of NFPA 13 requirements for solid-shelf rack storage would require in-rack sprinklers under each solid or slatted shelf in racks, unless transverse flue spaces at least 6 in. (152 mm) wide are provided no more than 4 ft (1.22 m) apart. With carpet racks having only one tier for each roll of carpet, installation of in-rack sprinklers becomes problematic. A reasonable compromise is to provide minimum 3-in. (51-mm) wide transverse flue at all vertical supports, which are normally 10 to 12 ft (3 to 3.7 m) apart, and providing in-rack sprinklers (including face sprinklers) at approximately every third tier, with a maximum vertical dimension of 10 ft (3.05 m) between levels of in-rack sprinklers.

Figure 16.5.20 illustrates racks for storing carpeting on slatted shelves. The tiers' closeness to each other, plus their depth, complicates problems of providing in-rack sprinkler protection.

Carpet Padding

Padding or backing for carpet is typically expanded plastic. When stored in carpet warehouses, it should be protected as an expanded plastic, which will typically require in-rack sprinklers at every level of storage.

Baled Fibers

The main hazard of baled cotton and other fibers of vegetable origin comes from the multitude of exposed minute fibers on

FIGURE 16.5.20 Racks for Storing Carpeting on Slatted Shelves (Source: Clark Material Handling Company)

the surfaces of the bales. Fire can flash quickly over these vertical surfaces, loose particles on the floor, and lint on overhead piping and structure. Fire on one side of an automatic-closing fire door can progress through the open doorway on loose floor scraps before the door can close automatically. Housekeeping, therefore, is especially important.

Fire also can easily penetrate between and into bales, requiring their removal from the building for extinguishment. Considerable smoke emission can complicate fire fighting. Certain fibers, such as jute, swell when wet, so they should be piled with regard to stability in a fire and with proper clearance from walls.

NFPA 13 limits the height of tiered or rack storage to 15 ft (4.6 m) and pile sizes to 700 bales, with a 12 ft (3.7 m) main aisle and 4 ft (1.2 m) cross aisles, in maximum fire divisions of 10,000 bales. The standard calls for large operating areas for sprinklers. (Factory Mutual Research Corporation's Loss Prevention Data Sheet 8-7 covers baled combustible fibers generally, including wool, which burns much more slowly than most fibers.)

Ordinary dry chemical (BC-type) fire extinguishers very effectively knock down surface fires on bales. However, they should be backed up by water spray from small hose or garden hose or by water-type extinguishers with spray nozzle attachments to extinguish smaller fires that may have penetrated the bales. Preferably, "wet water," which is water with a chemical additive that increases its penetrating and spreading ability, should be used.

Baled Waste Paper

Like baled fibers, baled wastepaper is typically stored in solid piles in which fire can easily burrow. Fire can flash over the surface of finely shredded paper bales, as it does over baled fiber. Wastepaper becomes mushy and difficult to handle when wet; in fact, the bales' integrity slowly disappears as the hose stream application progresses, making removal of burning bales difficult. Smoke can also be troublesome. Baled paper sometimes is stored at great heights because of its low unit value, but fire protection standards utilizing conventional sprinklers do not apply to storage over 30 ft (9.1 m) high, except in racks. Baled wastepaper is often stored in sheds with only partial walls, if any. Anecdotal loss experience suggests that even relatively light winds can significantly increase the intensity of baled wastepaper fires. It is best that, wherever possible, baled waste storage be well separated by distance or substantial walls from valuable equipment or finished goods.

Pesticides

Poisonous to insects and small animals, pesticides can harm and even kill humans when ingested or breathed as combustion products. They are stored as solutions in flammable or combustible liquids, as powders or granules in combustible packages, or as compressed gases for fumigation. Special attention must be given to the personnel hazard in addition to the commodity's combustibility. Pesticide fires can endanger persons fighting the fire or standing nearby, and poisonous runoff from fire fighting can pollute water or soil in the area.

Automatic sprinkler protection is advisable with provision for safe accumulation and disposal of water runoff. Fire-fighting strategy should include plans to use protective clothing and respiratory equipment, spray nozzles rather than straight streams to reduce water runoff, and specialized medical backup services. Container breakup and pesticide dispersal must be avoided. NFPA 434, *Code for the Storage of Pesticides,* gives general requirements for both inside and outside storage of pesticides.

SUMMARY

Protecting storage facilities from fire presents a particular challenge. An efficient use of space, such as small flues between stored materials, is also conducive to maximum burning rate and fire spread. An effective fire protection strategy needs to take into account various factors, including the commodity classification, the storage arrangement, the storage height and clearance from top of storage to sprinklers, water supply, and construction. These factors and others determine the sprinkler types, designs, sizes, and installation arrangements of the automatic sprinkler system.

Incentives for More Widespread Use of Residential Sprinklers

Key Terms

automatic sprinkler system, Home Fire Sprinkler Coalition, quick-response (QR) sprinkler, residential sprinkler system, response time index (RTI)

Automatic sprinkler systems have been successfully used to protect industrial and commercial buildings and their occupants for more than 100 years. Historically, the place that has offered the least amount of fire protection to occupants was and still is their own home. This situation was brought to light in 1973 by the Report of the National Commission on Fire Prevention and Control, *America Burning.*[1] At the time of the report, approximately 8000 people died in fires every year in the United States. Eight out of ten of those victims died in their homes.

In the more than 30 years since *America Burning* was published, the number of lives lost in fires in the United States has decreased to less than 4000 per year. Unfortunately, 8 out of 10 victims still die in home structure fires.[2] Although residential sprinkler installations are increasing, it is estimated that less than 3 percent of all residential dwellings in the United States have them installed.[3]

In response to the information from the *America Burning* report, the National Fire Protection Association's Technical Committee on Automatic Sprinklers assigned a subcommittee to develop a standard for residential sprinkler systems in 1973. NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes,* was adopted in May 1975, based on expert judgment and the best information available at that time.

Significant testing and development of residential sprinkler systems has continued since then, resulting in the evolution of NFPA 13D and the development of NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height.*

The purpose of a residential sprinkler system built to the standard is to "provide a sprinkler system that aids in detection and control of residential fires, and thus provides improved protection against injury, life loss, and property damage."[4] From a performance perspective, if the room of fire origin is sprinklered, a sprinkler system designed and installed in accordance with the residential sprinkler standards is expected to prevent flashover and improve the occupant's opportunity to escape or to be rescued.[4]

Residential sprinkler systems designed and installed in accordance with NFPA 13D or NFPA 13R have significantly different requirements than those for residential occupancies designed in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems.* NFPA 13D and NFPA 13R systems have been optimized for certain types of residential occupancy buildings in an effort to minimize the cost of the system while improving the degree of fire safety.

New developments in residential sprinkler system technology continue to be made in an effort to increase the ease of installation and reduce the cost of installation while maintaining the effectiveness and reliability of the system. Residential sprinkler systems have been required in dwellings in several communities for more than a decade. Information from these communities is providing compelling data concerning the effectiveness of residential sprinkler systems. These data, in addition to code requirements and other incentives, are increasing the numbers of sprinkler installations around the country.

Daniel Madrzykowski, P.E., is a fire protection engineer with the Building and Fire Research Laboratory of the National Institute of Standards and Technology in Gaithersburg, Maryland. He has served on many different NFPA technical committees, including the Technical Committee on Residential Sprinkler Systems.

Russell P. Fleming, P.E., is executive vice-president of engineering for the National Fire Sprinkler Association, Inc., in Patterson, New York. He has served on more than a dozen different NFPA technical committees, including the Technical Correlating Committee on Automatic Sprinklers.

For related topics, see Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection"; and Section 16, Chapter 8, "Water Mist Fire Suppression Systems."

DEVELOPING A SPRINKLER SYSTEM IN RESPONSE TO THE HOME FIRE PROBLEM

The development of a residential sprinkler standard with the main focus on life safety required a multifaceted approach. Fire incident data had to be collected and analyzed to obtain an understanding of the nature of the residential fire safety problem. In addition, technical challenges had to be overcome to develop an effective, practical, and economically acceptable residential sprinkler system design.

The more common home fire hazards had to be characterized in terms of leading areas of origin. The rankings and percentages have changed little since then, and more recent data are shown in Table 16.6.1, which demonstrates the number of fire fatalities and injuries based on the area of origin. Over 50 percent of home fires, over 70 percent of home fire fatalities, and over 70 percent of home fire injuries are the result of

TABLE 16.6.1 Structure Fires in Homes by Area of Origin, 1999–2002 Annual Averages

Area of Origin	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Kitchen or cooking area	95,200	(26%)	460	(16%)	4620	(30%)	761	(14%)
Bedroom	44,800	(12%)	760	(26%)	3820	(25%)	928	(17%)

fires starting in a living room, bedroom, or kitchen. The impact sprinklers would have in these locations was clear. Analysis of this data was used to determine those rooms of a residence in which sprinkler protection would have the most positive impact on life safety. Table 16.6.2 shows the first items ignited in home fires.[4] It shows that over one-fourth of all home fire deaths involved the initial ignition of furniture or bedding. Other data showed that these ignitions were most often caused by a smoldering heat source (e.g., cigarette) or a small open flame source (e.g., match or lighter). This information provided a sense of the types of fire hazards that residential sprinklers would have to mitigate.

Another aspect of the residential fire problem concerns those who typically die in residential fires. Figure 16.6.1 presents the number of fire deaths per million people of a given age range, and Figure 16.6.2 presents the relative risk of dying in a fire by age.[3] Both figures show the trends that children 4 years of age and under and adults 65 years of age and older are more likely to die in a residential fire than are other segments of the population. For adults 65 and older, the risk increases significantly with age. Because these high-risk groups may depend on assistance to exit the dwelling, anything less than automatic suppression may not be enough to save them.[5]

TABLE 16.6.2 Structure Fires in Homes by Item First Ignited, 1999–2002 Annual Averages

Item First Ignited	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*

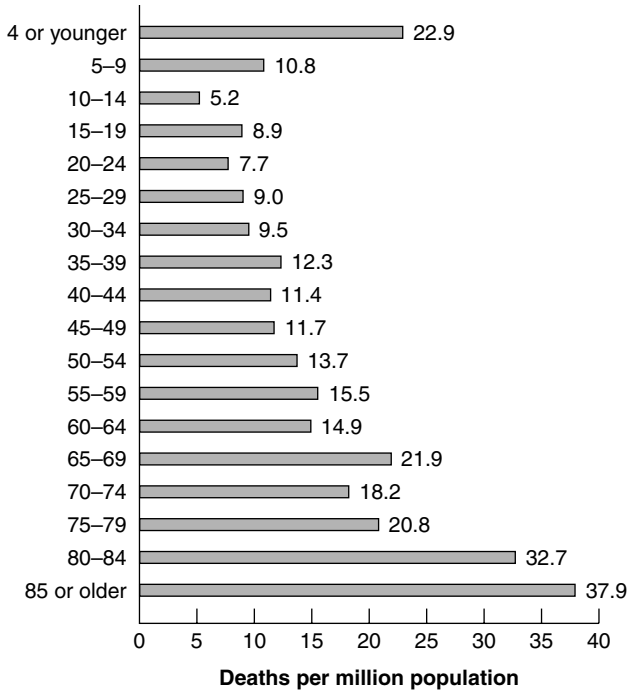

FIGURE 16.6.1 Home Fire Deaths per Million Population by Age from 1992 to 2001. Note: Data have been adjusted to account for unknown or unspecified ages. (Source: Data from NFIRS, NFPA, and U.S. Census Bureau; in *Fire in the United States 1992–2001,* 13th ed., Federal Emergency Management Agency, United States Fire Administration, National Fire Data Center, FA-286, Oct. 2004, Figure 10, p. 42.)

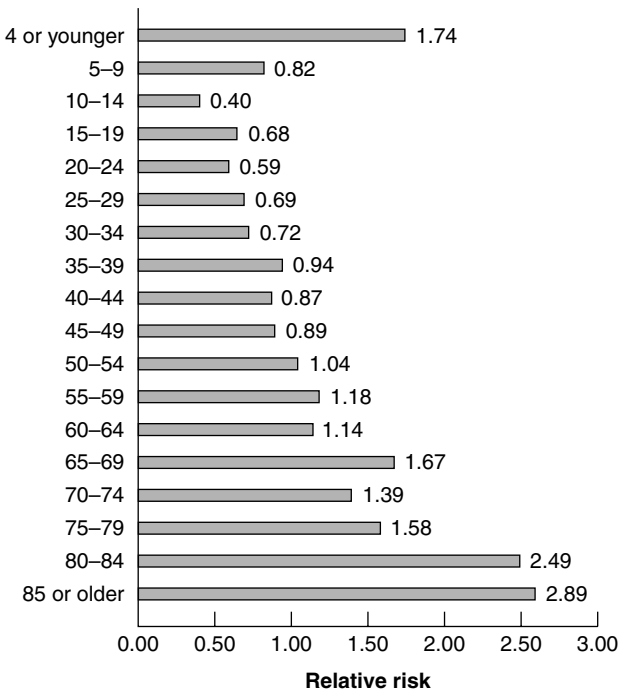

FIGURE 16.6.2 Relative Risk of Home Fire Deaths by Age from 1992 to 2001. Notes: 1. *Relative risk* compares the per capita rate (Figure 16.6.1) for a particular group (here, an age group) to the overall per capita rate (i.e., the general population). For the general population, the relative risk is set at 7. 2. Data have been adjusted to account for unknown or unspecified ages. (Source: Data from NFIRS, NFPA, and U.S. Census Bureau; in *Fire in the United States 1992–2001,* 13th ed., Federal Emergency Management Agency, United States Fire Administration, National Fire Data Center, FA-286, Oct. 2004, Figure 11, p. 43.)

Once it was determined where sprinklers in a home would be most effective in reducing life loss, the technical challenge of developing an effective and economically viable sprinkler system was pursued. The sprinkler system would have to activate automatically while a fire was small and the smoke and heat conditions in the home were survivable. Once the system was activated, it needed to control the fire with a smaller amount of water relative to a commercial sprinkler system, because the water supply to a home is typically less than the water supply to a commercial or industrial occupancy.

NFPA 13D, First Edition, 1975

Based on the review of then-available fire incident data, NFPA's Technical Committee on Sprinkler Systems developed a residential sprinkler installation standard that covered the principally occupied areas of a dwelling and that met the goals of (1) preventing flashover, (2) providing sufficient time for safe egress or rescue, and (3) economic viability.

As specified in the initial version of NFPA 13D, a residential sprinkler system would use a ½ in. (12.7 mm) orifice, standard response sprinkler, with a maximum of 256 ft^2 (23.8 m^2) coverage, and a spray density of 0.10 gpm/ft^2 (4.1 L/m^2), yielding a flow rate of 25 gpm (94.6 L/m^2). If the system was not supplied by an adequate public water source, a 250 gal (946.3 L) stored water supply was required to provide a 10-minute water supply.

To keep costs down, it was proposed that sprinklers be located only in principally occupied rooms. For this reason, sprinklers were not required in bathrooms 40 ft^2 (3.7 m^2) or less, small closets 24 ft^2 (2.2 m^2) or less, attics not used as a living space, porches, carports, garages, and foyers. Table 16.6.1 shows how much of the home fire problem begins in these excluded spaces, as well as in or on concealed spaces and exterior surfaces, which were also excluded. The system was to have a local waterflow alarm. NFPA 13D permitted sprinklers to be omitted from certain areas where the incidence of life loss from fires was statistically shown to be low. NFPA 13 had always required complete sprinkler protection in order to safeguard property adequately. In departing from the concept of complete coverage, the 1975 edition of NFPA 13D became the first "life safety" sprinkler standard. In spite of these concessions, actual installations based on this standard were rare, primarily due to cost.

The initial residential sprinkler system was crafted from existing technology and improvements were needed. Jensen noted that "much of this first edition was based on the collective experience of the committee members; little was based on real-world fire testing."[6]

Residential Sprinkler Research

Beginning in 1976, the National Fire Prevention and Control Administration, renamed the United States Fire Administration (USFA) in 1979, supported a significant number of research programs on a wide variety of topics relating to residential sprinkler systems. The objective of the USFA research program was to assess the impact sprinklers would have on reducing deaths and injuries in residential fires.[7] The USFA—working in conjunction with the National Fire Protection Association, Factory Mutual Research Corporation, Underwriters Laboratories, and many other groups and individuals—evaluated the design, installation, practical usage, and water acceptance factors that would have an impact on achieving reliable and acceptable systems,[8] the minimum water discharge rates and automatic sprinkler flow required; and response sensitivity and design criteria.[9–11] Full-scale fire experiments were conducted to develop residential sprinkler designs and validate their effectiveness.[12–16] In addition, standards for testing and evaluating residential sprinklers were developed. These included tenability criteria for occupants that the sprinklers were required to maintain in the room of fire origin.

Residential Sprinkler Sensitivity and Response

Although researchers at the Factory Mutual Fire Insurance Companies recognized the need for "faster" or more "sensitive" sprinklers in 1884, it was not until the late 1960s that a "quick-response sprinkler" subcommittee was formed within the NFPA 13 technical committee.

Research showed that a more sensitive sprinkler was needed to respond faster to both smoldering and fast-developing home fires for two reasons. First, fires had to be controlled quickly in order to prevent the development of lethal conditions in typically small home compartments. In addition, fires had to be attacked while still small if they were to be controlled with the water supplies typically available in single-family dwellings, that is, 20 to 30 gpm (76 to 114 L/min).

Measuring Sprinkler Sensitivity

Much of the original work in the area of measuring sprinkler sensitivity was done at FM Global Research under the sponsorship of the United States Fire Administration (USFA) during the development of the residential sprinkler.[17,18] Important contributing research was also performed at the British Fire Research Station and the National Institute of Standards and Technology (NIST).[19–22]

The progress in this area climaxed late in 1990, when an agreement was reached within the working group on sprinkler and water spray equipment of the International Standards Organization (ISO) for a standardized approach to sprinkler sensitivity requirements and testing. The agreement, included in ISO 6182/1, "Requirements and Methods of Test for Sprinklers," uses a combination of sprinkler test procedures developed by laboratories in the United States and Europe and establishes the three ranges of sprinkler sensitivity characteristics, shown in Figure 16.6.3.

These ranges of sensitivity are based both on the response time index (RTI) of the device and on its conductivity (C). RTI is a measure of pure thermal sensitivity, which indicates how fast the sprinkler can absorb heat from its surroundings sufficient to cause activation. The conductivity factor is important in measuring how much of the heat picked up from the surrounding air will be lost to the sprinkler fittings and waterway.[23] Figure 16.6.3 shows three broad ranges of sprinkler sensitivity: standard, special, and fast response. Traditional sprinkler hardware falls into the standard-response category. The fast-response category is used for new types of sprinklers for which fast response is considered important. The special-response category is used in some countries for special types of sprinklers that may be installed in conformance with appropriate national installation standards. In the United States, this category includes some of the extended coverage sprinklers.

Sprinkler response time as a function of the temperature rating of the operating element is well understood; that is, a 165°F (74°C) rated sprinkler will operate when its temperature reaches 165°F (74°C), plus or minus a few degrees. Because of the "thermal lag" of the link or bulb mass, however, the air temperature may be significantly higher before the element operates. The

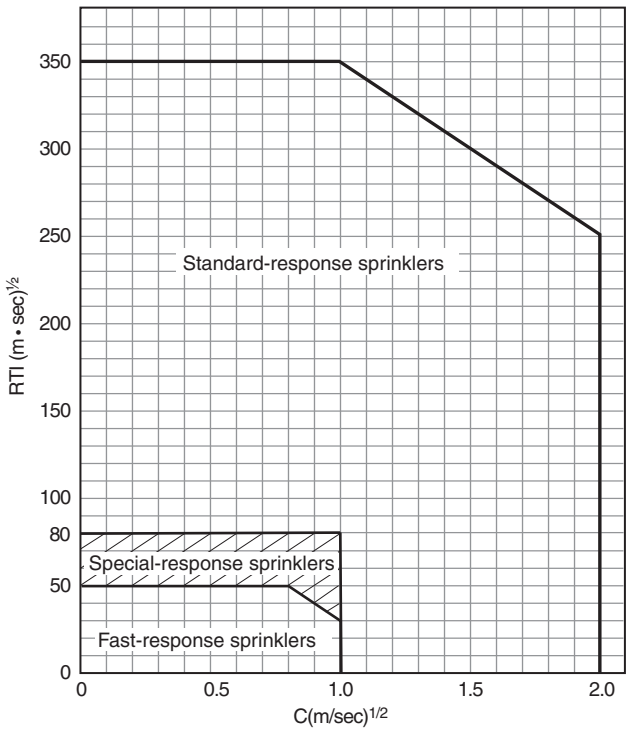

FIGURE 16.6.3 International Sprinkler Sensitivity Ranges, Response Time Index (RTI) versus Conductivity (C). For SI units: 1 ft = 0.305 m.

smaller mass of the operating element of a fast-response sprinkler permits it to follow a temperature rise in the surrounding air more rapidly, resulting in faster operation. The actual sensitivity requirements of the first fast-response sprinklers, intended as residential sprinklers, were arrived at somewhat by trial and error during developmental test work. To measure sensitivity, FM Global Research researchers first applied the concept of the "tau" (τ) factor and later developed the RTI.

Sensitivity Testing

Both the τ factor and RTI refer to the performance of a sprinkler or its operating element in a standardized air oven tunnel or thermal sensitivity test. The test is known as a "plunge" test because a sprinkler at room temperature is plunged into a heated airstream of known constant temperature and velocity.[17,18] In the plunge test, the τ factor is the time at which the temperature of the sensing element of the sprinkler is approximately 63 percent of the difference between the hot gas temperature and the original temperature of the sensing element. In other words, the τ factor is the time at which the temperature of the sprinkler thermal element has risen 63 percent of the way to the higher temperature of the heated air. The smaller the τ factor, the faster the sprinkler sensing element heats up and operates. Figure 16.6.4 shows a time-temperature graph for several τ values ranging from 25 to 200.[24]

The τ factor is independent of the air temperature used in the plunge test, but is inversely proportional to the square root of the air velocity. During the early development of the residential sprinkler, a τ factor of 21 seconds was considered to indicate the needed level of sensitivity, but this was associated with the specific velocity of 5 ft/sec (1.52 m/sec) used in the FM Global Research plunge test. Since the τ factor changes with the velocity of heated air moving past the sprinkler, it is a fairly inconvenient measure of sprinkler sensitivity.

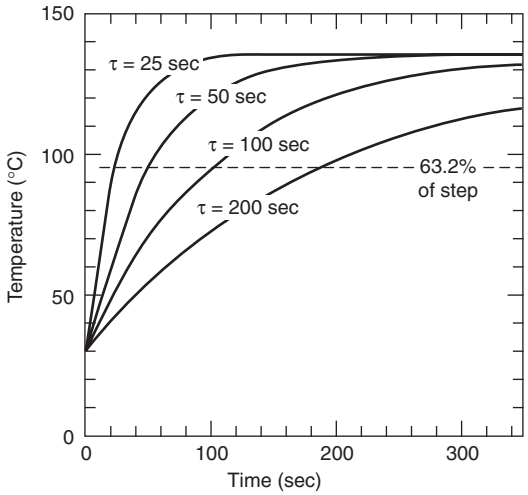

FIGURE 16.6.4 Calculated Sprinkler τ Values Responding to a Step Change Temperature Increase of 105°C with a Gas Velocity of 8.33 ft/sec (2.54 m/sec)

The RTI has replaced the τ factor as the measure of sensitivity and is determined simply by multiplying the τ factor by the square root of the air velocity at which it is found. The RTI is therefore practically independent of both air temperature and air velocity. Comparisons of RTI give a good indication of relative sprinkler sensitivity. The smaller the RTI, the faster the sprinkler operation. Standard-response sprinklers have RTIs in the range of 180 to 650 $sec^{½}ft^{½}$ (100 to 350 $sec^{½}m^{½}$), whereas the RTI range for residential sprinklers is about 50 to 90 $sec^{½}ft^{½}$ (28 to 50 $sec^{½}m^{½}$).

The need to add a conductivity term to the model of sprinkler response was recognized in 1986.[23,25] The conductivity term accounts for the loss of heat from the sprinkler operating element to the sprinkler frame, its mounting, and even the water in the pipe. These losses can become significant under low-velocity conditions, particularly for some of the flush-type sprinkler designs with little insulation between the operating element and the sprinkler body.

Fast-Response Sprinkler

Full-scale tests conducted by FM Global Research resulted in the development of a prototype fast-response sprinkler that could control or suppress typical residential fires with the operation of not more than two sprinklers. It could also operate fast enough to maintain survivable conditions within the room of fire origin.[12] Survivable conditions were established as follows:

- Maximum gas temperature at eye level of 200°F (93°C)
- Maximum ceiling surface temperature of 500°F (260°C)
- Maximum carbon monoxide concentration of 1500 ppm

Thus, the sprinkler concept expanded from the traditional role of property protection to include life safety. Full-scale field tests were then conducted in Los Angeles to establish system design parameters using the new prototype fast-response residential sprinkler.[13–16] Data from these tests were studied by the National Fire Protection Association Technical Committee on Automatic Sprinklers and used to establish the criteria for the 1980 edition of NFPA 13D.

RESIDENTIAL SPRINKLER STANDARDS

It is important to recognize that, in addition to their fast-response characteristics, residential sprinklers have a special water distribution pattern. Because the effective control of residential fires often depends on a single sprinkler in the room of fire origin, the distribution of residential sprinklers must be more uniform than that of standard spray sprinklers, which in large areas can rely on the overlapping patterns of several sprinklers to make up for voids. Additionally, residential sprinklers must protect sofas, drapes, and similar furnishings at the periphery of the room. In their discharge patterns, therefore, sprinklers must not only be capable of delivering water to the walls of their assigned areas but also be high enough up on the walls to prevent the fire from getting "above" the sprinklers. The water delivered close to the ceiling not only protects the portion of the wall close to the ceiling but also enhances the capacity of the spray to cool gases at

the ceiling level, thus reducing the likelihood of excessive sprinkler openings.

Residential Sprinkler Testing

Because of their differences, residential sprinklers are not listed by product evaluation organizations under the same product standards as standard sprinklers. Underwriters Laboratories Inc., for example, has developed UL 1626, *Standard for Safety for Residential Sprinklers for Fire-Protection Service,* for residential sprinklers, and FM Global Research has published Approval Standard FM 2030, *Research Approval Standard for Residential Automatic Sprinklers,* for residential sprinklers. Both of these standards include a plunge test with specific sensitivity requirements and a distribution test that checks the spray pattern in the vertical plane as well as the horizontal plane. Product standards for standard spray sprinklers contain neither test. Both UL 1626 and FM 2030 also include a fire test that is intended to simulate a residential fire in the corner of a room containing combustible materials representative of a living room environment.

UL 1626 Test Procedures. The UL 1626 fuel package and test procedure was recently revised to (1) enhance the reproducibility of the tests and (2) increase the similarity between the fire performance of the fuel package used in the standard tests and that of the fuel packages used as part of the principal residential sprinkler research effort.[13,15,16] Details of the UL 1626 simulated furniture are shown in Figure 16.6.5. The arrangement of the fuel package within the test room is shown at the upper left of the figure.

The three fire test configurations are shown in Figures 16.6.6, 16.6.7, and 16.6.8. Figure 16.6.6 shows the configuration used to test pendent, upright, flush, recessed pendent, and concealed sprinklers. Figures 16.6.7 and 16.6.8 present the configurations used to test sidewall sprinklers; in the first case the sprinklers are located opposite the fuel package, and in the second case the sprinklers are located on the same wall as the fuel package.

The floor plan dimensions of the test room depend on the rated sprinkler coverage. As shown in Figure 16.6.5, the width of the test room, w, equals the rated sprinkler coverage width, and the length of the test room equals twice the rated coverage length, L. For the sidewall sprinkler configurations, the dimensions of the test room should be the rated sprinkler coverage length, L, by 1½ times the sprinkler coverage width, w, plus 9 ft (2.7 m). The ceiling height in all cases is a nominal 8 ft (2.4 m). The fuel package is composed of several different components: a wood crib, two simulated sofa ends covered with foam, two sheets of ¼ in. (6.3 mm) Douglas fir plywood, a pan with heptane, and two heptane-soaked cotton wicks. The wood crib is composed of 16 pieces of nominal 1½ in. by 1½ in. (38 mm by 38 mm) kiln-dried spruce or fir lumber 12 in. (300 mm) in length and 5.5 to 7.0 lb (2.5 to 3.2 kg) in weight. The pieces of lumber are to be arranged in four layers, with four pieces of wood per layer. The pieces of lumber should be evenly spaced along the length of the previous layer of wood members and stapled in place. The layers of lumber are to be placed at right angles to the layer below. The finished size of the wood crib is approximately 12 in. (305 mm) on a side and 6 in. (152 mm) high.

The simulated sofa ends are composed of a wood frame support and a ½-in. (12.7-mm) thick piece of plywood, 33 in. by 31 in. (840 mm by 790 mm) high in a vertical position. The plywood has 3-in. (76-mm) thick uncovered urethane foam cushions 30 in. (760 mm) high by 32 in. (810 mm) wide attached to the side facing the crib. The foam has a density of 1.70 to 1.90 lb/ft^3 (27.2 to 30.4 kg/m^3). The walls of the test room are covered with 4 ft by 8 ft by ¼ in. (1.2 m by 2.4 m by 6.4 mm) Douglas fir plywood paneling (flame spread rating 130 ± 30) attached to wood furring strips. The ceiling of the test room is 8 ft (2.4 m) high and covered with 2-ft by 4-ft by ½-in. (0.61-m by 1.20-m by 12.7-mm) thick acoustical panels (flame spread rating 25 or less) with a density of 13.5 ± 1.5 lb/ft^3 (216 ± 24 kg/m^3) attached to wood furring strips.

A 12-in. by 12-in. by 4-in. (305-mm by 305-mm by 104-mm) high steel pan containing 16 oz. (0.5 L) of water and 8 oz. (0.24 L) of heptane is positioned under the wood crib and ignited to start the test.

Fire Control Requirements. To meet the UL 1626 test criteria, residential sprinklers, installed in a fire test enclosure with an 8-ft (2.4-m) ceiling, are required to control a fire for 10 minutes with the following limits:

1. The maximum gas or air temperature adjacent to the sprinkler—3 in. (76.2 mm) below the ceiling and 8 in. (203 mm) horizontally away from the sprinkler—must not exceed 600°F (316°C).
2. The maximum temperature—5 ft 3 in. (1.6 m) above the floor and half the room length away from each wall—must be less than 200°F (93°C) during the entire test. This temperature must not exceed 130°F (54°C) for more than a 2 minute period.
3. The maximum temperature—¼ in. (6.3 mm) behind the finished surface of the ceiling material directly above the test fire—must not exceed 500°F (260°C).
4. No more than two residential sprinklers in the test enclosure can operate.

The enclosure is kept at an initial ambient temperature of 80°F (27°C) ± 5°F (3°C) and it is ventilated through two door openings on opposite walls. The fire test is conducted for 10 minutes after the ignition of the wood crib. The waterflow to the first sprinkler that operates and the total waterflow when the second sprinkler operates are specified as part of the listing limitations for the sprinklers in the test. The total waterflow for two sprinklers must be a minimum of 1.2 times the minimum flow for a single sprinkler.

Water Distribution Requirements. The water distribution test requirements are based on the distribution pattern of the prototype residential sprinkler used in the Los Angeles test fires.[16] The distribution requirements involve collections in both the horizontal and vertical planes. All residential sprinklers in the test must discharge water at the flow rate specified by the manufacturer for a 10 minute period simulating one sprinkler operating and two sprinklers operating. The quantity of water collected on both the horizontal and vertical surfaces is measured and recorded.

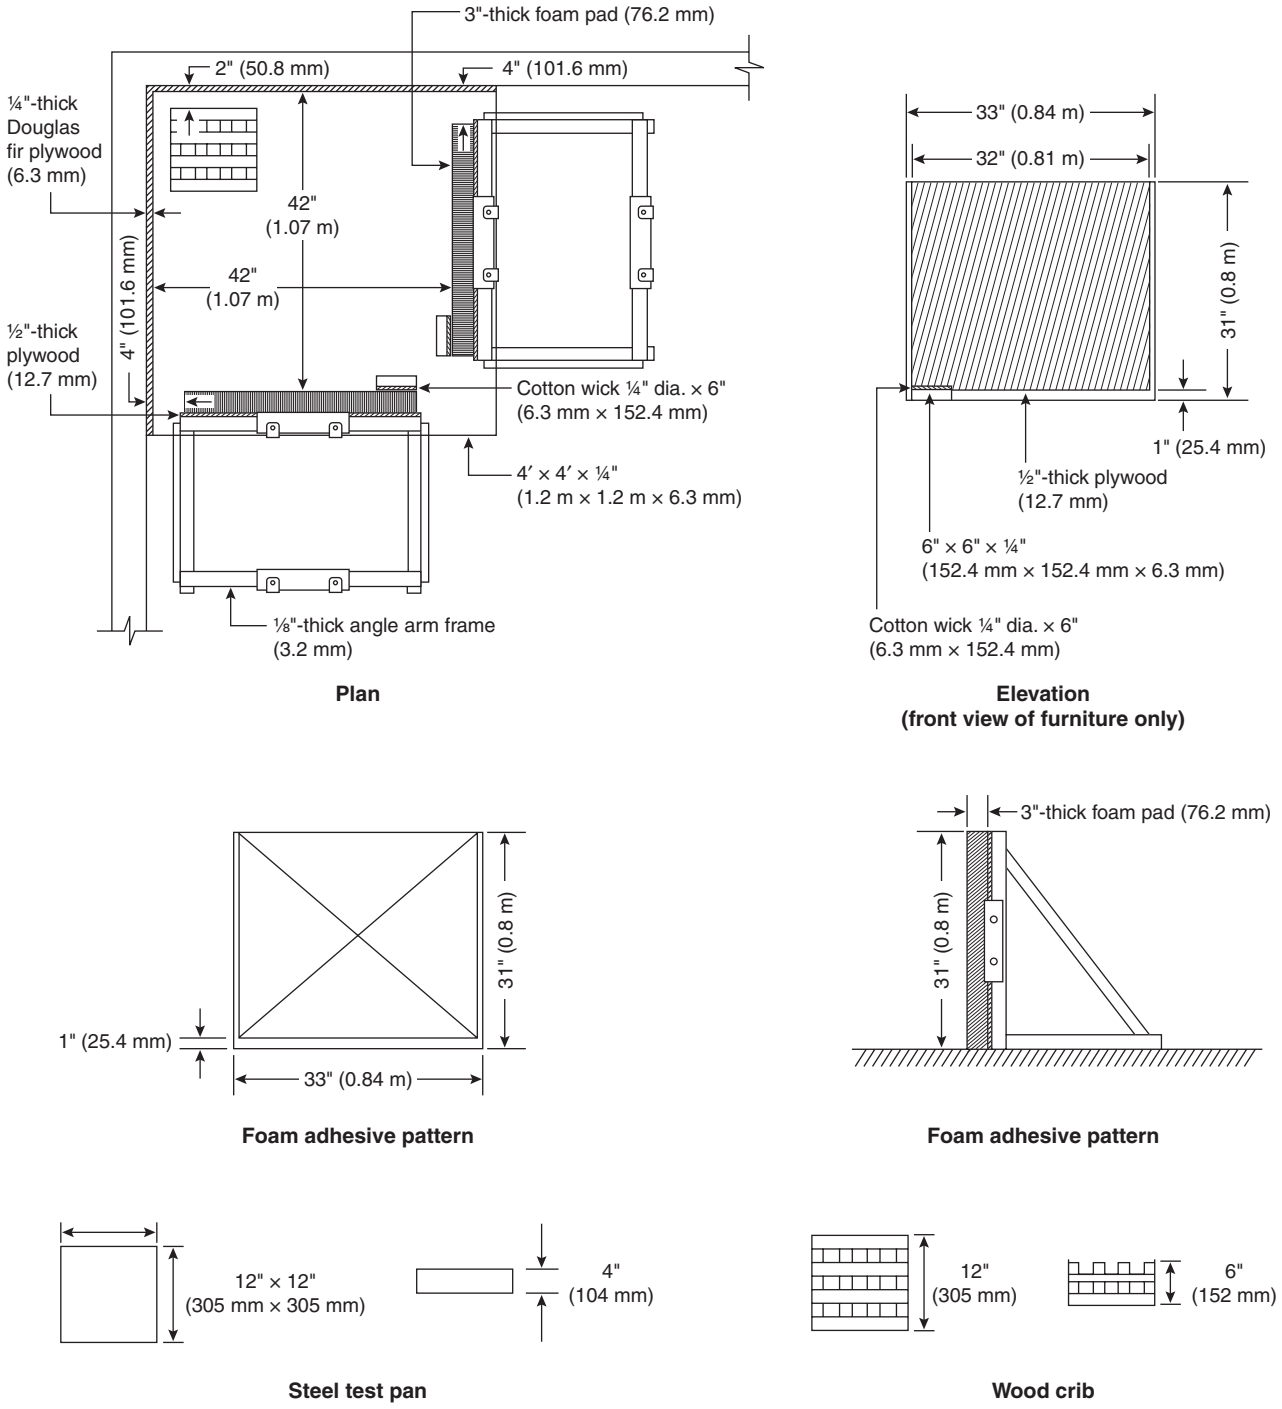

FIGURE 16.6.5 Simulated Fuel Package from UL 1626

Sprinklers being tested are required to discharge a minimum of 0.02 gpm/ft^2 [(0.8[L/min]/m^2) over the entire horizontal design area, with the exception that no more than four 1-ft^2 (0.09-m^2) areas shall be allowed to be at least 0.015 gpm/ft^2 (0.6[L/min]/m^2). They must also wet the walls of the test enclosure to a height not less than 28 in. (711 mm) below the ceiling with one sprinkler operating. Each wall surrounding the coverage area is required to be wetted with a minimum of 5 percent of the sprinkler flow.

Changes to the 2002 editions of NFPA 13D and NFPA 13R were coordinated with revised listings for residential sprinklers, calling for a minimum water spray density of 0.05 gpm/ft^2 (2.05 mm/min). Although the number of sprinklers to be included in the design area did not change for the 13D and 13R standards, the concept of the reduced multiple-sprinkler flow rate was abandoned. Residential sprinklers are now listed with a single minimum flow rate for a given area of coverage.

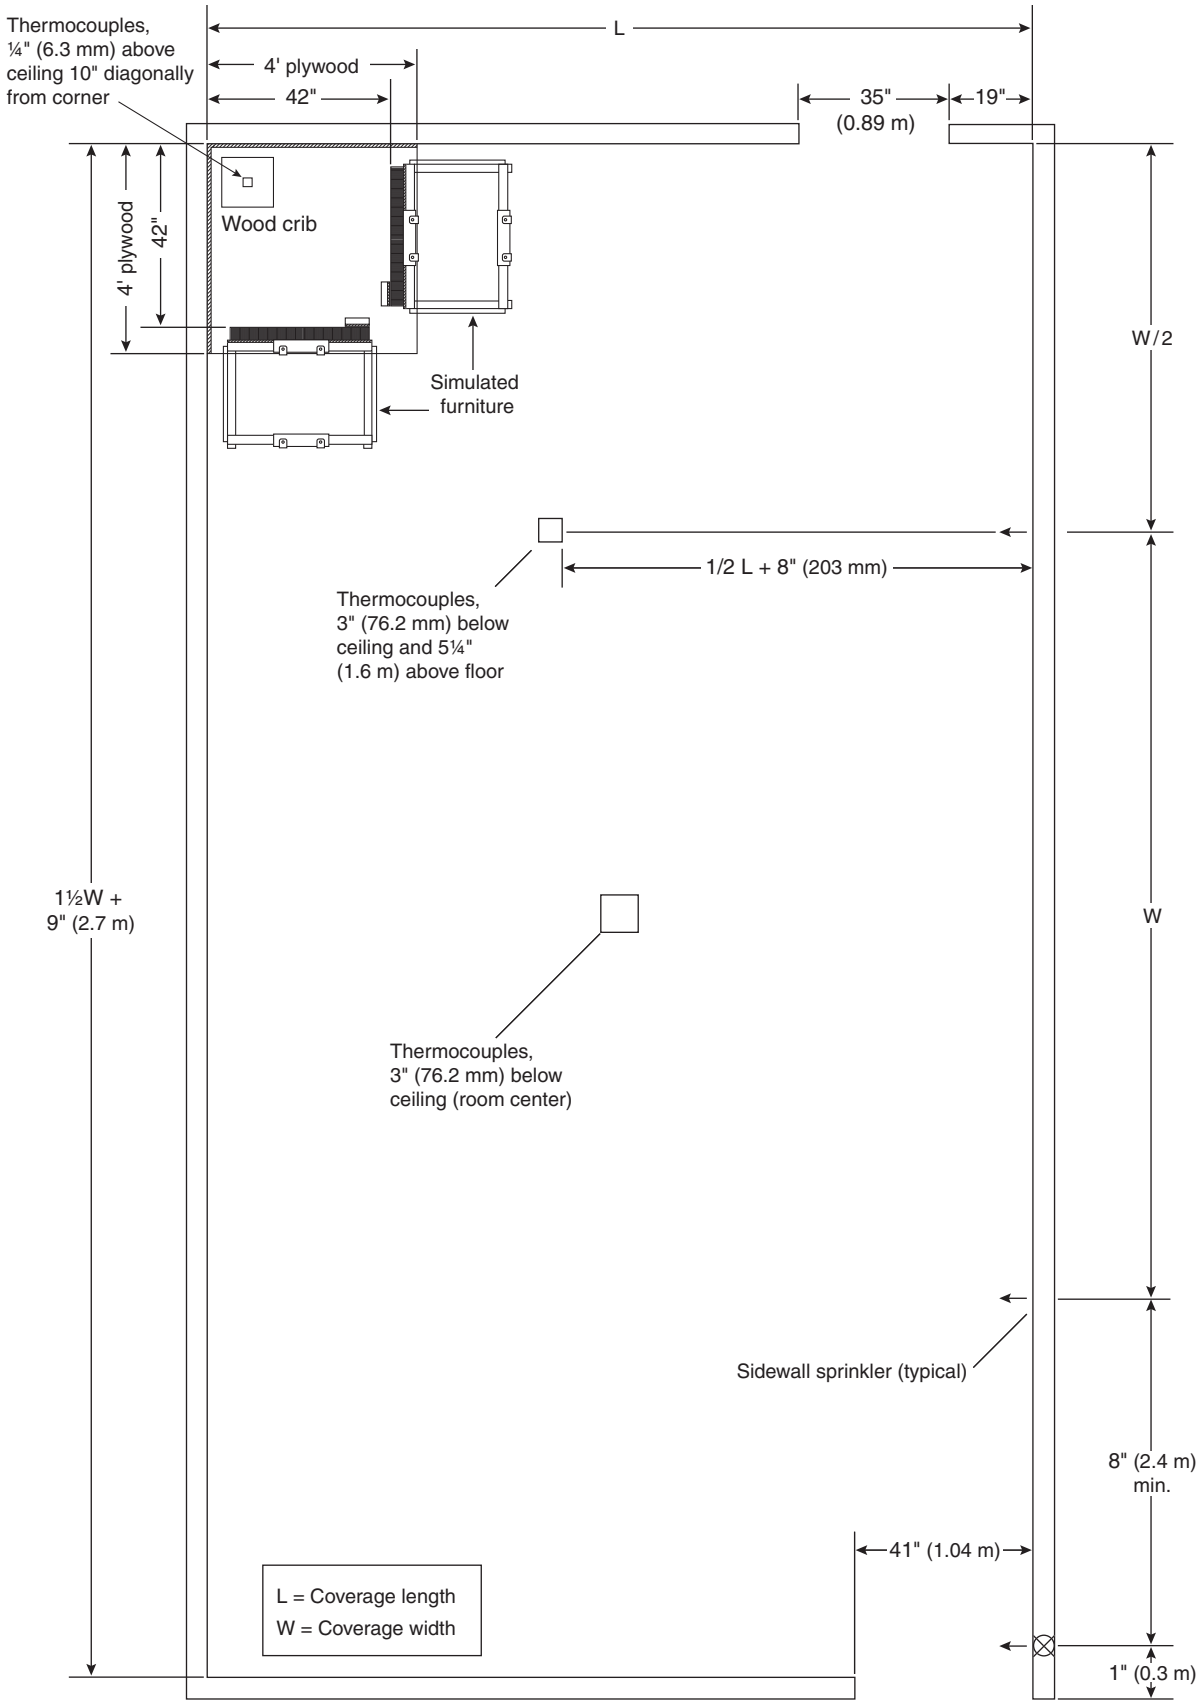

FIGURE 16.6.7 Fire Test Arrangement from UL 1626 for Sidewall Sprinklers, Test Arrangement 1

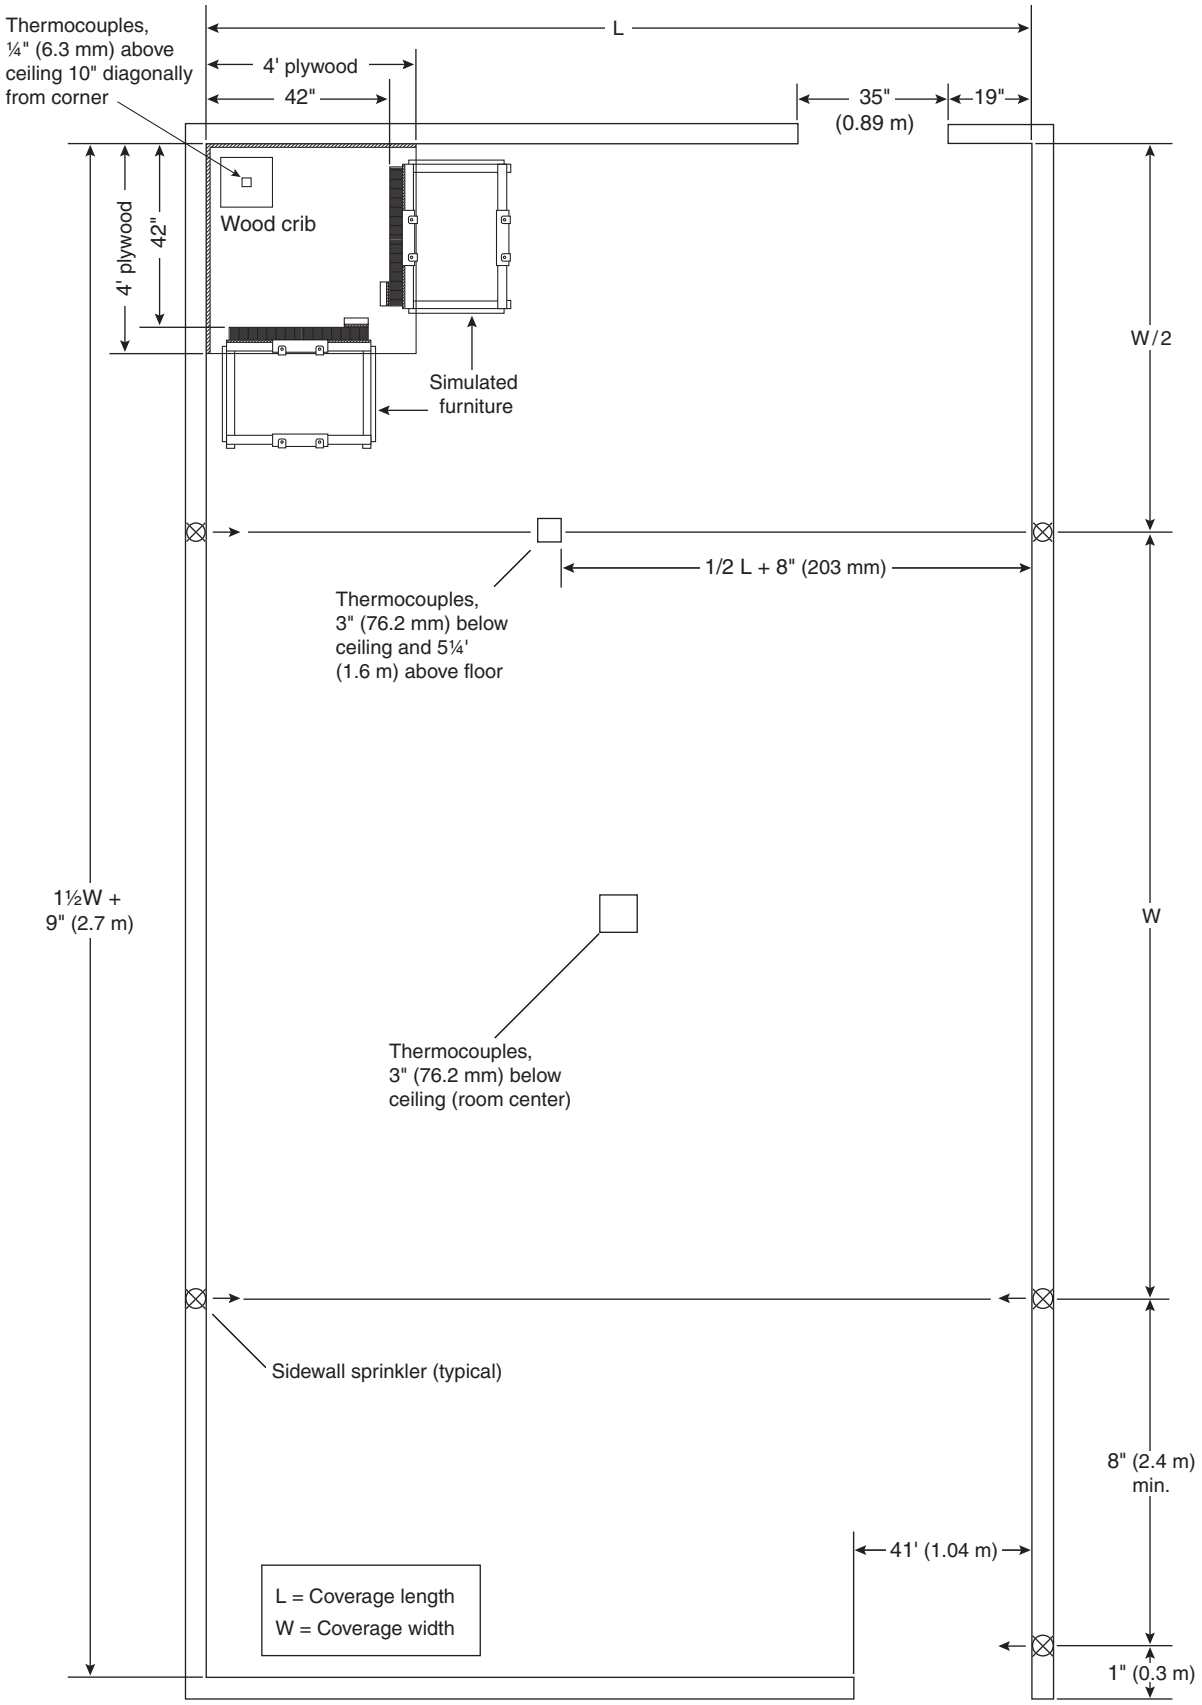

FIGURE 16.6.8 Fire Test Arrangement from UL 1626 for Sidewall Sprinklers, Test Arrangement 2

Research on residential and domestic sprinklers outside the United States supports the trend toward a single minimum flow rate for residential sprinklers. Swedish research published in 2001 indicated that the minimum water application rate of 0.05 gpm/ft^2 (2.05 mm/min) was sufficient to achieve reasonably good protection when the fire test scenario involved upholstered furniture.[26]

Revised NFPA 13D Design Requirements

The design criteria in the 1980 edition of NFPA 13D included for the first time the requirement that all sprinklers be "listed residential sprinklers" (Figure 16.6.9). Other initial basic design requirements in the revamped NFPA 13D were as follows.

Performance Criteria. To prevent flashover in the room of fire origin, when sprinklered, and to improve the chance for occupants to escape or be evacuated.

Design Criteria. Design criteria include the following:

- Only listed residential sprinklers to be used
- Minimum 18 gpm (68 L/min) to any single operating sprinkler and 13 gpm (49 L/min) to all operating sprinklers in the design area up to a maximum of two sprinklers
- Maximum area protected by a single sprinkler of 144 ft^2 (13.4 m^2)
- Maximum distance between sprinklers of 12 ft (3.7 m)
- Minimum distance between sprinklers of 8 ft (2.4 m)
- Maximum distance from a sprinkler to a wall or partition of 6 ft (1.8 m)

Application rates, design areas, areas of coverage, and minimum design pressures other than those specified above were permitted to be used with special sprinklers listed for such special residential installation conditions.

Sprinkler Coverage. Sprinklers to be installed in all areas, with the following exceptions:

- Sprinklers allowed to be omitted from bathrooms no larger than 55 ft^2 (5.1 m^2)

FIGURE 16.6.9 Listed Residential Sprinkler

- Sprinklers allowed to be omitted from closets where the least dimension does not exceed 3 ft (0.9 m), the area does not exceed 24 ft^2 (2.2 m^2), and the walls and ceiling are surfaced with noncombustible materials
- Sprinklers allowed to be omitted from open-attached porches, garages, carports, and similar structures
- Sprinklers allowed to be omitted from attics and crawl spaces that are not used or intended for living purposes or storage
- Sprinklers allowed to be omitted from entrance foyers that are not the only means of egress

In the 30 years following the development of the residential sprinkler, special listings involving expanded protection areas and reduced flows proliferated to the point that the original flow and spacing criteria have become all but obsolete. Residential sprinklers are now listed for coverage areas up to 400 ft^2 (37.2 m^2) per sprinkler.

Since 1985, the use of residential sprinklers has also been permitted under some conditions in accordance with NFPA 13. Essentially, NFPA 13 allows residential sprinklers in dwelling units located in any occupancy, provided they are installed in conformance with the requirements of their listing and the positioning requirements of NFPA 13D. A dwelling unit is defined as one or more rooms arranged for the use of one or more individuals living together, as in a single housekeeping unit, normally having cooking, living, sanitary, and sleeping facilities. Dwelling units include hotel rooms, dormitory rooms, sleeping rooms in nursing homes, and similar living units. Occupancies encompassing dwelling units include apartment buildings, board and care facilities, dormitories, condominiums, lodging and rooming houses, and other multiple-family dwellings. For NFPA 13 applications involving residential sprinklers in dwelling units, the design area must consist of the four most hydraulically demanding sprinklers (Figure 16.6.10).

Other areas, such as attics, basements, or other types of occupancies outside of dwelling units but within the same structure, must be protected in accordance with regular provisions of NFPA 13, including the appropriate water supply requirements. The decision as to which areas are to be protected with sprinklers is also regulated in accordance with the normal provisions of NFPA 13. This protection means, for example, that combustible concealed spaces generally require sprinklers. For NFPA 13 applications, although the four-sprinkler design area can be used in the dwelling units when protected with residential sprinklers, any sprinklers installed within such concealed spaces would have to use a different design approach.

Residential sprinklers installed in systems designed to NFPA 13 requirements are spaced and positioned in accordance with their residential listings, not with the spacing requirements of NFPA 13. The water demands for the residential sprinklers are the same as in NFPA 13 applications, except that the multiple-sprinkler flow requirement is extended to four sprinklers rather than the two stipulated for one- and two-family dwellings and manufactured homes in NFPA 13D. The more liberal piping, component, hanger, location, and water supply duration allowances of NFPA 13D are not permitted in these systems. Beginning in 1996, NFPA 13 requires residential sprinklers or quick-response sprinklers in residential areas.

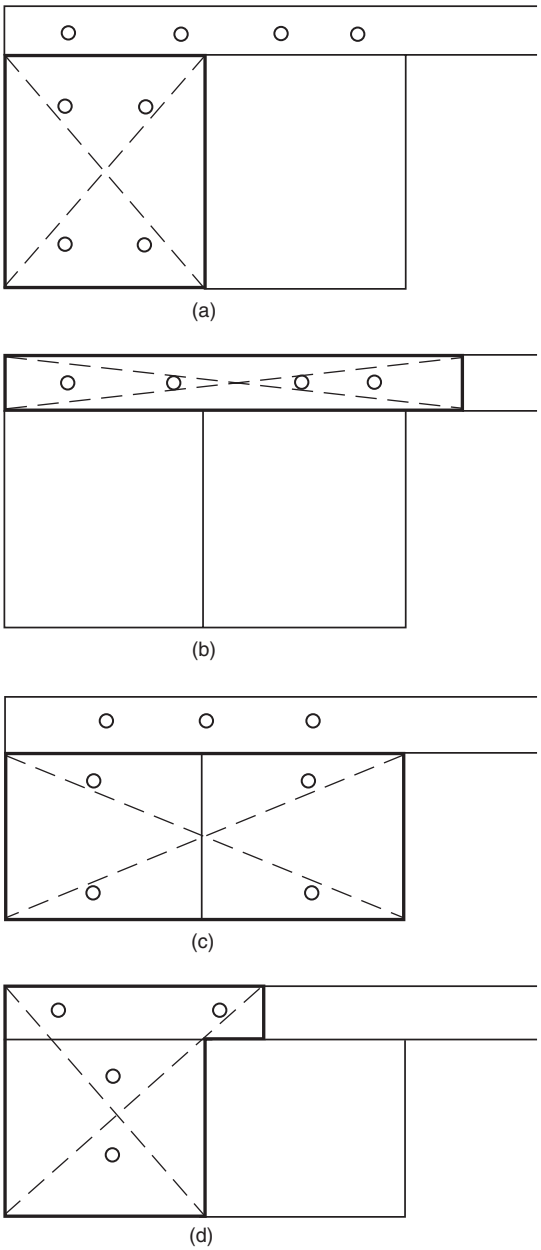

FIGURE 16.6.10 Design Areas for Dwelling Units

Ceiling Fan Criteria. Technical improvements to NFPA 13D are made with each new edition. One of the major areas of improvement to the 2007 edition was the development of criteria for the obstructions created by ceiling fans. Figure 16.6.11 shows a sprinkler obstructed by a ceiling fan. Research conducted in 2005 by the National Fire Sprinkler Association at the facilities of the Viking Corporation involved distribution and fire testing using three different styles of ceiling fans, one with the housing tight against the ceiling, one with a suspended housing, and one with large blades obstructing half of the plan view of the area swept by the blades.[27] Based on the results of the tests, the Committee on Residential Sprinkler Systems agreed that the minimum distance from a sprinkler to the center of a ceiling fan should be 3 ft (0.9 m) for pendent sprinklers and 5 ft (1.5 m) for sidewall sprinklers.

FIGURE 16.6.11 Residential Sprinkler Obstructed by Ceiling Fan

Development of NFPA 13R

Like NFPA 13D, NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height,* is oriented toward economical life safety protection from fire. Sprinklers can be omitted from building areas that have been found to have a low incidence of fatal fires, including combustible concealed spaces, small bathrooms and closets, and attached porches. As with NFPA 13D, residential sprinklers are required throughout dwelling units, with some minor exceptions. A four-sprinkler design area is required unless the largest compartment contains fewer sprinklers.

In recognition of the greater risk associated with multifamily occupancies, NFPA 13R is more conservative than NFPA 13D in some areas. Requirements for plans, hydraulic calculations, and system acceptance certificates parallel those of NFPA 13. Unlike NFPA 13D, NFPA 13R requires a consideration of the likelihood that simultaneous domestic flows might occur through combined service piping. In addition, pumps and other key equipment are required to be listed. In NFPA 13R systems, areas outside dwelling units can be protected with standard spray sprinklers, using NFPA 13 design criteria.

NEW TECHNOLOGY IN RESIDENTIAL SPRINKLER SYSTEMS

Multipurpose Piping Systems

Although NFPA 13D has had the option for a combined or multipurpose piping system for many years, in 1999 the committee further encouraged the use of this option by allowing nonlisted pipe to be connected to the sprinkler system for the purpose of supplying plumbing fixtures and by specifying a working pressure requirement of not less than 130 psi (8.9 bar) at not less than 120°F (49°C). The combined system may be a means to

integrate the sprinkler system into new homes as a standard feature instead of as an option.

The multipurpose system uses the cold water piping to serve as a supply for both the domestic fixtures, such as sinks and showers, and the fire sprinklers. Given the potential for a reduced amount of pipe and fittings, there is a potential for reduced system cost. Supplying the sprinklers from the domestic water system can provide increased system reliability because any impairment to the water supply would be more quickly recognized. In addition, a combined system eliminates the need for backflow prevention devices. This setup also helps to reduce the cost of the system and eliminates any water pressure losses that would be incurred by a backflow prevention device.

New piping materials composed of cross-linked polyethylene have recently been listed by UL for use in residential sprinkler systems.[28] This piping is similar to piping already used in domestic plumbing systems and is therefore easily used in combined systems.

Residential Water Mist System

Residential fire suppression/control systems are also being developed under NFPA 750, *Standard on Water Mist Fire Protection Systems.* A water mist system uses very fine water sprays to control or extinguish fires by cooling of the flame and fire plume, oxygen displacement by water vapor, and radiant heat attenuation.[29]

Water mist systems typically use smaller amounts of water at significantly higher pressures when compared to a NFPA 13D residential sprinkler system. The spacing of water mist nozzles tends to be smaller than the spacing of residential sprinklers; hence more nozzles are needed to provide fire protection for a given area. Studies sponsored by the U.S. Fire Administration showed that in some cases water mist systems could provide equivalent levels of fire safety relative to a residential sprinkler system, however, at a significantly higher cost.[30,31] (For further information, see Section 16, Chapter 8, "Water Mist Fire Suppression Systems.")

RESIDENTIAL SPRINKLER EXPERIENCE

Scottsdale, Arizona

Due to the proven effectiveness of residential fire sprinklers, communities in 25 states require sprinklers in one- and two-family homes.[32] One of these communities, Scottsdale, Arizona, has conducted a detailed 10 year study on the impact of residential fire sprinklers on its community. In June 1985, the city of Scottsdale passed a comprehensive fire sprinkler ordinance that required all new multifamily and commercial structures to be protected by sprinklers, beginning in July 1985, and all new single-family homes, beginning in January 1986.[33]

The results of the study held some surprises. The average installation cost of a residential sprinkler system decreased significantly over the 10 year period. In 1986, the average installation cost was $\$1.14/ft^2$. By January 1996, the average cost was $\$0.59/ft^2$, a decrease of approximately 45 percent.[33]

Surveys of the home insurance companies in the Scottsdale area yielded an average discount of 10 percent for homes with residential sprinkler systems installed.[33] The Scottsdale study also examined the issue of water usage during a fire incident. The first 38 sprinklered fire incidents, a combination of fires in commercial, multifamily, and single-family units, were investigated. Based on the incident time lines, the waterflow times for the sprinkler systems were determined and the total waterflow was calculated. The average amount of water used per fire was 357 gal. Assuming that manual suppression could be accomplished in the same amount of time as the sprinkler flow time, the average amount of water used per fire incident by the fire department would amount to more than 4800 gal.[33]

In 1996, a review of the 109 fires that had occurred in sprinklered buildings in Scottsdale included 44 residential fires. In over 90 percent of the incidents, the fire was controlled with one or two sprinklers activated. The average amount of water flowed by the sprinklers was 299 gal per fire versus an estimated manual suppression usage of approximately 6000 gal per fire.

In 2001, the Scottsdale data were updated to include 15 years of experience with the Scottsdale sprinkler ordinance.[34] The updated data show the trends continuing, with the average fire loss in a sprinklered home to be $2166, as compared to $45,019 in a home without sprinklers. Efforts are under way to update the study to include 20 years of experience.

Prince Georges County. Maryland

Prince Georges County, Maryland, enacted an ordinance in 1990 by which all new residential structures were required to be sprinklered beginning in January 1, 1992. A report of the first 8 years' experience was compiled in January 2001.[35] The total fire loss in 117 fire incidents in which sprinklers were involved was reported as $401,220, as compared to an estimated $38,230,000 had sprinklers not been present. Although 7 minor injuries were reported in these fires, 154 lives were reported as having been saved by the sprinkler systems.

Among the 121 reported fire incidents, more than one residential sprinkler operated in only 11. In 7 of those, more than two sprinklers operated. An investigation revealed that those 7 involved some extenuating circumstance, such as the use of an accelerant or human intervention, which contributed to the operation of the additional sprinklers. During this same time period, there were only 4 incidents of sprinkler discharge for reasons other than a fire.

Residential Fire Sprinkler Activation Project

Starting in July 2003, the National Association of State Fire Marshals established a residential fire sprinkler activation reporting system on its website (http://www.firemarshals.org). The objective of the project is to collect current and detailed data pertaining to residential sprinkler activations.[36] There are 18 data fields, which include the type of occupancy, number of stories, story of origin, room of origin, area of the room of fire origin, number of sprinklers installed in room of origin, number of sprinklers activated, type of sprinkler activated, and reason for activation. Other inputs regard smoke detectors, and esti-

mates for lives saved, dollar loss due to fire, and dollars saved by sprinkler activation.

During the first two years of the project, 448 incidents were submitted by 167 different fire departments. Over 60 percent of the sprinkler activations documented occurred in apartment buildings. The sprinkler activations in kitchens accounted for 40 percent of the recorded incidents. Of the incidents where the number of sprinklers was reported, approximately 83 percent of the activations involved only a single sprinkler. This project is supported by a grant from the U.S. Fire Administration.

INCENTIVES FOR MORE WIDESPREAD USE OF RESIDENTIAL SPRINKLERS

Certain incentives can stimulate interest in residential sprinklers. These incentives are discussed in the following paragraphs.

Reduction in Government Spending

Reduction in all forms of government spending, resulting from public pressure to reduce property taxes, is a prime factor in the future growth of the residential sprinkler concept. Many fire departments are forced to protect larger areas and more subdivisions with the same number of or even fewer people because financial restrictions hamper a fire department's ability to grow with the community. As a result, alternatives to traditional firefighting techniques must be found. One of them is the use of residential sprinklers. San Clemente, California, was the first community in the United States to pass a residential sprinkler ordinance in 1980 as part of the fire department's master plan. This ordinance requires automatic sprinkler systems to be installed in all new residential construction. The prime motivation for the passage of this ordinance was San Clemente's cutbacks in government spending brought about by Proposition 13, the state's tax-capping measure. Many communities across the country face similar situations. Automatic sprinklers in residences may be the answer to fewer fire fighters and longer response times from the fire department.

Insurance Savings

Although the greatest benefit from widespread installation of residential sprinklers will be the lives saved and injuries prevented, lower property losses will be a secondary and substantial benefit. An ad hoc committee from the insurance industry sponsored a number of test fires in Los Angeles during the early 1980s and concluded that residential sprinklers have the potential for reducing homeowners' claim payment expenses.[37] As a result, the Insurance Services Office (ISO) Personal Lines Committee recommended that a 15 percent reduction in the homeowner's policy premium be given for installation of an NFPA 13D residential sprinkler system. Although this would not pay for the system over a short period of time, as is the case in many commercial installations, the continuing increases in the cost of insuring a single-family home make this a significant incentive nonetheless. NFPA analysis indicates that home sprinklers, like other sprinkler installations, reduce average fire loss per home fire by a much larger one-half to two-thirds.[38]

Real Estate Tax Reductions

In 1981, the state of Alaska enacted into law a significant piece of legislation that has a dramatic impact on the installation of sprinkler systems throughout that state. The law provides that 2 percent of the assessed value of any structure is exempt from taxation if the structure is protected with a fire protection system. The word *structure* is significant in the law, because it also applies to homes. In effect, if a home were assessed at $100,000 for purposes of taxation, the assessed value would be computed at $98,000, provided that it contained a fire protection system.

It actually may be considered an incentive simply to add the value of a fire sprinkler system to the assessed value of a property. In a national poll commissioned by the Home Fire Sprinkler Coalition in December 2000, it was found that 69 percent of homeowners believe having a fire sprinkler system increases the value of a home, and 38 percent said they would be more likely to purchase a new home with sprinklers than one without.[39]

Zoning

Greater land use may be possible with zoning changes that would permit fully sprinklered residences to be built on smaller parcels of land. The assumption is that the space between houses will not be as important from a fire protection standpoint if an entire street or neighborhood is fully sprinklered. One could argue, however, that if the sprinkler system fails, the resultant fire involving a number of residences could be much greater. The more complex analysis required to assess the net effects of full sprinklering of a neighborhood with smaller lot sizes has yet to be conducted.

Sprinkler Legislation

In addition to the San Clemente ordinance, a number of other California communities have passed residential sprinkler legislation, including Orange County and Los Angeles County. In 1993, more than 4 million Californians lived in communities in which residential sprinklers were mandated in all new homes.[40] Since 1982, Greenburgh, New York, and several surrounding communities have enacted sprinkler ordinances that require the installation of automatic sprinklers in virtually all new construction, including all new multiple-, one-, and two-family dwellings. A similar law went into effect in Prince George's County, Maryland, in 1992.

The state of Florida in 1983 passed a law requiring that all public lodging and time-share units three or more stories high in the state be sprinklered. It also required that all existing units be sprinklered by 1988.

In 1983, the city of Honolulu, Hawaii, adopted legislation that required all new and existing high-rise hotels, which are those more than 75 ft (23 m) above grade, to be sprinklered.

In the late 1980s, additional jurisdictions, including Atlanta, Georgia, the state of Connecticut, and the commonwealth of Massachusetts, acted to require retroactively the installation of sprinkler systems in high-rise residential buildings. In 1990, the federal government enacted the Hotel and Motel Fire Safety Act, which contains strong incentives for complete sprinkler

protection of hotels, because only hotels with satisfactory levels of fire protection are eligible for federal employee travel.

The Federal Fire Safety Act of 1992 requires automatic sprinkler systems or an equivalent level of safety in all federally assisted housing four or more stories in height, as well as in office buildings owned or leased for more than 25 federal employees. Perhaps the most significant legislation promoting the use of sprinkler systems, however, is the 1990 Americans with Disabilities Act. In 1991, the U.S. Department of Justice published criteria that became mandatory for places of public accommodation and commercial facilities designed for first occupation after January 26, 1993. Alterations to existing buildings must also comply. A key feature of the criteria is the need for areas of refuge. Floors of buildings that do not have direct access to the exterior at grade must provide areas of rescue assistance, except those buildings that have a supervised automatic sprinkler system.

Adoption of fire sprinkler ordinances continues in various areas. One of the most active areas in the early twenty-first century are the suburbs of Chicago. Between 2000 and 2005 the number of communities that had adopted an NFPA 13D ordinance grew from 3 to 35, with 14 of those adopted in 2005.[41] Lessons learned from the experience of communities that have adopted ordinances is being used to provide guidance to others that might wish to pursue their own ordinances.[42]

Construction

Many authorities having jurisdiction have used building code modifications as an incentive to install sprinklers. Cobb County, Georgia, was one of the first communities to amend its Buildings and Construction Code to include such an approach for multifamily structures equipped with residential sprinkler systems. Although these construction alterations can be a major incentive to install residential sprinklers, the disaster potential must always be considered if a fire, for whatever reason, should overpower the sprinkler system. This possibility of disaster is especially true if the system is designed with the minimal water supplies required by NFPA 13D.

The city of Dallas, Texas, adopted a building code that requires all new buildings or those undergoing major renovation, having an area greater than 7500 ft^2 (697 m^2), to have automatic sprinklers. At the same time, this building code encourages the installation of sprinkler systems by allowing design options that may allow different levels of "passive" fire protection features in exchange for "active" automatic sprinkler alternatives.

Code Requirements

Beginning with the 1991 edition, NFPA *101*®, *Life Safety Code*®, required the use of quick-response or residential sprinklers in new health care occupancies in smoke compartments that contain patient sleeping rooms. This generally means all patient rooms and their adjacent corridors. Beginning with the 1994 edition, quick-response or residential sprinklers were also required in all new hotel and dormitory guest rooms and guest room suites. Beginning in 1996, NFPA 13 requires quick-response or residential sprinklers in all new light hazard construction.

Because of these and other incentives, the use of new technology, such as residential and quick-response sprinklers, increased by a factor of 15 in the United States between 1990 and 2000, while the total number of sprinklers installed nearly doubled.[43] There is growing recognition of the enhanced ability of residential and other types of fast-response sprinklers to protect life and property from fires.

A major milestone for residential sprinkler came in August 2005 with the issuance of the 2006 editions of NFPA *101*® and *NFPA 5000*®, *Building Construction and Safety Code*®, both of which require fire sprinkler systems in all new one- and two-family dwellings.

SUMMARY

Residential sprinkler systems are an effective means of controlling fire in the home, allowing occupants the time to escape or be rescued. Several different systems exist, and research is ongoing to develop systems that are more efficient and cost-effective. The design and installation must take into account where sprinklers in a home are most effective in reducing the risk to life and property. The sprinkler system needs to activate automatically while a fire is small and the smoke and heat conditions in the home are survivable. Once the system is activated, it needs to control the fire with a smaller amount of water relative to a commercial sprinkler system.

Although most fire-related deaths in the United States occur in the home, it is estimated that less than 3 percent of one- and two-family dwellings have sprinkler systems installed. This percentage will rise as more legislation is passed requiring new homes to have sprinkler systems and as technology and costs continue to improve.

Ultra-high-speed suppression systems for explosive hazards have come to symbolize many things to different people. To fire protection engineers, they are the cutting edge of today's fire protection technology. To some contractors, they may be too difficult to install. To the general public, they may connote an air of mystery and foreboding. Clients may consider them to be temperamental or hard to maintain. It is this diversity of impressions that has necessitated further developments in ultra-high-speed fire suppression system technology.

Two fundamental types of suppression systems are available to fire protection professionals for the control or extinguishment of explosive hazards: (1) ultra-high-speed water spray systems, which are discussed in significant detail in this chapter, and (2) explosion suppression systems, covered briefly in this chapter and well detailed in Section 17, Chapter 8, "Explosion Prevention and Protection."

Since the ultra-high-speed water spray system is essentially a highly sophisticated water spray system, a review of the fundamentals of water spray system design may be of considerable assistance. See Section 16, Chapter 9, "Water Spray Protection."

Further information is available in Section 2, Chapter 8, "Explosions"; Section 6, Chapter 15, "Explosives and Blasting Agents"; Section 14, Chapter 2, "Automatic Fire Detectors"; Section 16, Chapter 9, "Water Spray Protection"; Section 17, Chapter 8, "Explosion Prevention and Protection"; and Section 18, Chapter 4, "Venting Practices."

SYSTEM DEFINITION AND APPLICATION

Definition

An ultra-high-speed water spray system is defined by NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection,* as one that can commence the initiation of discharge of water to a volatile commodity within 100 milliseconds of detection, measured from presentation of an energy source to the detector to flow of water from the nozzle being tested. This level of response is required where materials of very high flame spread and heat release, such as propellants and pyrotechnic materials, are involved. With recent advancements in detection and electronic technology, ultra-high-speed water spray system response times in the 10 millisecond range are achievable, with 10 milliseconds being a mandatory response time for very rapidly spreading fires.

The NFPA Technical Committee on Water Spray Fixed Systems has determined that a line of demarcation must exist between ultra-high-speed water spray systems, covered in NFPA 15,

Robert M. Gagnon, P.E., SET, FSFPE, is president of Gagnon Engineering, a fire protection consulting firm in Woodbine, Maryland. He is chair of NFPA's Committee on Foam-Water Sprinkler Systems and secretary of NFPA's Committee on Water Spray Fixed Systems and Committee on Water Tanks. He is a member of NFPA's Committee on Automatic Sprinkler Systems, Committee on Private Water Supply Piping Systems, and Committee on Water Cooling Towers. He also serves on the Technical Correlating Committee on Automatic Sprinkler Systems. Mr. Gagnon has served as a lecturer at the University of Maryland Department of Fire Protection Engineering since 1993, and formerly served as a lecturer at Montgomery College. He is the author of four books on detection and suppression design.

and explosion suppression systems, covered in NFPA 69, *Standard on Explosion Prevention Systems.* Explosion suppression systems are required to be designed in accordance with NFPA 69 for enclosed vessels or other devices or conveyances where overpressurization or rupture is the primary concern. Ultra-high-speed water spray systems are predominantly designed in accordance with NFPA 15 for rooms or open, unconfined areas where rupture resulting from overpressurization is not the primary concern. Tightly sealed rooms and enclosed, or partially enclosed, process equipment are examples of applications that may be appropriate for the design of either ultra-high-speed water spray systems or explosion suppression systems, depending on the configuration of the commodity and its associated manufacturing process. Explosion suppression systems are not normally used in ordinance operations, because their response time is slower than ultra-high-speed water spray systems for the volume of the space requiring protection.

When personnel are present in a room with the potential for a rapidly spreading fire, room overpressurization and rupture are not the primary concerns because personnel are in jeopardy well in advance of an impending room rupture. An ultra-high-speed water spray system is needed to halt the expanding flame front before room overpressurization becomes a concern.

Both ultra-high-speed water spray systems and explosion suppression systems can be satisfactorily designed for the suppression of deflagrations or fires where the expanding flame front travels at a velocity less than the speed of sound. Neither system has been found to be effective for applications where a detonation, or a fire where the expanding flame front travels at a velocity greater than the speed of sound, could occur. Laboratory test data or empirical field testing of the commodity with respect to flame spread and heat release may be necessary before selecting a suppression system for a particular explosive hazard.

Application

Examples of facilities where ultra-high-speed water spray systems are advantageous include rocket fuel manufacturing or processing; solid propellant manufacturing or handling; paint spray can filling; ammunition manufacturing; pyrotechnics manufacturing; maintenance/renovation/demilitarization of ordinance items containing pyrotechnic materials; and the manufacture or handling of other volatile solids, chemicals, dusts, and gases. An example of a situation where an ultra-high-speed suppression system is not likely to be effective would be the protection of stored munitions whose manufacture has been completed.

Certain types of munitions, such as C-4 explosives, may promote a fire scenario that transitions from a deflagration to a detonation. An ultra-high-speed water spray system has been found to be effective for the suppression of such fires when the expansion of the flame front has been halted in its incipient stages.[1]

For military applications, it has become customary to use a nine-hazard classification system developed by the United Nations Organization (UNO) to promote the safe manufacture, storage, and transport of explosives. Class 1 contains the majority of energetic materials that are ordinarily protected by ultra-high-speed water spray systems. Class 1 is subdivided into six divisions, with Divisions 3 and 4 providing the most opportunity for high-speed suppression (Table 16.7.1).

REACTION TO FIRE EVENTS

Reaction Time

Reaction time is defined as the total time required from initiation of combustion and detection to the presence of water at the nozzle. It can be broken down into 11 segments for clarity as to what is included in reaction time and what is currently not being considered during the testing of ultra-high-speed water spray systems (Table 16.7.2).[2]

The 100 millisecond maximum response time required by NFPA 15 considers the period from detector reaction to flow at nozzles, or the time elapsed from segments 4 through 9. Since different detectors have differing reaction times, it is imperative that a detector be chosen with the shortest reaction time available, that the detectors be placed as close as possible to the target, and that no retards or delays be present.

Of great concern to fire protection engineers is the time required for the water to travel from the nozzle to the target, segment 10. To minimize water travel time, nozzles must be placed as close as physically or practically possible to the target. Increased nozzle pressure can increase water velocity and decrease travel time. It is highly recommended that the water travel time be considered in the total response time where feasible. High-speed photographic equipment or other sophisticated

TABLE 16.7.1 Classification of Explosives

Class 1, Division 1	Mass detonation. Includes explosives, ammunition, and liquid propellants that are too energetic to be protected by an ultra-high-speed water spray system.
Class 1, Division 2	Explosion with fragments. Includes ammunition and explosives that may be too energetic to be protected by an ultra-high-speed water spray system.
Class 1, Division 3	Mass fire. Includes ammunition and explosives that may be extinguished during manufacture if suppressed at an early stage. The majority of ultra-high-speed water spray systems protect commodities within this division.
Class 1, Division 4	Moderate fire. Includes ammunition and explosives that can be extinguished by an ultra-high-speed water spray system.
Class 1, Division 5	Very insensitive explosives
Class 1, Division 6	Extremely insensitive ammunition

TABLE 16.7.2 Reaction Time

1 The energetic material is subject to excessive energy input.
2 Deflagration begins.
3 The deflagration develops to a point that puts it in the detector's field of vision.
4 The detector begins to react to the fire.
5 The detector determines that there is sufficient light energy to be considered a fire.
6 The detector sends out a fire signal.
7 A high-speed module on the control panel receives the signal from the detector and activates the squib or solenoid-actuated valve.
8 Mechanical components associated with the ultra-high-speed water spray system go into motion.
9 Water leaves the nozzle and travels toward the target.
10 Water spray impinges on the target.
11 Waterflow is maintained to achieve cooling, dispersion, or extinguishment.

time measurement tools are needed to measure water travel time as a component of the total response time.

When no explicit guidance is given for specific situations, 36 in. (914.4 mm) is frequently used as a default distance between a point hazard and ultra-high-speed water spray system nozzles and detectors. Although increased nozzle pressure can reduce water travel time, pressurization of a nozzle beyond its effective range can result in distorted and inefficient nozzle spray patterns.

General Detection Concerns

To achieve the aforementioned rapid response time, optical flame detection for open areas or pressure detection for areas subject to overpressurization is necessary. Examples of optical flame detection devices include ultraviolet (UV) or infrared (IR) detectors placed in close proximity to the hazard. Such detectors instantaneously detect flashes of light associated with the wavelengths normally found in combustion. Pressure detectors sense a buildup of explosive pressure in an enclosure; they are very effective but generally provide slower actuation times than optical flame detectors.

Multiple-band optical detectors are now being specified for use with ultra-high-speed water spray systems. The U.S. Army's Advanced Fire Protection Deluge System Project (AFPDS) investigated multiband IR/IR and UV/IR multiple-band optical detectors as possible replacements for UV detectors and found that they can be as fast as the UV detectors and less likely to falsely actuate. False actuations of ultra-high-speed water spray systems are a major concern for defense and industrial applications. Furthermore, environmental concerns relative to containment and disposal of potential pollutants mixed with water from ultra-high-speed water spray systems may also be a major concern and a rationale for selection of multiple-band optical detectors.

The signal emitted by a detector is received by a high-speed module on the fire alarm control unit. To enhance actuation response times, it is necessary that the control unit be specifically designed for ultra-high-speed systems. It is the fire alarm control unit and its associated detection system that makes an ultra-high-speed suppression system unique from other types of water-delivery fire protection systems. The proper choice and design of supervisory equipment is essential to the successful functioning of the system.

NFPA 70, *National Electrical Code®*, and *NFPA 72®, National Fire Alarm Code®,* must be followed closely for all detection system wiring, component placement, and connections. Circuits between sensing devices and their controllers must be continuous with no splices and must be individually shielded.

GENERAL SYSTEM CONCERNS

Piping Methods

The piping methods associated with agent delivery to the hazard are as varied as the hazards they protect. The nozzles should be in very close proximity to the hazard with water in the piping and primed up to the nozzle, prepared for quick delivery of water to the hazard. One type of ultra-high-speed water spray system, the squib-actuated system, involves loosely capped nozzles, and/or a rupture disc at each nozzle, a preprimed piping system, and a deluge valve with an explosive squib (Figure 16.7.1). Another type, the solenoid-actuated system, involves pilot-actuated nozzles with a solenoid valve or system of solenoid valves installed on the pilot piping, which actuate upon receiving a signal from the detection system (Figure 16.7.2). A third type, possessing explosive squibs at each nozzle, is a variation of the squib-actuated system. Its distinguishing features (i.e., prepriming and squib actuation) will be covered in detail in this chapter.

Approaches to Detection

Two general design approaches, point protection and area protection, will apply to ultra-high-speed water spray system design. Point protection is the application of concentrated high-speed water spray onto a fixed point of ignition, such as a band saw blade for cutting solid munitions, and is accomplished by providing two or more counteropposed nozzles at positions as close as physically possible to the point of ignition (Figure 16.7.3). Area protection is the application of high-speed water spray over the area of a room or over the surface area of an object (Figure 16.7.4). In both cases, the nozzles must be as close to the intended target as possible to minimize the time for the water to travel from the nozzle to the target. Some hazards may be conducive to using the attributes of both point protection and area protection. This hybrid system is referred to as a combination system (Figure 16.7.5).

Nozzles and detectors should be placed no further than 36 in. (914.4 mm) from a point hazard and must be carefully coordinated with the process to avoid interference with the hazardous operation. Nozzles placed for point protection should have very narrow water spray angles for the efficient application of water density onto the point of hazard.

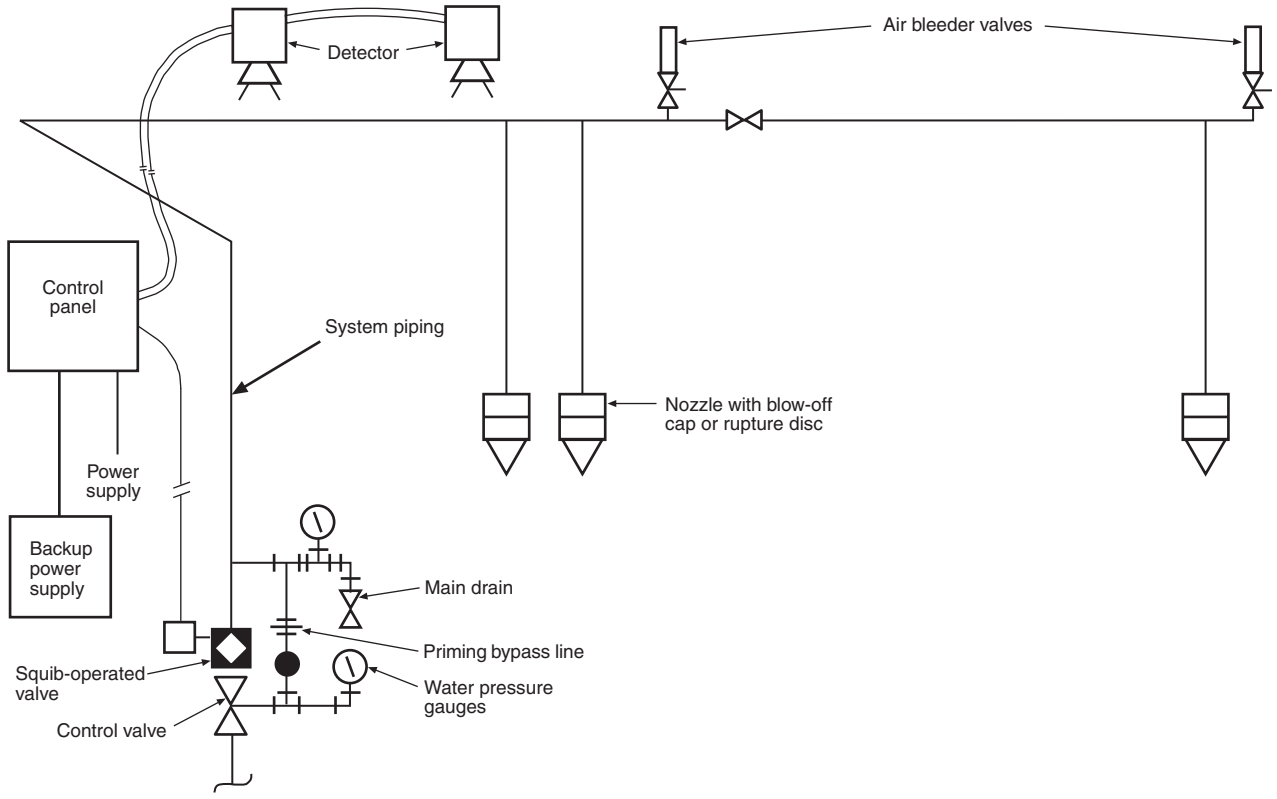

FIGURE 16.7.1 Squib-Actuated System

Nozzles spaced for an area hazard must be placed at a distance from the floor that permits the overlap of nozzle spray patterns on the floor or on the surface of interest. Although wide nozzle spray angles (about 120°) are likely to easily overlap, narrower spray angles (60° or 90°), spaced closely together, are more likely to provide efficient spray density, water velocity, and enhanced water travel time.

The process of detection, transfer of signal to the fire alarm control unit, interpretation of the signal, transmission of signal to the valve, and delivery of water to the hazard happens before one's senses are aware of a problem. It is not unusual for an installer to receive complaints of false trips after the installation of an ultra-high-speed water spray system. These occurrences may actually be real fires, undetectable by human senses. It is recommended that a diary of events be kept before and after system installation for analysis.

The first high-speed systems that protected munitions and propellant facilities were primarily preprimed deluge systems that used standard deluge valves, pneumatic detection, and enhanced pressurization. Response times for such systems were in the vicinity of 1 second. This type of system can still be used when it is desired that standard water spray deluge systems have an enhanced response time. The movement of the deluge valve clapper slows system actuation time considerably. However, improvements and innovations were developed to protect processes involving materials that require faster response times than the preprimed deluge system. The currently available ultra-high-speed water spray systems are covered in the sections that follow.

DETECTION SYSTEM SELECTION

In order to provide the best possible results in protecting munitions and other hazards requiring rapid-response technology, it is recommended that a four-step method be used to select a detection system:[3]

1. Choose a detector capable of reacting to the wavelengths expected to be encountered in a fire involving the hazardous material in question. For example, a UV detector will respond to a hydrogen fire, but an IR detector operating in the 4.4 micron range will not.
2. Survey the hazard area, the process, and the adjoining areas to determine sources of false signals that may exist. For example, if arc welding is expected to occur within the view of a detector, UV detectors must be either shielded from view or repositioned.
3. Determine elements that could interfere with the optimum operation of the detector. Dust or ice could severely hamper the detector's ability to function in accordance with its design parameters and will determine a detector's features or placement. Detectors with air shields to automatically clear dust from the detector lens are available.
4. Using test data or empirical results, ascertain the speed with which the detector is required to respond.

Two basic categories of flame detection systems are used as releasing systems for ultra-high-speed water spray systems. One type, UV detectors, responds to radiation in the range of 1850 to

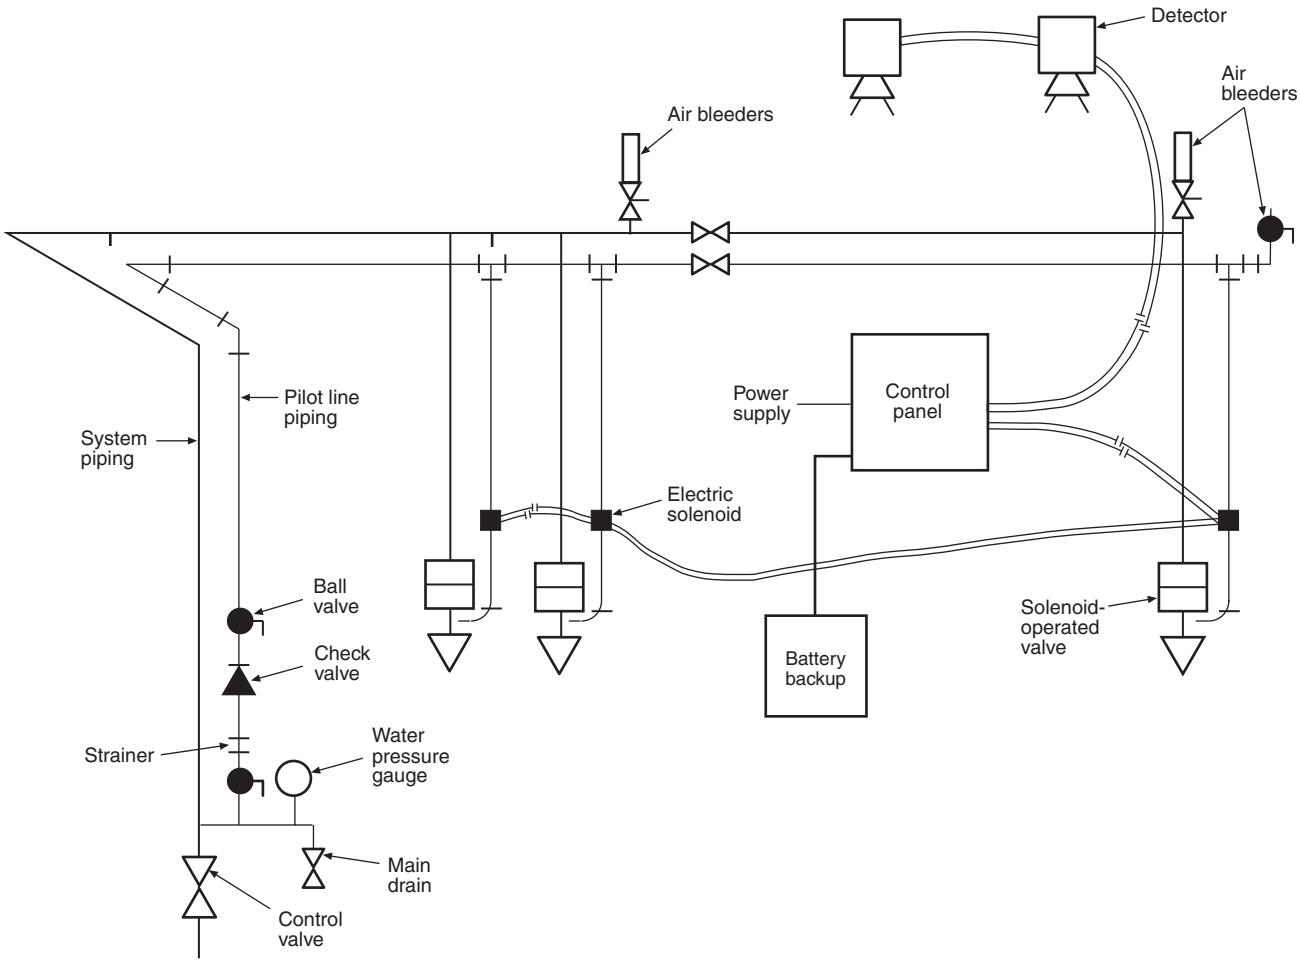

FIGURE 16.7.2 Solenoid-Actuated System

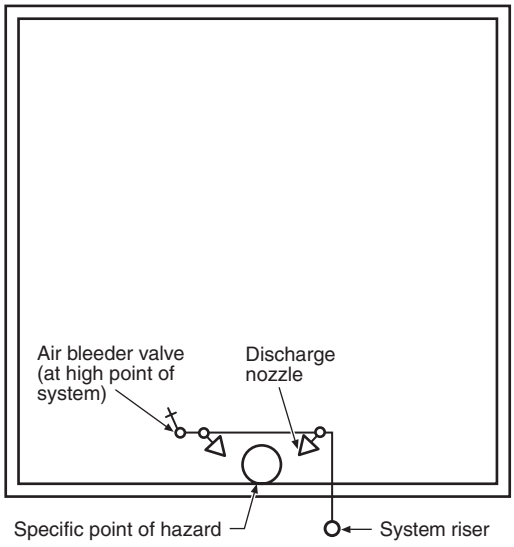

FIGURE 16.7.3 Local Point Application Design

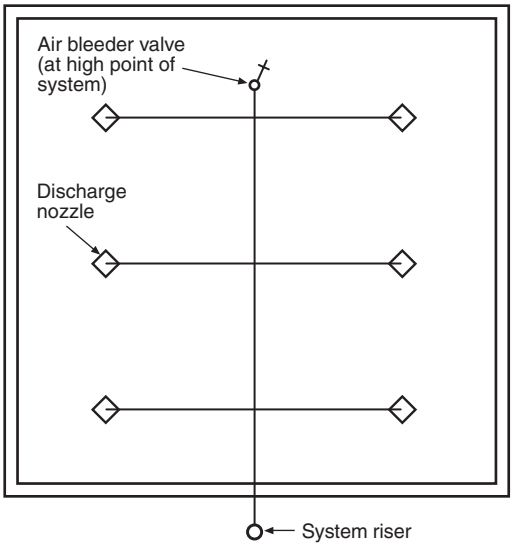

FIGURE 16.7.4 Area Application Design

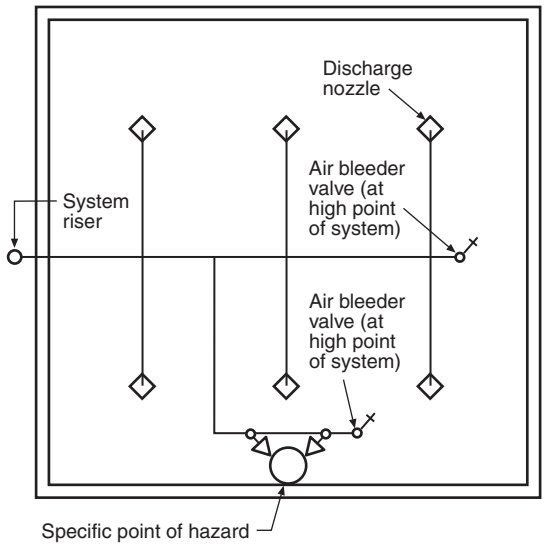

FIGURE 16.7.5 Combination Application

2850 angstroms (0.185 to 0.285 microns). Detection ranges are graphically shown on a radiation spectrum chart (Figure 16.7.6). The other type of flame detector is the IR detector.

Multiple-band optical detectors, such as dual-band or triple-band IR or UV detectors and dual-band UV/IR detectors, may also be used. A multiple-band IR detector, for example, searches a hazard for more than one band of IR radiation from the IR spectrum, providing the potential for a more reliable detection signal.

Note how the radiation spectrum chart shows an intersection between the IR detector sensitivity (between 0.8 and 1.0 microns) and the graph of solar radiation that reaches the earth. One can surmise by this intersection that an IR detector would be receptive to and would be adversely affected by sunlight radiation. This radiation spectrum correlation will strongly affect the manner in which IR detectors are used. UV detectors are not affected by sunlight, according to the graph, and can be located without regard to sun exposure. High-intensity lights and high-temperature bodies will affect IR detectors with no effect on UV detectors. However, arc welding, lightning, X-rays, and gamma rays will affect UV detectors more than IR detectors that have been properly aimed and shielded.

Since the two predominant types of ultra-high-speed system detectors (i.e., UV and IR) are searching for differing types of radiation and are affected by differing interfering media, their applications are generally quite different. UV detectors, being insensitive to sunlight, would be well suited for surveillance of an entire process area or a process requiring a wide angle of vision, whereas IR detectors would be better suited for close surveillance of a specific contact point within a processing machine or supervision of the interior of an enclosed vessel (Figure 16.7.7).

UV detectors are subject to the inverse square laws of optics, where detector sensitivity varies inversely with the distance between the detector and the energy source:

$$S = \frac{(\mathrm{K})pe^{cd}}{d^2}$$

where

S = Radiation power reaching the detector

K = Constant

p = Radiation power emitted by the fire, which is a function of the fuel characteristics and fire size

e = Base logarithm

c = Extinction coefficient of air, or the radiation energy absorbed or diffused by air, a function of humidity, dust, and so on

d = Lineal distance from the fire to the detector

From this famous law of physics, one can see that doubling the sight distance of the detector results in a dramatic reduction in the radiation received by the detector. Conversely, reducing the sight distance greatly increases the radiation received by the detector.

In cases where the point of ignition could be anywhere in a room, the wisest use of UV detectors is to provide area detection of the entire process by overlapping the area detection system

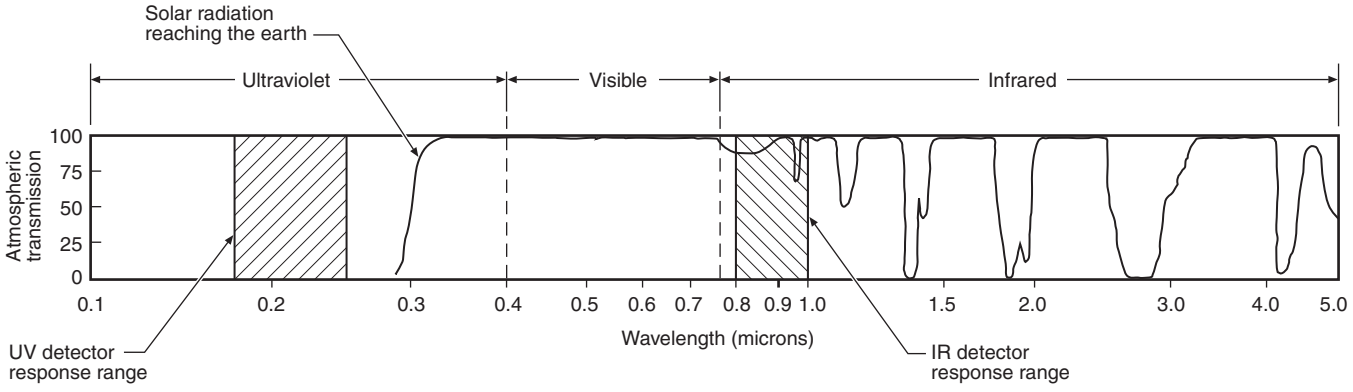

FIGURE 16.7.6 Radiation Spectrum Chart

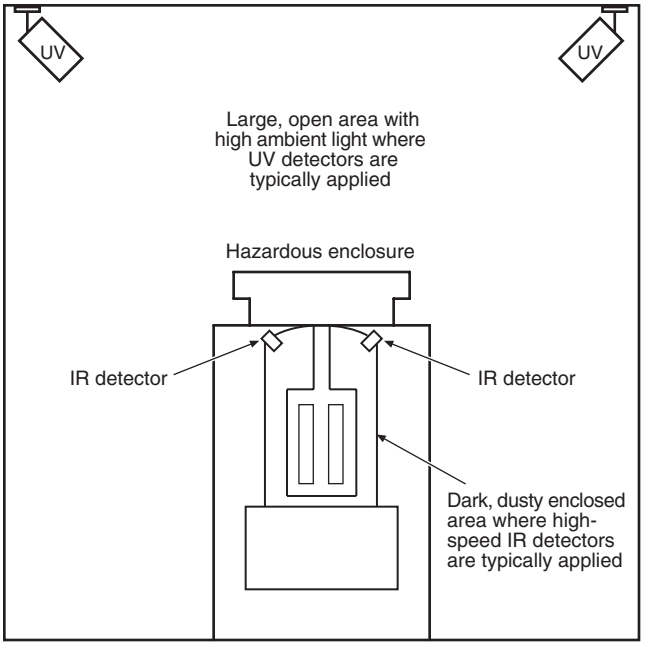

FIGURE 16.7.7 UV and IR Detectors

to cover all room areas, with additional detectors that closely view critical points in the process. For point protection, reliability increases dramatically when critical areas are viewed by overlapping cones of vision from counteropposed detectors in the same detection zone.

Because of their sensitivity to sunlight, IR detectors are best located in enclosed spaces, partially enclosed spaces, or spaces shielded from sunlight. Although IR detectors also obey the inverse square law, the hazard of receiving unwanted sunlight signals negatively affects their performance at extended detection distances. Shields are available to restrict the cone of vision of an IR detector to prevent unwanted actuation, and downward positioning reduces dust buildup on the lens.

The actuation or release apparatus for an ultra-high-speed suppression system consists of detectors (Figure 16.7.8), a specialized high-speed controller capable of monitoring and supervising up to eight detectors (Figure 16.7.9), a relay module to alert personnel and provide remote annunciation capability, and a detonator module that activates the squibs or solenoids that release an ultra-high-speed deluge system. Figure 16.7.10 illustrates the wiring of the detector and the controller shown in Figures 16.7.8 and 16.7.9. The modular control components are installed in a mounting cage and are served by a voltage converter that transforms ac building current into dc system current.

THE MUNITIONS MANUFACTURING PROCESS

The munitions manufacturing process is one of the most prominent applications for ultra-high-speed water spray systems and is among the most hazardous fire protection challenges that a

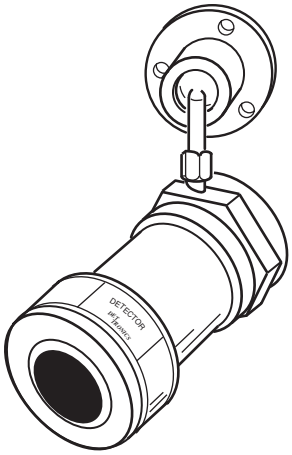

FIGURE 16.7.8 Ultraviolet Optical Detector on Swivel-Mount Base

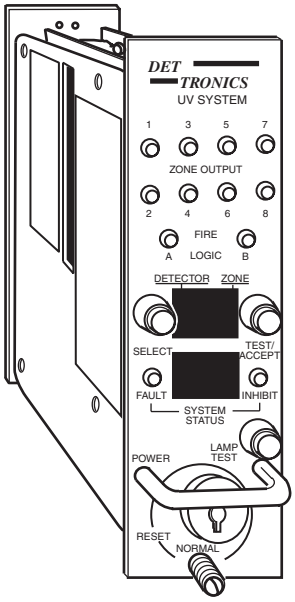

FIGURE 16.7.9 High-Speed Module

system designer or contractor can encounter. A delay of only a few milliseconds can mean disaster. The stakes are frighteningly high, and munitions manufacturing personnel are routinely required to perform operations involving significant risk. The U.S. Army Operations Support Command and its army ammunition plants and depots have played a leading role in the development and improvement of ultra-high-speed water spray systems.

Ultra-high-speed water spray systems have been successfully employed to protect the manufacture of many types of munitions, including propellants, diazodinitropherol (DDNP), trinitrotoluene (TNT), tetranitromethylaniline (TETRYL), tetranitrocellulose-type explosives (RDX), C-4, black powder,

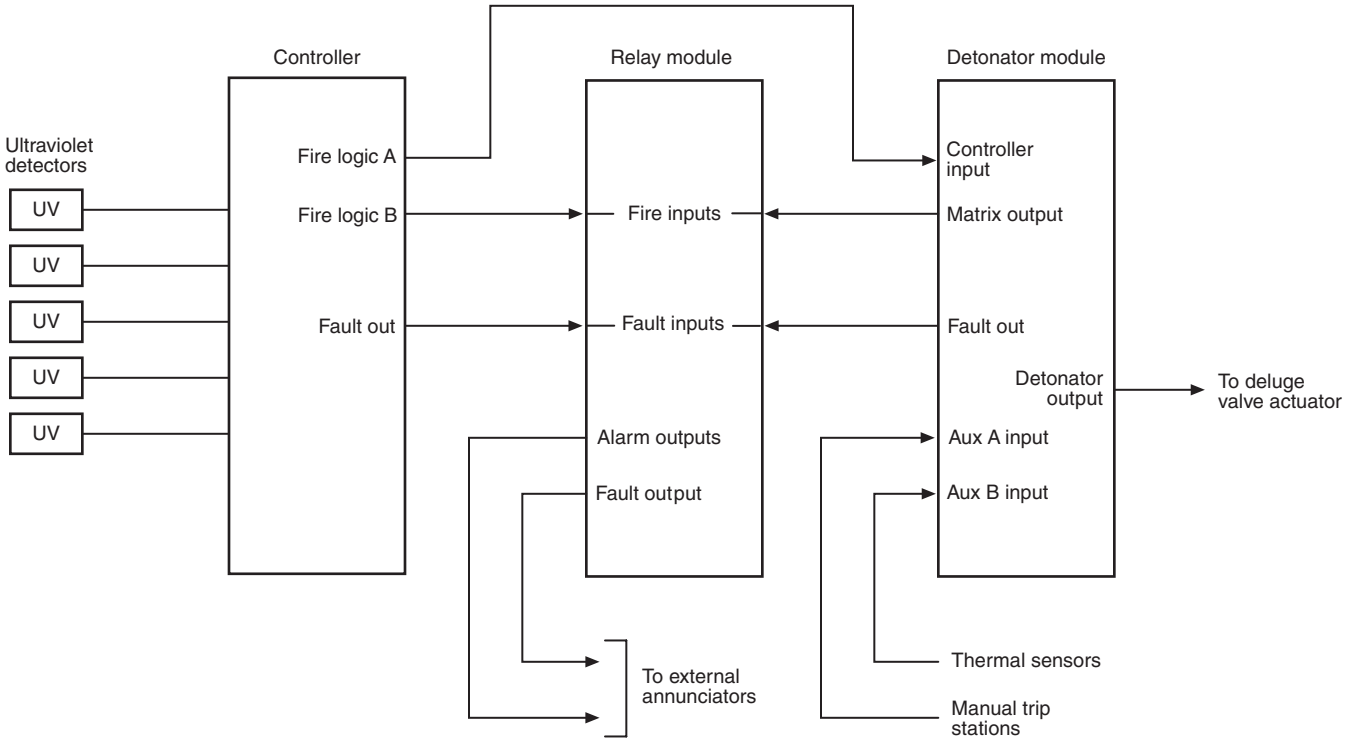

FIGURE 16.7.10 UV Block Diagram

pyrotechnics, fireworks, magnesium Teflon™ flares, and smoke-generating devices. Each commodity involves differing manufacturing processes and protection schemes.

Manufacturing Operations

In general, the 14 processes[1,4] that describe most munitions manufacturing operations include the following:

1. Weighing
2. Pressing
3. Pelletizing
4. Propellant loading
5. Melting
6. Extrusion
7. Mixing
8. Blending
9. Screening
10. Sawing
11. Granulating
12. Drying
13. Pouring
14. Machining

Each of these munitions manufacturing operations requires individual consideration and careful engineering to fully analyze the entire munitions manufacturing process and determine the proper and appropriate protection measures. In each case, the specifying engineer or designer must determine the objective of the system.

The three performance objectives that are to be considered in ultra-high-speed suppression system design are (1) life safety and personnel protection, (2) equipment protection and facility protection, and (3) total extinguishment or propagation cessation. The location and extent of protection and detection varies with the size of the operation, location of critical friction points, and the presence and location of the operating crew. A thorough risk analysis of the hazard is required and an evaluation of the financial and life safety effects of a catastrophic event in a processing area must be completed in advance of selecting the choice of objective or combination of objectives. If a catastrophic event would have a major effect on any objective, then prevention of such an event is a critical component of ultra-high-speed system design.

A strong consideration to be given in the choice of general area protection versus specific point protection is the mobility of the equipment. In many cases munitions processing machinery can be moved from one location to another, making protection at specific contact points impractical or impossible. It is recommended that a combination of area protection and point protection be provided wherever feasible and that protection for personnel be provided in all cases. Perhaps a way of solving the dilemma of frequently relocated point hazards is to provide area protection at the ceiling, supplemented by a portable ultra-high-speed water spray system, as discussed later in this chapter, for protection of the movable point hazard.

Weighing. If the munition is a powder, a special situation will arise as a result of the dust created by the operation. Ungrounded

static charges could result in ignition of the dust. The detection system should be as close to the hazard as possible, while maintaining the ability to perform and observe the pouring operation. Nozzles should be placed in such a way as to wet down the entire operation, including the operator, with overlapping sprays from opposing angles and with as heavy a density as possible. Extra nozzles may be required at critical points in the process. Solid weighing processes will involve, in general, detectors and nozzles placed throughout the hazard area. By protecting the entire room, the pathways between operations will be supervised and protected by heavy-density water spray.

Pressing and Pelletizing. A major risk in pressing and pelletizing operations is associated with ignition of the munition at the contact points of the operation and propagation of flame to the bulk storage of the munition. Detection and protection must be located as close to the points of contact as possible. Normally, the operator's arms will be protected by water spray applied to the contact points. Strong consideration should also be given to adding nozzles for the protection of the entire machine and the operator. Also, the designer should ensure that the bulk storage of the commodity is physically isolated from the manufacturing operation, or is otherwise protected.

Propellant Loading. The fire protection objective in explosive propellant loading is to halt the flame front caused by an ignition of propellant, thereby preventing propagation from the loading area to the main hopper, preventing a deflagration in the hopper.

Area protection and detection is recommended for the loading area, the storage area, and the travel routes between the munitions operation, the storage area, and the loading area. Additional point protection is recommended for critical friction or contact points.

Melting. Kettles are used to melt munitions, employing steam or hot water as the predominant energy source. One or more detectors, placed as close to the kettle as possible, and nozzles directed over the exterior of the kettle, especially at the opening where materials are added, will be required. The close proximity of detection and nozzles with respect to the kettle is critical to successful fire protection during a melting operation.

Detectors are never placed within melt kettles. Such environments are conducive to severe fogging of the detector lenses, negating their value in a very short time. Furthermore, the temperature encountered within melt kettles often exceeds the upper operating limits of most detectors and will not permit the internal installation of detectors. For such applications, mount the optical detectors on the exterior of the melt kettle as close as physically possible.

Extrusion of Explosives, Pyrotechnics, and Propellants. Extrusion involves the process of pressing the propellant or pyrotechnic material through an opening or die to form it into a desired shape. The point of fire protection interest here is the opening through which the munition exits. Detection and nozzle placement close to this point should prevent any ignited munition from spreading to the bulk storage area of the machine. Personnel and machine protection should also be considered.

Mixing and Blending. Mixing and blending of munitions can take place in an open vat or in a closed container. The open mixing or blending process may be approached in a manner similar to the melting process. If the container is closed, the detector and nozzle should penetrate the enclosure, with appropriate precautions taken to avoid dust loading or obscuration of the detector and nozzle. Heat, mechanical damage, and dust must be considered when placing detectors or nozzles within closed containers.

Screening, Sawing, and Granulating. Common hazards to be considered in these processes are friction, dust, and sparks that can occur during these operations. Points of contact must be completely observed by detection and protected with point-protection ultra-high-speed water spray. Locating the nozzle as close to the point of contact as possible will enhance timely delivery of water to the critical point most likely to support ignition.

Drying, Pouring, and Machining. Drying operations are usually done in ovens or heating cabinets, with area nozzle protection over the surface area of the cabinets, especially where the operator opens the cabinet to remove or add items to be dried. Pouring requires point nozzle protection, and area nozzle protection is also often required. Machining operations require point nozzle protection similar to extrusion operations with area coverage also often required.

Choice of Agent for Munitions Manufacturing Protection

Water is the agent of choice in the protection of explosive munitions hazards for its ability to cool the combustible, insulate the exposed surfaces, dilute a hazardous material, knock down suspended dust, and cool the expanding flame front. Water is an inexpensive and readily available suppressant.

Munitions and propellants differ from most fire protection hazardous commodities in that they contain a built-in supply of their own oxidizer mixed in with the fuel. The oxidizer is needed to ensure rapid burning of the material on demand in tightly enclosed areas or oxygen-deficient atmospheres, such as rocket motor combustion chambers or artillery gun tubes. Most oxidizer additives in the munitions industry fall under the general classification of nitrates and chlorates, such as potassium nitrate and potassium chlorate.

In the choice of an agent for munitions manufacturing, the presence of this built-in oxygen supply effectively eliminates from consideration the commonly available smothering or blanketing agents, such as carbon dioxide. Halon clean agents and other gaseous suppressants typically fail to stop the flame front in munitions fires. These agents begin to chemically break down and, therefore, fail to provide the cooling necessary to inhibit propagation. It must, therefore, be concluded that the primary objective in munitions protection is cooling by using water, not unlike most hazards encountered

by the fire protection engineer. By introducing a cooling agent in the early stages of a deflagration, one prevents the feedback of heat energy from spreading to unburnt fuel, thus effectively limiting and then ceasing combustion. Failure to apply water in the very early stages of munitions combustion could result in burrowing or flame propagation within a pile of munitions mixture covered by extinguished and water-soaked munitions material.[1]

Also to be considered are the combustion gases produced by burning munitions. There exists in munitions fires a point of no return, where the production of combustion gases creates a barrier sufficient to prevent water spray from reaching the fuel. This explains why sophisticated mechanical and electrical fire protection equipment, designed for response in a few milliseconds, is essential for the protection of munitions hazards. Retardation of ultra-high-speed fire suppression system response time from 100 milliseconds to 1 second or more can create a scenario whereby the deflagration reaches a point that the expanding flame front gets out of control, negating the effectiveness of the suppression system and resulting in the loss of the process.

An automatic sprinkler system should be specified for adjacent storage or operations areas if there is a possibility of a fire occurring in other materials that could result in a fire propagating to the munitions, such as a fire starting in combustible packaging material and spreading to a munitions item.

Flame Detection Devices

Flame detection is the detection method of choice for ultra-high-speed deluge systems. Two types of flame detectors in common usage are UV detectors and IR detectors, both consisting of a photoelectric cell and a photoconductive cell.

Ultraviolet Detectors (UV). UV detectors are designed to detect radiation falling within the ultraviolet wavelengths below 4000 angstroms (0.4 microns). Fires emitting radiation with wavelengths of this nature generally have high-intensity flames associated with diffusion flame combustion. Close proximity of the detector to the source of the combustion is critical to operation within its intended range of sensitivity.

Shielding or screening may be necessary to isolate the UV detector from unwanted signals, such as lightning and welding arcs. It should be noted that a UV detector is an efficient flame detector, but must see the fire to be effective. An anticipated fire that is preceded by or accompanied by significant quantities of thick or dark smoke may not be amenable for UV detection, since the smoke could prevent or delay the operation of a UV detector. UV detectors cannot see through Lexan shielding. It is, therefore, necessary to ensure that each area bounded by shielding is individually detected within the shielded zone.

A limitation to the use of UV detectors is the fogging or loading of the lens that can occur when these detectors are used in dusty or moist atmospheres, adversely affecting their reaction time. Unless special arrangements are provided, such as air shields to divert dust away from the lens, or a tightly controlled 24 hour maintenance and supervision program, UV detectors may be unsuitable for some dusty or greasy environments.

Infrared Detectors (IR). IR detectors are amenable for use at distances up to 50 ft (15.3 m), and respond to infrared radiation involving wavelengths from 8500 to 12,000 angstroms (0.8 to 1.2 microns). Using IR detectors at extended distances is generally not recommended for ultra-high-speed suppression systems for explosive hazards. There is, however, research currently under way on possibly using some of the newer IR detectors that show great promise as a possible detection source for ultra-high-speed water spray systems for specialized applications.

Some common heat sources that can be sources of false alarms for IR detectors include automobile headlights, direct or reflected sunlight, room lighting, heaters, lighted tobacco products, and matches. IR detectors may not be able to discriminate between a common heat source and a combustion scenario.

Most IR detectors have a built-in timing unit that can delay actuation by as much as 1 to 30 seconds. This length of delay is usually unsuitable for the detection of munitions fires. If IR detectors are used, the distance between hazard and detector must be kept to a minimum, effectively screening out most sources of unwanted signals, and the time delay must be eliminated or minimized. A special ultra-high-speed IR detector is available with the delay feature eliminated.

Detector Listing. Most UV and IR detectors are listed by Underwriters Laboratories Inc. (UL) and are approved by Factory Mutual Research Corporation (FMRC) for fire protection use. Although they are approved for both indoor and outdoor use, it is recommended that they not be used outdoors for ultra-high-speed detection, so that unwanted signals can be minimized. Sources of flickering light, such as lights mounted on operating or vibrating machinery, may be perceived as being a fire by the detector and should be screened or eliminated.

Multiband Detectors. Multiband IR/IR and UV/IR detectors are commercially available, and recently manufactured units have been found to provide rapid response times while lowering incidences of false actuation. Multiband detectors search for more than one band of spectral radiation and confirm receipt of such signals in advance of notification of the fire alarm control unit of a fire.

SQUIB-ACTUATED SYSTEMS

The squib-actuated ultra-high-speed deluge system is a preprimed deluge system with a squib-operated deluge valve, a system of piping preprimed with water, specially capped nozzles and/or rupture discs, and an ultra-high-speed flame detection system. Developed in the early 1960s, it was the first commercially available ultra-high-speed water spray system and continues to be in active use today.

It is recommended that this system be used for hazards such as ammunition loading, explosive powder drying operations, high-energy fuel processing, self-oxidizing fuel processing and storage, silane containment cells, explosive dust collecting and conveying operations, roll mills, and casting pits. Other hazards requiring enhanced reaction times may be suitable for the squib-actuated ultra-high-speed water spray system.

Preprimed Piping System

The preprimed piping system on a squib-actuated system is supplied by a priming bypass valve that provides a water head of up to a maximum of 12 psi (82.74 kPa) to the blow-off caps installed to hold back the pressurized priming water. Water pressure required to remove the blow-off caps will vary with the make and model of cap used. A wire retains the blow-off cap to the nozzle for ease of retrieval and to prevent it from falling into material or devices being protected. It is recommended that the nozzles be as close as possible to the hazard being protected, and directed toward the critical points of the hazard (Figure 16.7.11).

Allowing the water to be preprimed in the piping has a strong advantage over standard evacuated piping deluge systems. The time it would have taken for the water to travel from the deluge valve to the nozzle has been eliminated. This can be a significant difference, especially for systems requiring the deluge valve to be remote from the hazard. The preprimed aspect of this system requires that the hazard area and valve riser be heated. Heat tracing of the piping is not recommended because loss of power, improper tracing installation, cracking or crimping of the tracing wire, or other potential failures of the tracing would damage and compromise the ability of the system to function when required.

The priming static pressure that can be maintained on the blow-off caps for a squib-actuated system, without danger of accidental leakage, is 12 psi (82.74 kPa) or less, depending on the cap manufacturer. Rupture discs or other devices capable of maintaining a minimum system static pressure of 50 psi (344.75 kPa) are strongly recommended. The system must be hydraulically designed to ensure a minimum residual pressure of 50 psi (344.75 kPa) at each nozzle, with sufficient static pressure to allow for automatic removal of all blow-off caps or rupture of all rupture discs on system actuation (Figure 16.7.12).

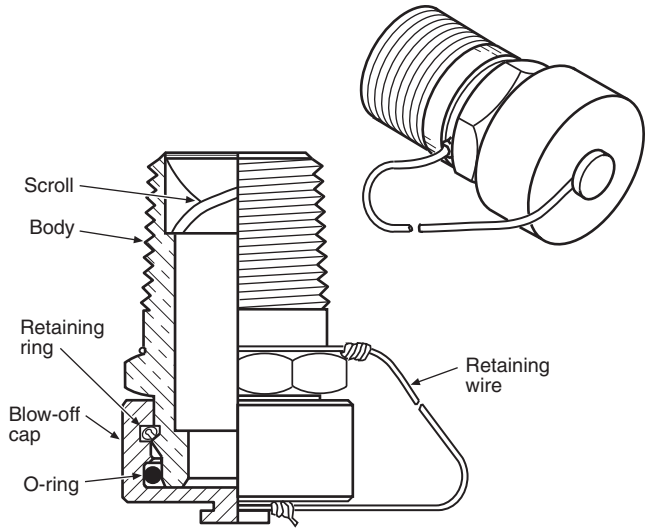

FIGURE 16.7.11 Nozzles and Blow-Off Caps

Squib-Actuated Valve

The squib-actuated valve is an electrically actuated valve with two explosive primers wired in parallel (Figure 16.7.13). The

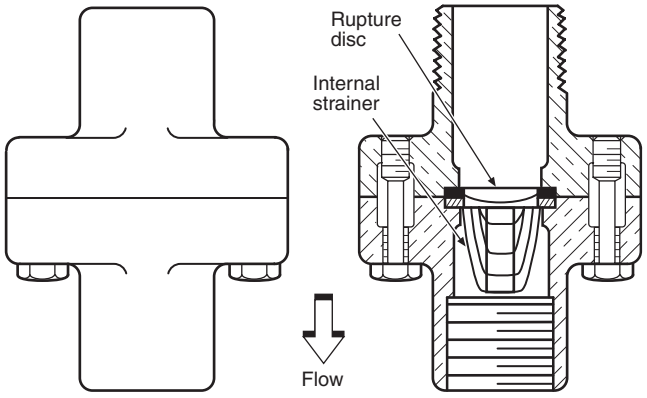

FIGURE 16.7.12 Rupture Discs

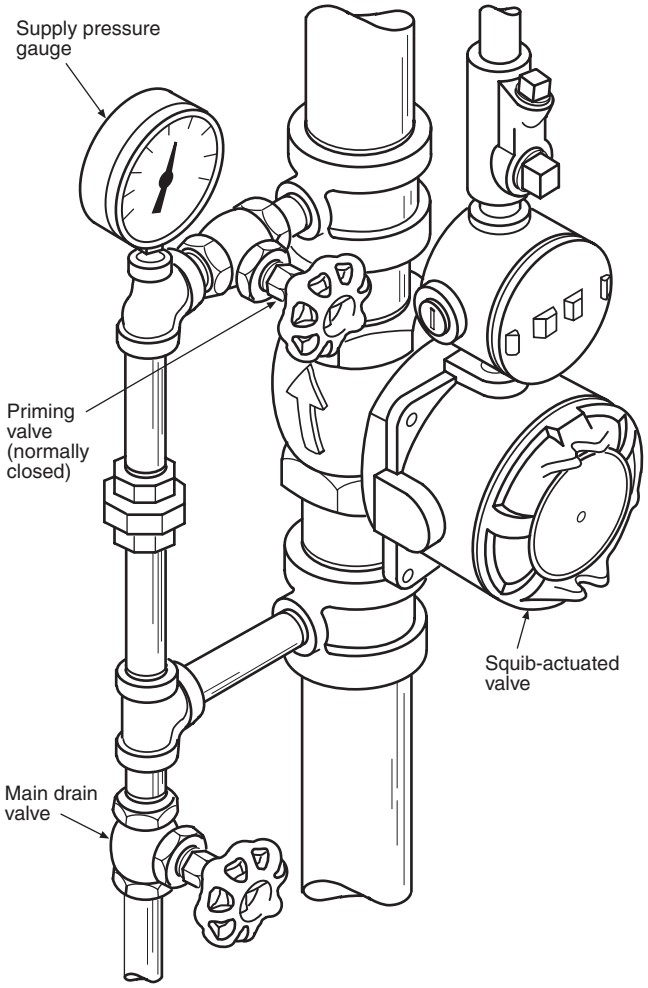

FIGURE 16.7.13 Squib-Actuated Valve

valve is intended to be installed vertically but will also function with increased response times in the horizontal position. The primers consist of 0.004 oz (0.12 g) of lead styphnate charge and actuate upon the receipt of an electric signal from the detection system.

The primers are designed so that the force of only one primer is needed to actuate the system. Firing of the primers shears a rod holding the clapper latch, allowing the plunger to rise, resulting in the rapid movement of the clapper and rapid pressurization of the priming water as water begins to flow through the valve. The blow-off caps are ejected or rupture discs broken once their inlet pressure exceeds their respective release pressure (Figure 16.7.14).

Although squib-actuated valves are rated for use in Class II (electrical rating) locations, it is recommended that the valve not be located directly adjacent to a hazardous process and in a nonhazardous area, if physically possible.

Squib-actuated valves are available for use with 2 in. (51 mm) and 2½ in. (64 mm) risers, and releases are available for 4 in. (102 mm) and 6 in. (152 mm) deluge valves. Increased system size has a very strong effect on the increasing of response time. A 500 gal (1893 L) water-holding capacity is recommended as the maximum system size, and best results would be obtained by subdividing the systems such that the number of nozzles served by one squib-actuated valve is between two and six nozzles with separate detection systems and suppression system actuation valves.

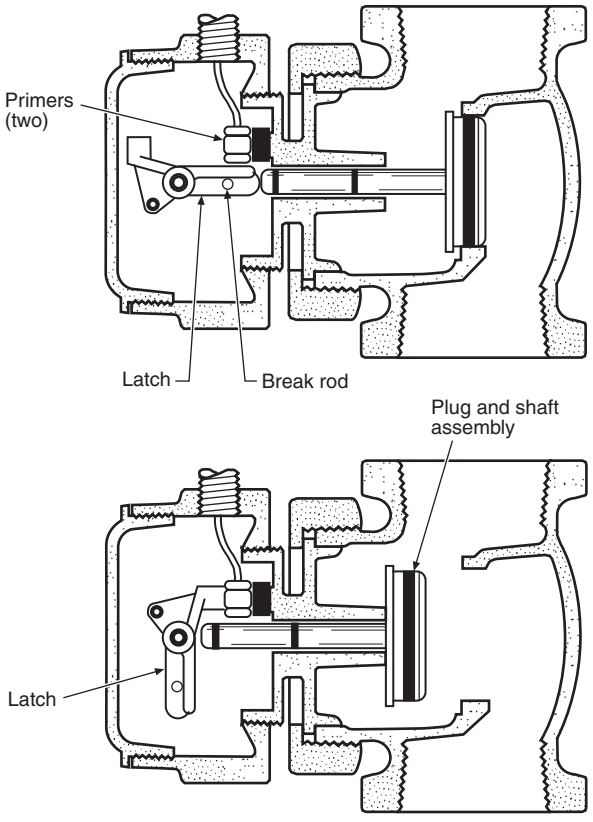

FIGURE 16.7.14 Squib-Actuated Valve Unlatching

Squib-Actuated Detection System

The detection system for a squib-actuated system (Figure 16.7.15) is ordinarily an optical flame detection system. These photoconductive cells monitor the hazard and can detect small amounts of radiant energy emitted by a fire in the hazard area. Such detectors are monitoring light within certain predetermined wavelengths normally associated with fire. Should the photoconductive cells receive more light than was specified to be ambient, the cells' resistance will change, sending a signal to an amplifier in the control panel. This amplifier increases the signal's strength and sends it to the primer for actuation. Signal transmission time is normally 2 or 3 milliseconds.

Normal actuation times for a squib-actuated system can vary with piping configuration, size of the system, distance from the valve to the nozzles, water pressure, and hazard conditions. Response times in the 100 millisecond range are possible for very small systems with risers very close to the hazard and with high water supply pressures.

Resetting a Squib-Actuated System

After operation, the two primers and primer holders are replaced, and a new break rod installed. Nozzles are then recapped or plugged or rupture discs replaced. Breakglasses must be replaced if the system was operated manually. The system is then reprimed by slowly opening the priming bypass valve and bleeding the air from bleeder valves located at high points in the piping system. Care must be taken to purge all air to ensure complete priming of the system. The control panel is then reset and returned to service. It is recommended that spare primers, holders, rods, blow-off caps, rupture discs, and breakglasses be kept in a convenient nearby location for ease of resetting. It is essential that the system be functionally tested and operated at least once a year to ensure that all parts are functioning properly and ready for use.

System Actuation Time

The piping in a preprimed deluge system must be sloped, with air bleed valves placed at the piping high points, to facilitate the

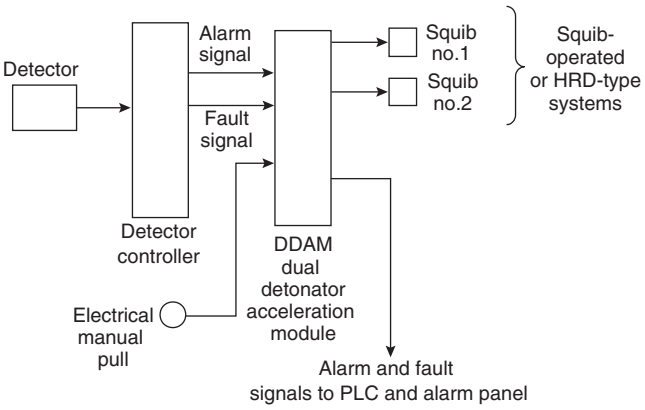

FIGURE 16.7.15 Squib-Operated Electrical Flow Diagram (Source: Pyrotech International)

removal of trapped air bubbles in the piping, which are known to have the effect of increasing response time.

Another major factor influencing actuation time is the system water supply pressure. When all other variables are held constant, the actuation time decreases with increasing water supply pressure. For example, if one could double the supply pressure from 50 to 100 psi (344.75 to 689.5 kPa), the actuation time would decrease by about 20 to 25 percent. Actuation times assume that the priming water is at rest at the nozzle orifices. The system pressure and the resulting enhanced actuation times, therefore, result from inertia effects and are effectively independent of pipe friction, head elevation, and nozzle orifice coefficients.

Other factors influencing the effectiveness of a squib-actuated system are the quantity of nozzles on the system, orifice diameter of the nozzles, length of piping from deluge valve to the nozzles, number of fittings on the supply and branch pipes, cap or disc blow-off pressure, and cross-sectional area of the supply pipe.

Actuation time for squib-actuated systems is shown in Figure 16.7.16. The valve unlatching time and cap blow-off time are strong functions of system pressure. The graph also shows that 4- and 6-in. (102- and 152-mm) squib-actuated valves take 3 milliseconds longer to unlatch than the 2- and 2½-in. (51- and 64-mm) valves.

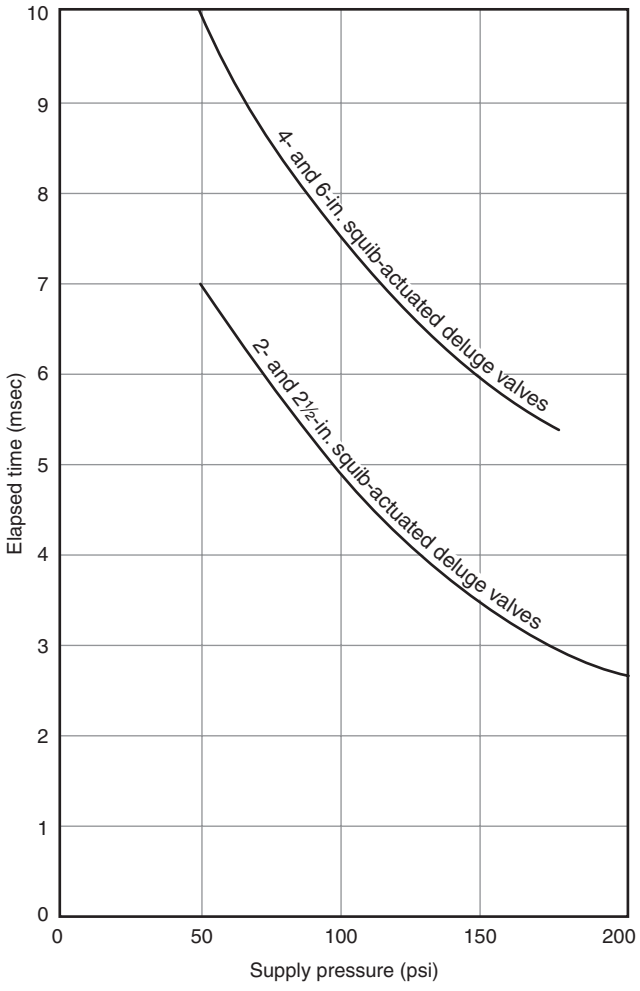

FIGURE 16.7.16 Valve-Unlatching Time

Most U.S. Army ammunition plants maintain static pressure for ultra-high-speed water spray systems in the range of 50 to 75 psi (344.75 to 517.13 kPa), usually supplied by elevated gravity tanks, to enhance actuation time.

Squib-Actuated Ultra-High-Speed Water Spray System Design

Recommendations for a squib-actuated ultra-high-speed water spray system design are as follows:

1. It is recommended that the squib-actuated valves be installed in the vertical position, even though a horizontal position is possible. Installation in the horizontal position could trap air, negatively affecting actuation time.

2. Care should be taken to make the pipe routing from squib-actuated valve to the nozzles as direct as possible, with as few fittings and bends as possible.

3. Slope all piping up to vent valves at piping high points to facilitate the elimination of air from the system. The pipe should be sloped as radically as possible, especially for smaller pipe sizes.

4. For point protection, position the nozzles into counter-opposed groups of no fewer than two nozzles for efficient delivery of water to a likely source of ignition. Counteropposition of the nozzles involves nozzles aimed from differing directions at a common point.

5. Ensure the highest possible water supply static pressure, enhancing system pressure with a surge (pressure) tank or an excess pressure pump if city or plant supply is insufficient. A minimum of 50 psi (344.75 kPa) static pressure is recommended.

6. Perform hydraulic calculations of the system to verify pipe sizes and ensure minimum nozzle discharge pressures of 50 psi (344.75 kPa). Densities must be calculated based on water that actually impinges on the hazard area. Unless the nozzles are wisely placed, the spray that impinges on areas of little consequence could be considerable, reducing the actual delivered density on the hazard area. Also care must be taken to overlap sprays as much as possible to supplement the lighter densities that are normally found along the outside perimeters of the conical spray patterns. For spot protection, it is recommended that the concept of average density (raw gal [L] available at nozzle divided by total ft^2 [m^2] of floor area covered) be replaced by experienced engineering evaluation of actual nozzle distribution to the hazard area in question. Each nozzle is required by NFPA 15 to discharge no less than 25 gpm (95 L/min) per nozzle for point protection, nor less than 0.50 gpm/ft^2 (20.37 L/min·m^2) for area protection. Some commodities, such as especially volatile pyrotechnics, may require densities as high as 3.0 gpm/ft^2 (122.24 L/min·m^2).

PILOT-ACTUATED SYSTEMS

Early Development

The first pilot-actuated nozzle was introduced in the early 1960s. This early system (Figure 16.7.17) has as its basis mechanical

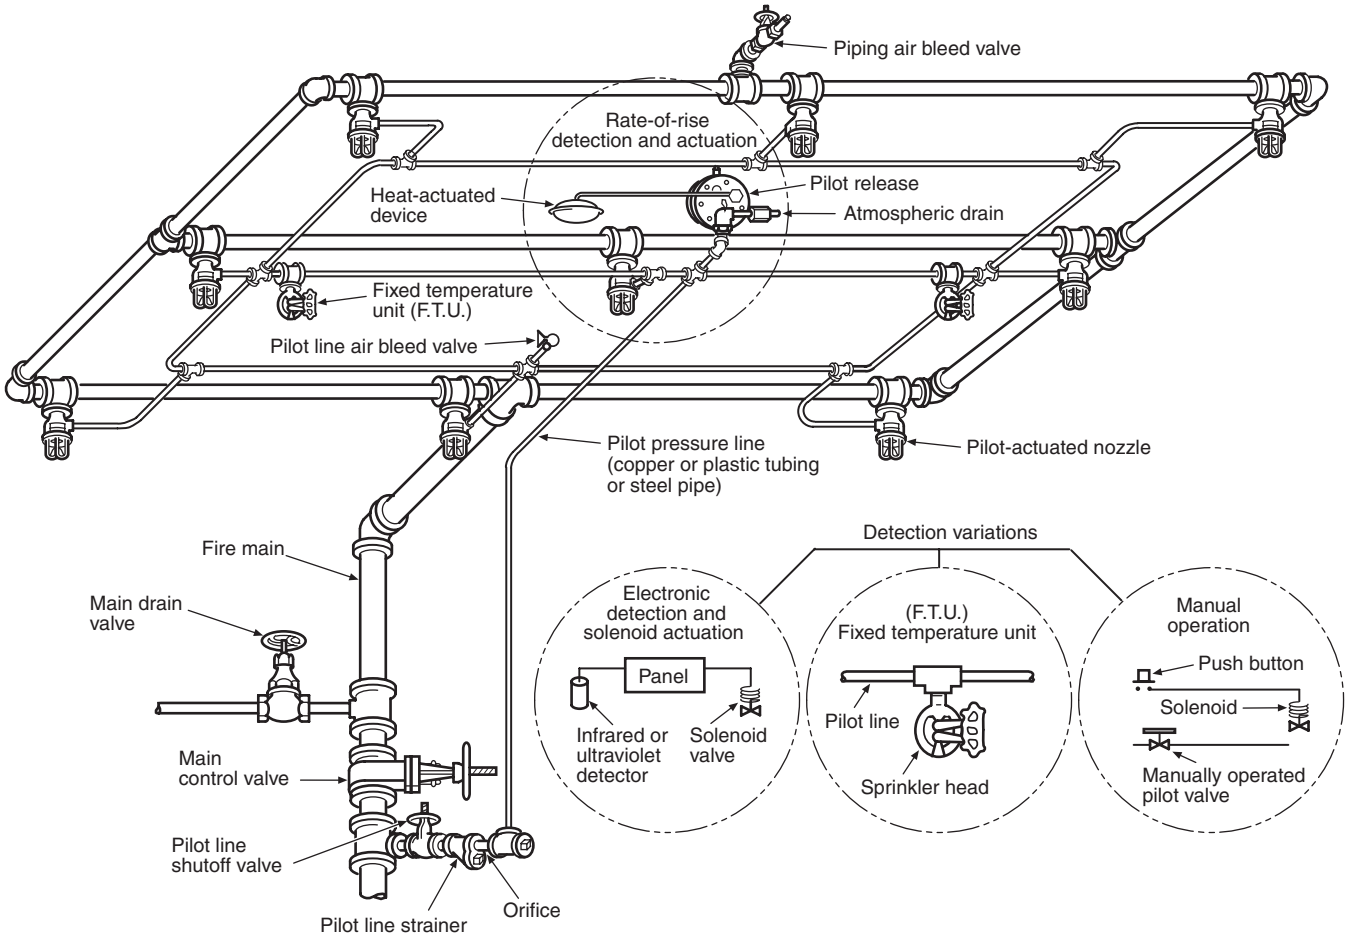

FIGURE 16.7.17 Early Pilot-Actuated System (Obsolete)

components similar to types in the present system. Each revision to the early concept was in the interest of speed, which became possible with the advent of more sophisticated electronic technology.

The first pilot-actuated nozzles had an integral deflector attached to the lower body with a male adapter for connection of a water spray nozzle. Today the integral deflector has been augmented by the addition of other bodies capable of accommodating a wide variety of water spray nozzles, allowing engineering flexibility. Each nozzle individually functions similarly to a wet-pilot-actuated deluge valve. In its earliest incarnation, the pilot-actuated nozzle was called the "aerospace" nozzle, as a result of its use in hyperbaric chambers for the space program[5] (Figure 16.7.18).

The standard detection arrangement for early systems was a system of pilot piping with a heat-actuated pilot release. This method was developed specifically for and became commonly employed with naval ship munitions magazine protection systems. The naval requirement for the early pilot-actuated system response was 150 milliseconds, with an operation time, measured from release of the pilot line to delivery of water, in the 10- to 20-millisecond range. The time that it took for the heat-actuated device to actuate and commence evacuation of the pilot line was not included in this time. The heat-actuated means of detection eventually gave way to ultraviolet electronic detection with solenoids on the pilot line as the method of choice, once the electronic detection and control technology became available.

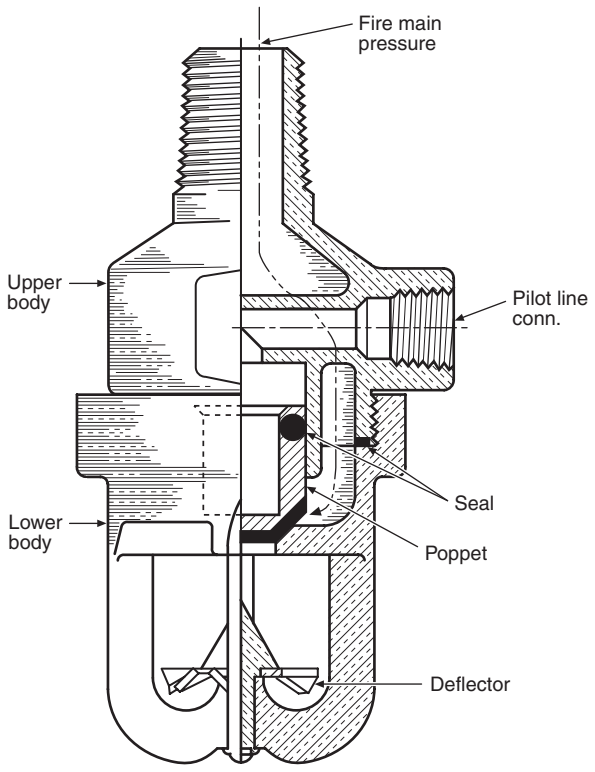

FIGURE 16.7.18 Early Pilot-Actuated Nozzle

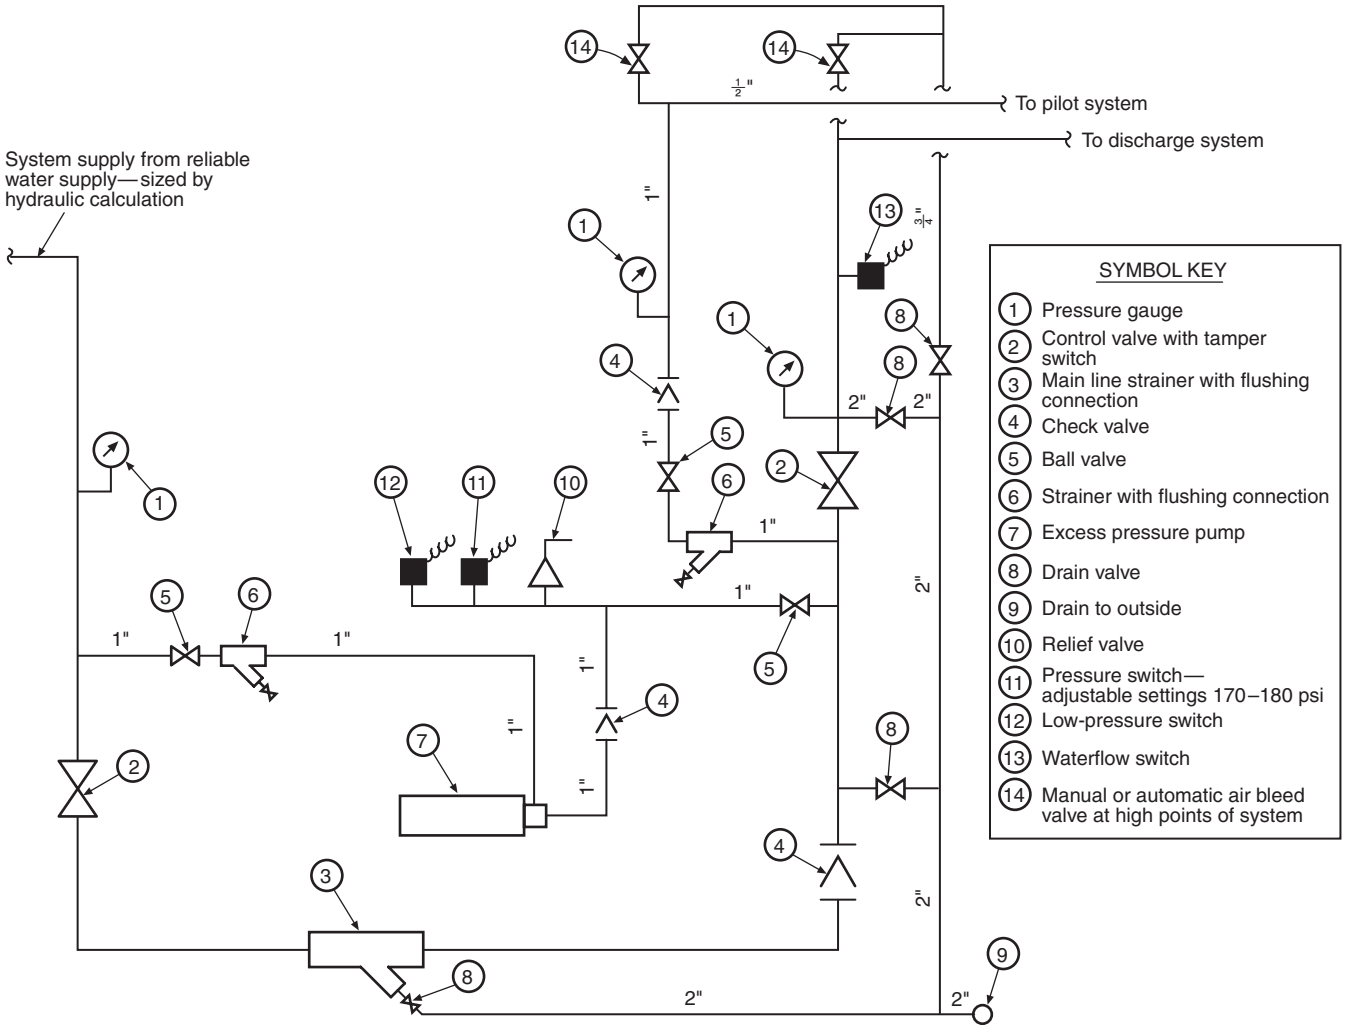

FIGURE 16.7.19 Control Riser Solenoid Operating System

What made the pilot-actuated system different was its positive priming at fire main pressure, its poppet-valve nozzle and pilot system, and simultaneous opening of all nozzles connected to one pilot line. The basic system in its earliest form had certain similarities to the pneumatically actuated deluge system and also bears a strong resemblance to a wet-pilot-actuated deluge system.

Pneumatic heat-actuated and eutectic heat-actuated devices are significantly slower than an electronic UV-actuated release system. With the development of more sophisticated circuit boards, microprocessors, high-speed release modules, solenoid improvements and other response time innovations, improvements in system actuation time were possible.

Current Arrangement

A fixed pilot-actuated ultra-high-speed water spray system consists of a primed discharge system with pilot-actuated nozzles; a hydraulic wet pilot system, supervised and discharged by high-speed solenoid valves; a UV or IR flame detection system; and a central fire alarm control unit with standby batteries and charger (Figures 16.7.19 and 16.7.20).

Discharge System. Although the pilot-actuated nozzle has been available for many years, recent developments in control modules and panels make the pilot-actuated system more amenable to hazards requiring extremely rapid response times. The pilot-actuated nozzle consists of a two-piece body, with ½ in., 1 in., or 1¼ in. (12.7 mm, 25.4 mm, 31.8 mm) male National Pipe Thread (NPT) threaded connection for attachment to the deluge piping system, a ¼ in. (6.4 mm) female inlet for connection to the pilot piping system, and an outlet for the insertion of water spray nozzles with male NPT connections.

The pilot-actuated nozzle is connected to two piping systems, discharge and pilot (Figure 16.7.21). The discharge piping system, normally filled with water to the nozzle, delivers the water for distribution to the hazard. The pilot piping system applies pressure onto a poppet valve in such a way that water in the discharge system, in its standby state, is prevented from flowing through the nozzle. The nozzles are located as close to the hazard as possible. Release of pilot pressure allows the deluge system to overcome the pressure differential, forcing the poppet valve up and initiating instantaneous discharge.

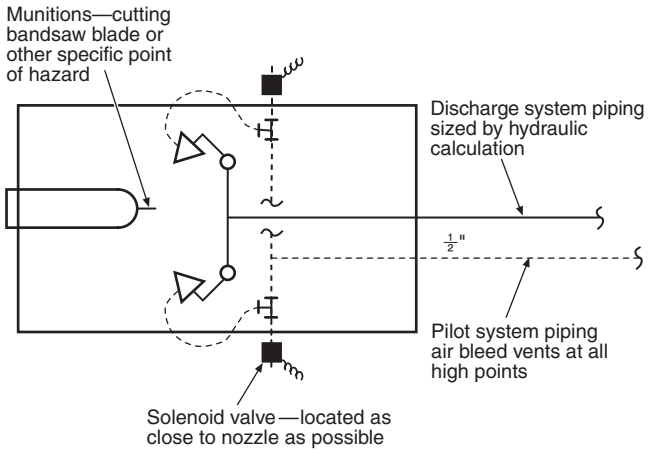

FIGURE 16.7.20 Plan View

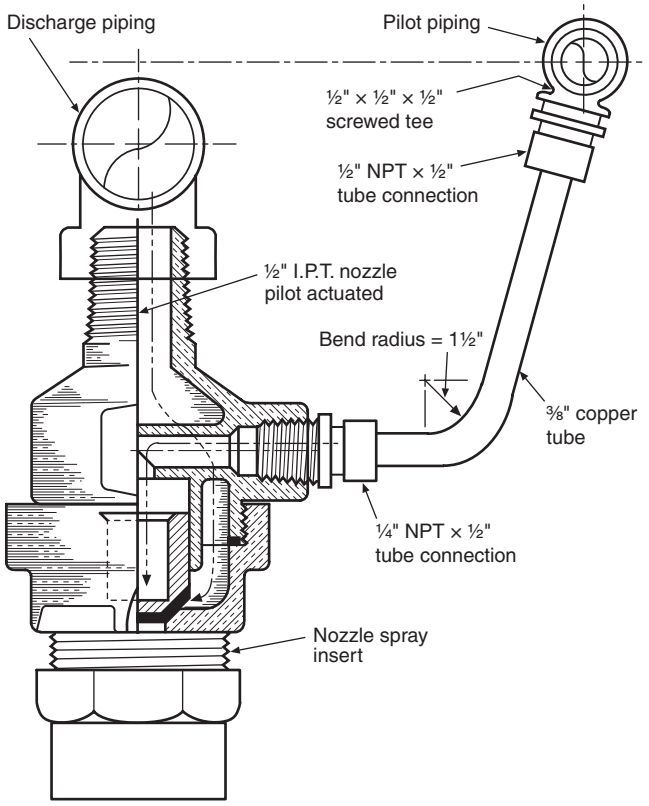

FIGURE 16.7.21 Pilot Connection

Pilot-actuated nozzles are capable of accepting inserts that allow custom designing of water application to the specific hazard in question. Discharge piping can be gridded when an area protection concept is employed. A strainer is required on the main riser of the discharge system to minimize debris that may accumulate between the poppet and the poppet seat and may cause leakage from the nozzle and possible system actuation. Sloping of the discharge system to air vents will serve to purge air from the discharge system and reduce system discharge time. Discharge and pilot piping is required by NFPA 15 to be sloped a minimum of 1 in. (25.4 mm) per 10 ft (3.1 m) of pipe.

Pilot System. The pilot system is monitored by normally closed two-way solenoid valves spaced throughout the system (Figure 16.7.22). Ideally, a solenoid valve should be provided for every pilot-actuated nozzle, but in certain cases one solenoid valve could control up to three nozzles. Engineering judgment must be exercised in determining a solenoid-to-nozzle ratio, since the response time increases as the distance between the pilot-actuated nozzle and the solenoid increases. Solenoids should be equipped with an enclosure-rated NEMA type 4 (watertight), NEMA type 7 (hazardous locations Class I, Group C or D), and NEMA type 9 (E, F, or G hazardous locations, Class II, Group E, F, or G). Detectors and detector housings should be rated for Class I and Class II locations.

It is essential that every effort be made to minimize air pockets in the pilot line, with piping radically sloped to air vents placed at all high points, facilitating the bleeding of air from the pilot system and enhancing the speed of reaction. The pilot line slope should be equal to or greater than the discharge piping slope, but should not be less than 1 in. (25.4 mm) per 10 ft (3.1 m) of pipe. For best results, keep branch lines and their associated pilot lines very short and slope them as radically as possible.

Air in the pilot line is of paramount concern because of its effect on the function of the pilot valve operation. The larger the air cushion, the longer the delay in response time. An automatic air vent is an option (Figure 16.7.23). To protect the solenoid orifices, a strainer must be installed on the pilot line feed.

The two systems of piping (i.e., pilot line and discharge) can be simultaneously pressurized by an excess pressure pump or some other pressure maintenance device, with static system pressure normally ranging from 170 to 180 psi (1172.2 to 1241.1 kPa), with a relief valve and pressure-limiting switch ensuring this range. An elevated gravity tank with a minimum static pressure of 75 psi (517.13 kPa) may provide acceptable response times. A specially designed orifice union in the pilot line maintains the pressure ratio necessary to keep the pilot-actuated nozzles open and allow smooth operation of all solenoid-

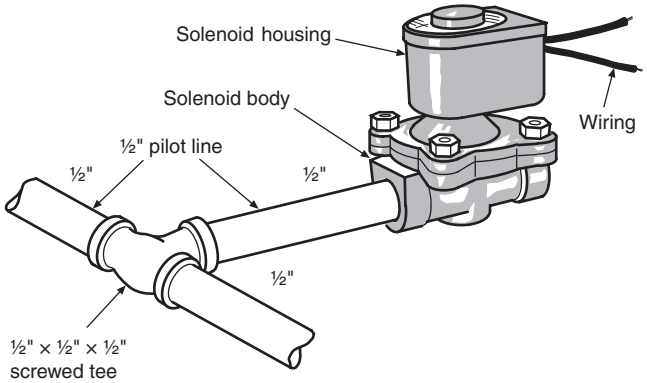

FIGURE 16.7.22 Solenoid Valve

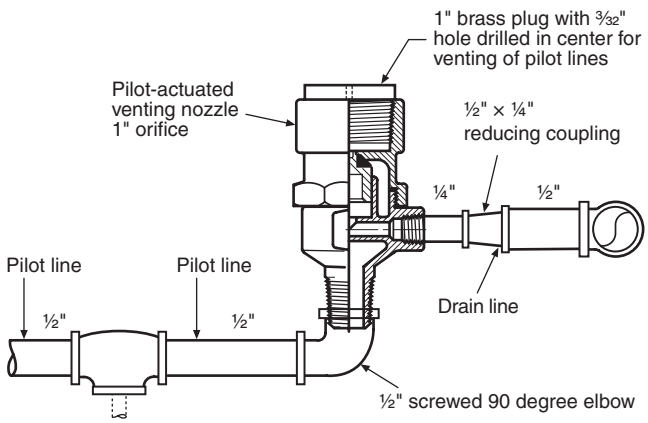

FIGURE 16.7.23 Automatic Pilot Vent

operated valves. The orifice retards the rush of pilot pressure so that the solenoids can exhaust enough water to permit full and even opening.

The Detection System. UV, IR/IR, and UV/IR detectors currently used on the pilot-actuated systems shown in Figures 16.7.24 and 16.7.25 comprise an extrasensitive detection tube housed in a stainless steel, brass, or aluminum explosionproof housing. The detector is mounted on a swivel base to give maximum field adjustment up to an angle of 240 degrees. Most UV and IR detectors have a field of vision between 80 and 90 degrees.

Flame detectors are installed as close to the points of anticipated hazard as practicable and angled and spaced so that all areas where the volatile substance might be found are observed by the detectors. Placement of detectors on an ultra-high-speed water spray system requires experienced judgment and thorough field inspection.

Fire Alarm Control Unit. The control unit, with its sensitive high-speed modules, is kept in a protected area remote from the hazard, usually an area classified safe for nonexplosionproof equipment. Where it is necessary or required to install the control unit in the hazard area, it must be installed in a rated enclosure. The detector, module, and control unit system are specifically designed and customized for the hazard in question. The primary concern of each component is speed, and, as a result, the telemetry system is considerably faster than the systems of the early 1960s. The control system is designed to provide supervision over all electronic devices.

A fire alarm control unit that is placed outside or otherwise exposed to the elements must be installed within a weatherproof enclosure. It is possible that a weatherproof enclosure might be needed for an interior location if it is possible that roof leakage, sprinkler discharge, or other potential waterflow could enter the control unit.

The control unit should include a controller, high-speed modules, control relays, a lamp test push button, trouble silence switch, panel reset button, ac power fail light, waterflow lamp, tamper switch fault lamps, alarm lights, and indicators for special functions for pumps and tanks, with terminals for other functions, if required. The controller powers and monitors the ultraviolet detectors and their signals and notifies the high-speed modules of a trouble or fire signal from the detectors. The high-speed module receives a signal from the controller and will operate the high-speed solenoids on receipt of a fire signal, thus purging the pilot system of hydraulic pressure and opening the nozzles. An example of a currently manufactured ultra-high-speed water spray system module is the Response Acceleration Module (RAM), shown in Figure 16.7.25.

Control relays supervise gate valves, pressure switches, alarm bells or other notification appliances, and the control unit operation. Electrical contacts can be provided for customer functions, such as shutting down equipment. An automatic reset capability option allows the high-speed module to cease water

distribution after a predetermined period of time (usually 2 minutes), provided that the detectors no longer view a hazard. Electric push buttons and LED indicators annunciate the control functions of the panel and display the status of the pilot-actuated system. The control unit should be equipped with a capability for resetting the solenoids automatically from the unit, eliminating lengthy system shutdowns.

A battery charger recharges the batteries when needed and rectifies the 120 V ac input power to 24 V dc for system use. Upon loss of primary 120 V ac power, the charger will transfer to the secondary 24 V dc battery supply.

Sequence of Operation for a Pilot-Actuated System

The flame detectors constantly view the hazard areas, searching for changes in light intensity. The status is reported to the controller for analysis. Light intensities are screened by the detectors' ability to recognize common signals, such as house lighting and sunlight. Physical screening may be necessary to prevent detector signals from such intermittent light sources as welding torches, lightning, or sun reflecting from the windshield of a car.

Upon detection of a valid signal, the controller, constantly interpreting system status, receives the signal. The signal is interpreted and relayed to the appropriate high-speed module. Indicator lights and indicating devices commence operation, and a signal is sent simultaneously to all the high-speed solenoids on the system.

The normally closed solenoids open, allowing water to flow through the solenoids, thus purging the pilot system of water and relieving the pilot pressure. The pressure drop allows the poppet valves in the pilot-actuated nozzles to move, allowing water to flow through the nozzle and onto the hazard, as shown in Figure 16.7.26 and Figure 16.7.27. The pilot-actuated nozzle insert directs the waterflow into a wide-, medium-, or narrow-angle spray. Minimum static pressure at each nozzle should be no less than 50 psi (344.75 kPa), with 180 psi (1241.1 kPa) strongly recommended.

Factors Influencing Speed of a Pilot-Actuated System

There are many variables that can enhance the speed of a pilot-actuated system, and all are considered in each engineered layout. For example, trapped air in the pilot line can be a significant hindrance to the hydraulic evacuation of the pilot line. To prevent this, the pilot line is sloped as radically as possible, with air-release vents, either manual or automatic, at all high points of the pilot system. It is a common practice to bleed air from the system after it is reset and repeat the process at the start of the next working day to ensure that all air is removed from the system.

Excess system volumetric capacity of a pilot-actuated system is a substantial contributor to increasing the response time of the system. It is important to maintain a maximum system volumetric capacity of less than 500 gal (1892.5 L), as required by NFPA 15. Where response times of less than 100 milliseconds are required, it may be necessary where possible to subdivide the systems such that the maximum number of nozzles on a single system is about 10. It is also advantageous to minimize the number of fittings and changes of water direction and to minimize the length of the feed main to the system.

The distance from the solenoid valve on the pilot line to the pilot connection of the pilot-actuated nozzle can be a major factor in the speed of evacuation of the pilot line. The ideal situation would be to place a solenoid on the pilot line adjacent to each nozzle. This would release the pilot pressure to the noz-

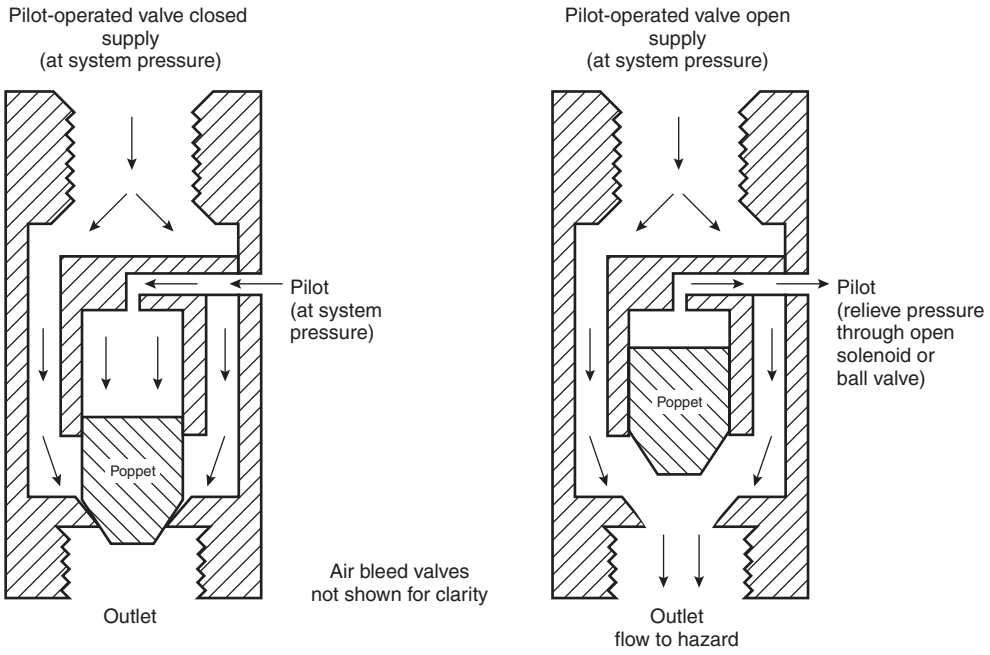

FIGURE 16.7.26 Modern Pilot Valve Operation (Source: Pyrotech International)

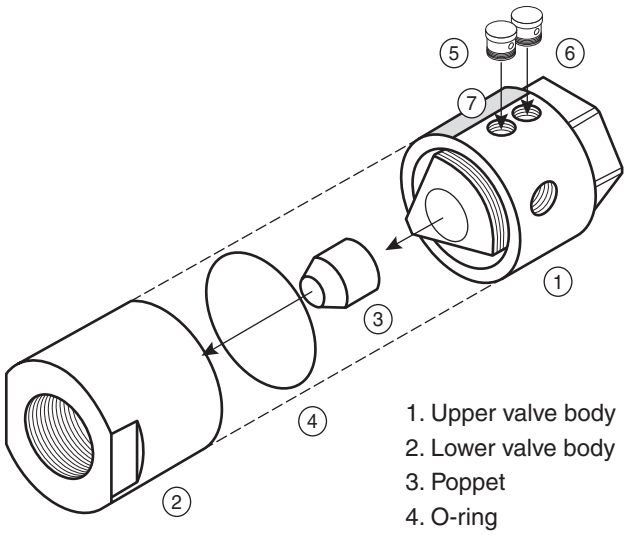

FIGURE 16.7.27 Pilot-Operated Valve (Source: Pyrotech International)

zle almost immediately, and evacuation of the entire pilot line would not become a factor. When large systems are necessary, it may be electronically impractical to provide a ratio of one solenoid per nozzle.

System pressure can be a major factor in response time. An excess pressure pump can be provided for each system or group of systems to maintain 170 to 180 psi (1172.2 to 1241.1 kPa) static pressure on the system piping and pilot line. Pressure of this magnitude at each nozzle provides the impetus for rapid evacuation of pilot pressure and rapid delivery of water to the hazard. Another alternative is the use of an elevated gravity tank that would provide a minimum of 75 psi (517.13 kPa) static pressure on the system. An orifice restriction device, either an orifice union or a drilled ball valve, is placed in the pilot line at the riser to maintain proper functioning of the pilot valves. Once the solenoids open, residual pressure drop in the pilot line is minimized by this restrictor, increasing the speed of pilot evacuation. The diameter of the pilot line can also be a factor in pilot evacuation. For short runs of pilot piping, ½ in. (12.7 mm) galvanized steel pipe is sufficient, with a very short run of ⅜ in. (9.5 mm) internal diameter copper piping for the nozzle pilot connections.

To increase the speed of solenoid actuation, the initial voltage provided to the solenoids from the panel, upon receipt of a signal from the detectors, should provide delivery of a high-voltage signal, enhancing the solenoid operating time. Although the voltage eventually levels off to 24 V dc, which is the normal control system operating voltage, the initial burst of energy may damage solenoids rated for less than the maximum voltage encountered.

No less than 25 gpm (95 L/min) per nozzle is required by NFPA 15 to be designed for point protection, nor less than 0.50 gpm/ft^2 (20.37 L/min·m^2) of exposed area for area protection. Point protection should be accomplished with no fewer than two counteropposed nozzles per point of likely ignition, and area protection should be accomplished with a nozzle spacing of between 30 and 60 ft^2 (2.8 and 5.6 m^2), depending on the configuration of the hazardous commodity or process.

Counteropposition of the nozzles involves nozzles aimed from differing directions at a common point. Some commodities, such as certain pyrotechnics, may require densities as high as 3.0 gpm/ft^2 (122.24 L/min·m^2).

Response Time for Pilot-Actuated Systems

Specifications written for pilot-actuated systems mandate a response time not to exceed 100 milliseconds, measured from presentation of an energy source to the detector to water discharge from the most distant pilot-actuated nozzle. Whenever possible, travel time for the water to hit its intended target should be included in the total response time. Research is ongoing that would evaluate and further define this time span.[1,6] The specifying engineer should evaluate test data and lower the required response time where warranted.

Method of Timing Response of a Pilot-Actuated System

The following procedure can be used to perform a functional time test of a pilot-actuated system:

1. Install a pressure switch on the nozzle being tested. Each nozzle on the system must be tested to ensure that the solenoids are functioning properly and that operation speeds are being maintained at each nozzle.
2. Slowly fill the system piping.
3. Bleed all air from the pilot system through air vent valves. Opening these valves too quickly may operate the system.
4. Close the air vent valves and record the static system pressure at the riser.
5. Connect the timer to the nozzle pressure switch and to the timing test jack on the RAM or high-speed module. High-speed photography is also an effective timing device.
6. Take three consecutive readings for each system.
7. Record the static pressure at the riser before and after each test.
8. A UV light source will be used to activate a UV detector for the system being tested. UV, IR, and UV/IR testing lamps for tripping ultra-high-speed water spray systems are commercially available.
9. An electrical impulse from the RAM time test jack will start the timers.
10. Two timers should be used in order to ensure accuracy.
11. The timers will be stopped by the water discharge reaching the pressure switch.
12. Record the test results, including residual pressure at the riser.
13. Reset the system at the control panel.

It has been found that when an ultra-high-speed water spray system has been discharged repeatedly, response times usually increase somewhat. This is the result of air bubbles created by the rapid movement of water through the piping collecting into pockets of air in critical segments of the piping system. When this phenomenon is identified through the observation of repeated declining response times, it may take several hours to permit air bubbles to migrate to positions in the piping where they can be completely expelled through the air bleeders.

Other Applications for Pilot-Actuated Systems

Although munitions provide the largest share of current pilot-actuated system applications, this system has been used with a preset timer to limit discharge to protect valuable commodities such as mail conveyors and chutes, ovens, and antique book storage facilities. Where enhanced system response is desired, but where a 100 millisecond response time is unnecessary, the system can be modified to resemble the early pilot-actuated system with thermal, pneumatic, or electric detection and standard control modules.

PORTABLE SYSTEMS

Portable ultra-high-speed water spray systems shown in Figure 16.7.28 have been created to supply cost-efficient, mobile, short-term protection for U.S. Army ammunition plants and other facilities requiring enhanced actuation times for exposed energetic materials.[7] This system is a portable, self-contained fire detection and suppression system capable of delivering water to the nozzles within 50 to 100 milliseconds from time of detection and can protect an area up to 100 ft^2 (9.3 m^2). The system features UV detection with a high-speed controller, a solenoid-actuated deluge valve, and a portable pressurized water storage tank that is capable of being temporarily cross-connected to a building water supply, if available.

Some portable ultra-high-speed water spray systems for use in explosive production facilities are supplied with 20 ft (6 m) extension hoses and are capable of reacting to a fire in less than 50 milliseconds. Reaction time interval is the time from the point of detection to flow at the nozzle. Because of their mobility, the portable units are well suited for use on short production runs where a fixed system is not practical. They can be rolled by one person and are designed with channels for forklift transport. Some units are of a size that allows them to be rolled through a

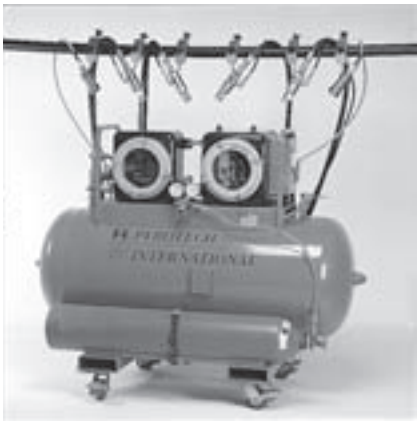

FIGURE 16.7.28 Portable Ultra-High-Speed Water Spray Systems (Source: Pyrotech International)

36 in. (91 cm) door with water tank capacity up to 100 gal (397 L) pressurized by a nitrogen bottle.

Units are provided with supervised ultraviolet detectors, solenoids, and pilot-operated valves, with tank pressure and water level also supervised. An integral power supply/charger and battery pack are normally provided. Electrical components should be housed in explosionproof enclosures with appropriate ratings. All necessary controls for normal operation (power switch and reset switch) are located on the outside of the explosionproof enclosure. The system could be reset with a switch or by means of automatic reset.

Applications for portable units include the following:

- Explosive or pyrotechnic spills, in which case the portable unit could be rolled into the hazard area and used to protect an area during the cleanup operation, where fixed fire protection may not normally be present
- Hazards for which there is not sufficient time or funding to install fixed fire protection quickly enough to satisfy the need
- Depot rework, where maintenance or operations often change and machinery is moved or replaced with different equipment. In some cases, fixed systems may not be practical from an operational, safety, or economic standpoint.
- Machining, milling, blending, or drying, where the portable unit could be attached to the machinery
- When the existing fixed system is shut down and production must go on; portable units can bridge the time involved in getting fixed systems back on line
- Cleanup and decontamination operations, when equipment is torn down or if there is fear of residual explosives. This presents one of the more hazardous conditions for operators at explosives facilities.
- Evaluation and burn testing of the design of fixed fire protection systems to prove the effectiveness of such configurations. This system would allow for easy modification and variations providing more comprehensive test results.
- Research, evaluation, and quality control laboratories. Hazards often vary in severity as do the processes and material to which the technicians are exposed. In most cases, the energetic material has known properties such as sensitivity to spark, friction, or impact. Sometimes in the case of experimental compounds the properties (possibly hazardous) are unknown. In either case, it would be advantageous to be able to roll in a portable unit to protect personnel and equipment. Processes in the laboratory environment are also quite likely to change, for example, blending, mixing, granulating, extruding, and drying. Changing operations (if hazardous) require an adaptable explosion or fire suppression system. Although personnel are more highly skilled and quantities often much smaller, the explosives laboratory can be a hazardous environment and in some cases warrants the use of such a system.
- Temporary depot and staging areas, possibly offshore or overseas, where fixed deluge systems could not have been considered possible because of installation time, lack of water supply, or varying processes
- Temporary storage protection for in-process work, in the situation of production overruns where surplus munitions ingredients must be stored and normal adequate fire protection is not available, or in the case of rejected production runs where the product must be stored until it can be reworked or destroyed
- Additional backup for existing systems or unforeseen changes in process

Additives can be included with the water supply. Antifreeze and wetting agents or water coloring may be added to help evaluate different spray patterns utilizing high-speed video (for added clarity). Possible advantages of water gels, "sticky water," could be tested.

Portable units can be moved to a shop or maintenance area for service, allowing them to leave the restricted (hazardous) area. Nozzles with different spray patterns can be adapted, moved, and configured depending on operation.

EXPLOSIVE SPHERE-HIGH-RATE-DISCHARGE (HRD) DEVICES

The explosive sphere-HRD-type device (Figure 16.7.29) is for rapid response deluge suppression in the munitions and explosives industries. It is an explosive squib-operated, high-pressure vessel (400 psi [27.579 bar]) with a rupture disk. It is compatible with all forms of high-speed detection and is actuated by the DDAM (Dual Detonator Acceleration Module) (Figure 16.7.30). Although the sphere-HRD-type device can achieve a reaction time under 15 milliseconds, it is limited to approximately 7 gal (26.5 L) of flow. For this reason, it is not a stand-alone device and must be used in conjunction with other rapid response deluge systems. These devices are often used for point protection.

When designing such systems, consideration must first be given to bringing explosive devices into a hazardous location to arm and reset the sphere. A source of high-pressure inert gas must also be available to prime the sphere-HRD-type device.

When a detector sends an alarm signal to the appropriate DDAM, the squib in the sphere-HRD-type device is detonated,

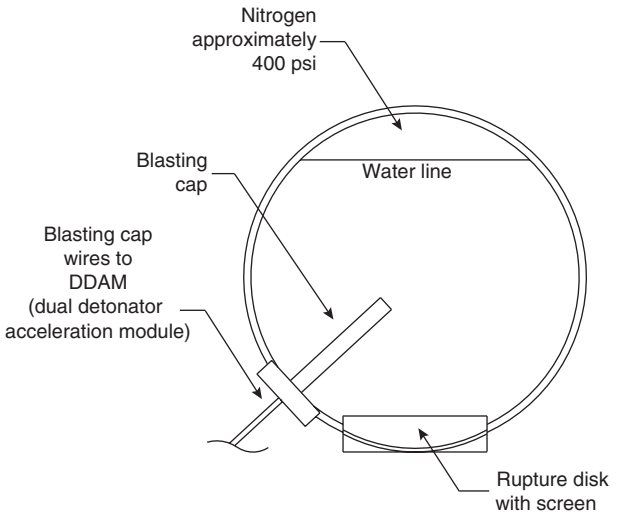

FIGURE 16.7.29 Explosive Sphere-HRD-Type Device (Source: Pyrotech International)

10. Reset/bypass key switch
11. Fastener cap screw (4 mm)

FIGURE 16.7.30 DDAM (Dual Detonator Acceleration Module) Frontplate (Source: Pyrotech International)

the rupture disk is broken, and the high-pressure chamber is emptied. Simultaneously, backup deluge is also discharged to the hazard. Even though the backup deluge may reset automatically, the sphere-HRD-type device must be reset manually. Sphere-HRD-type devices are squib actuated. Response time testing of the sphere-HRD-type device is best accomplished by the use of high-speed video.

EXPLOSION SUPPRESSION SYSTEMS

The first explosion suppression systems were introduced by the British in the late 1940s for protection of aircraft and were later extended to industrial use. Explosion suppression systems consist of a cylinder filled with a suppressing agent, a detection system, and a system of control circuitry. They can ordinarily be visually differentiated from ultra-high-speed water spray systems by their lack of system piping, by the existence of uniquely shaped agent containers, and by the use of a wide variety of agents, including water, that can be employed with such systems. Halon, which was once a commonly used agent for explosion suppression systems, has been scheduled for elimination by the Montréal Protocol.[8] A clean agent or halon substitute, in accordance with NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems,* may be required for a new explosion suppression system. Explosion suppression systems are designed in accordance with NFPA 69 to protect enclosed vessels or containers from rupture due to overpressurization resulting from a deflagration.

EXPLOSION VENTING

An enhancement to the effectiveness of an ultra-high-speed water spray system or an explosion suppression system is explosion venting. These passive vents are sometimes used in lieu of an ultra-high-speed water spray system or an explosion suppression system. Venting, however, will relieve pressure without any active effort to control the continued burning of the fuel in the hazard area. Care must be taken to avoid placing explosion venting louvers in a location where an operator or passerby could be injured by an explosion relief blast. NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* should be used when designing an explosion venting system.

An alternative to a suppression system could be to provide no protection of any kind. In a facility with an enclosed and separated or isolated automatic process that is normally unoccupied, where vessels are manufactured with sufficient strength to withstand overpressurization resulting from a deflagration, or where there is enough process redundancy to avoid process stoppage, a firm may consider the option of no protection. Repair or replacement of a process area, the spreading of fire or blast damage to adjacent areas with a corresponding result of possible deaths or injuries, unfavorable publicity, and loss of income could prove to be significantly more costly than an ultra-high-speed suppression system or an explosion suppression system.

RESEARCH AND DEVELOPMENT

The Air Force Research Lab's (AFRL) Fire Research Group at Tyndall Air Force Base, Florida, has been working to invent a more effective deluge system capable of stopping high-velocity fires caused by deflagration of explosives, propellants, and pyrotechnic materials. Initially, a system similar to that described in the section on explosive sphere-HRD-type devices was used. Compared to the NFPA requirement of 100 millisecond response from detection to initiation of waterflow, AFRL's Advanced Fire Protection Deluge System (AFPDS) reduced response time to about 8 milliseconds (6 milliseconds detection time and 2 milliseconds initiation time) and put water on a fire 36 in. (0.9 m) away from the nozzles in 18 milliseconds. Close behind, back-up water from a pressurized tank with solenoid-operated nozzles reached the fire in about 130 milliseconds. In 100 trials using ¼- to ½-lb (0.113- to 0.226-kg) samples of various pyrotechnic materials, most fires were extinguished by the initial water from the explosive sphere-HRD device, and the back-up water was redundant.

Effective as the AFPDS is on most propellants and pyrotechnic materials, it is not fast enough to stop fires from the fastest burning materials, exemplified by magnesium-Teflon pyrotechnic flare material. A new phototransistor-circuit flame detector was developed that cut detection time from 3 to 5 milliseconds to less than 1 millisecond, and a novel deluge system, the blast-initiated deluge system (BIDS), was developed that discharged water at nearly 500 ft/sec (152.4 m/sec). The heart of the BIDS consists of a steel cone set inside a steel cylinder (Figure 16.7.31). On detection of a fire, the controller sends an electrical signal to a small explosive charge fixed at the apex of the cone. Detonation of the charge causes a rapid rise in pressure inside the cone that forces the initial water out a burst disk and onto the fire. Holes in the side of the cone allow follow-on water

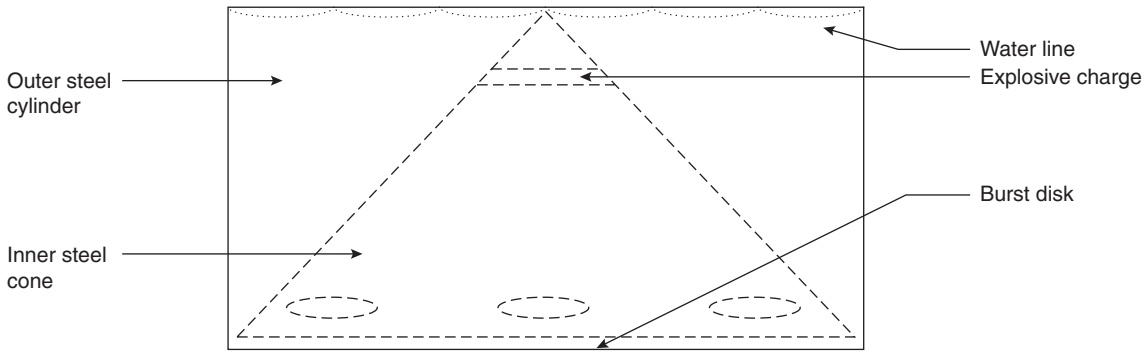

FIGURE 16.7.31 Blast-Initiated Deluge System (BIDS)

to flow through the cone and onto the fire. The BIDS reduced time from detection to water on a fire 36 in. (0.9 m) from the nozzle to 7 milliseconds, as compared to about 26 milliseconds for the AFPDS, and 130 milliseconds or longer for solenoid-activated systems. The BIDS extinguished 1 lb (0.453 kg) samples of magnesium-Teflon in an average of 15 milliseconds and 4 lb (1.81 kg) samples in 40 to 50 milliseconds, and significantly reduced heat flux levels.

SUMMARY

A major difference exists between ultra-high-speed water spray systems and explosion suppression systems. Even though both systems suppress explosive hazards, ultra-high-speed water spray systems are used predominantly for open machine protection or room area protection, whereas ultra-high-speed explosion suppression systems protect enclosed vessels. Although system names are sometimes used interchangeably, this chapter helps clarify correct terminology.

There is relatively little information available on practical testing of various munitions manufacturing explosive levels for differing munitions commodities and processes. However, years of successful field performance and experience, as well as system time and reliability testing demonstrate the effectiveness of ultra-high-speed water spray systems with respect to the suppression of munitions explosive hazards. Artificial retardation of the normal actuation times of ultra-high-speed water spray systems means the difference between extinguishment and total loss of control in the explosive process. A comparison of ultra-high-speed water spray systems is shown in Table 16.7.3.

TABLE 16.7.3 Comparison of Squib-Operated, Pilot-Operated, Explosive Sphere-HRD, and Portable Deluge Systems

	Squib-Operated	*Pilot-Operated*	*Explosive HRD*	*Portable*	
Complete electrical supervision		*		*	Solenoids are supervised for shorts, opens, and grounds. On a squib-operated system the igniter wire can be supervised but condition of explosive is not known.
Response time not affected by air in supply pipe		*	NA	*	Due to low-pressure prime and the remote location of the valve, air in the piping of a squib-operated valve can cause slow and fluctuating response times.
No recurring cost or replacement parts needed after each firing		*		*	After firing of the squib-operated systems, disc or caps must be replaced and explosive devices reinstalled. Nitrogen or other inert gas must be accessible to recharge a sphere-type device.
Programmable automatic reset feature available		*		*	An optional automatic reset feature is available. This allows automatic system reset after a present time as long as no fire is present.
System does not require explosives for operation		*		*	Pilot-operated valves do not present the problem of bringing explosives (squibs) into the hazard area.
System can be reset and back on line in less than 30 seconds		*		*	Primac and HRD-sphere type devices may require caps, discs, squibs, blocks, or pins
Limited shelf life of components	*		*		Squibs have a shelf life and should be periodically replaced.
Requires pilot line piping		*		*	Pilot line connections are necessary for pilot-operated valves to function.
Mechanical manual operation available		*		*	Mechanical manual release is possible even in the event of total power failure (including loss of primary power and battery backup).
Each head acts as an individual deluge valve (safety through redundancy)		*		*	The system does not depend completely on one device for operation. Redundancy of solenoids and valves provides a more reliable system.
Response time not affected by system size		*	*	*	Since each nozzle can be considered an individual deluge valve, system size does not affect response time.
Compatible with all forms of detection	*	*	*	*	Systems can be interfaced with any of the available detection devices.
System can be preprimed with high pressure		*	*	*	Since valve is at the nozzle, a high-pressure prime can be accomplished.
Unlimited available water supply	*	*		*	HRD-type devices require backup systems to be in place. Portable deluge may be connected to existing supply. A backup system must be fast enough to provide full waterflow before HRD system empties (approximately 250 milliseconds).
Nozzles can be directed very close to the hazard	*	*		*	Due to the size of the HRD-type devices, it may be physically impossible to locate the HRD close to the hazard. Water travel time may greatly compromise safety.
Adapts to various response time test equipment	*	*		*	HRD-type systems can only be response time tested by use of high-speed video.
Contaminants discharged with deluge	*		*		Squib and HRD-sphere type systems may contain debris from rupture discs, blasting caps, and/or blasting cap holders.

System Types
System Components
System Water Supply and Atomizing Medium Considerations
System Maintenance Considerations

Key Terms

atomization, constant pressure system, declining pressure system, drop size distribution, enclosure effects, fire test protocols, flame cooling, local application, nozzles, oxygen displacement, positive displacement pump, radiant heat blocking, single fluid, spray momentum, thermal management, total flooding, tunnel fire protection, twin fluid, vapor dilution, water mist, water vapor

Interest in the use of very fine water sprays (water mist) in fire suppression systems has been intense for the last 15 years. The economic force behind this interest has been driven by two major fire protection needs. First, in the early 1990s the international maritime regulatory organizations mandated the installation of sprinkler systems on passenger ships. This mandate inspired a search for a system that could be considered equivalent to sprinklers but that would discharge less water, use smaller-diameter piping, have lower overall weight than a standard sprinkler system, and hopefully cost less. The second driving force was the need to find a replacement for ozone-depleting substances such as the halons, which had been used for decades to protect machinery spaces, flammable liquids rooms, computer rooms, and rooms for materials sensitive to water damage. The halon alternative search included the possibility of using water in applications where water was not previously considered practical. Thus, a technology that could minimize droplet size and application rate, enhance evaporation, and help reduce oxygen levels to extinguish hidden fires began to have marketable value.

Spurred by receptive market conditions, innovative fire suppression systems have been conceptualized, tested against specific fire scenarios, and installed as working systems. A large number of the world's passenger ships are now equipped with marine water mist systems. Much of the early work in developing fire tests and performance criteria occurred in Europe at laboratories such as SP in Sweden, SINTEF in Norway, VTT in Finland, and the Danish Fire Research Institute. In North America, practical research was conducted in Canada at the National Research Council National Fire Laboratory and in the United States by Hughes Associates, Inc., with U.S. Navy and Coast Guard support. In 1993, the National Fire Protection Association (NFPA) began work on a design and installation standard, NFPA 750, *Standard on Water Mist Fire Protection Systems,* to consolidate design concepts emerging from the research and development work. In the last decade a number of European companies have obtained approvals from North American listing agencies such as FM Global Research and Underwriters Laboratories (UL) for machinery spaces, turbine enclosures, and wet benches. Several North American fire protection manufacturers have developed specialized water mist equipment with their own nozzle designs. There are now formal fire test protocols not only for marine applications, such as machinery rooms, turbine enclosures, accommodations, public spaces, and service areas, but also for land-based applications involving very large machinery spaces, local application systems, light and ordinary hazard applications, and "wet benches" for electronics manufacturing. Although the marine market for water mist systems remains the strongest, there is a steady growth in land-based applications.

The first chapter on water mist technology appeared in the 18th edition of the *Fire Protection Handbook* released in 1997. Since then, the technology has advanced from "potential" to "actual." There are installed systems in process modules in the Alaskan oil fields and in heritage buildings, hotels, art galleries, and computer rooms worldwide. Experience with design, installation, commissioning, and maintenance of systems has advanced steadily. The handbook chapter has been revised to reflect the changes and advances made. It must be noted that the growing experience

Jack R. Mawhinney, P.E., FSFPE, is a senior engineer at Hughes Associates, Inc., based in Baltimore, Maryland. Prior to joining Hughes Associates in 1996, he was a senior research officer at the Institute for Research in Construction, National Research Council Canada.

has not changed one important factor in water mist system design. As indicated in the first edition, there still is no generalized "first principles" approach to design of water mist systems. Design criteria for each manufacturer's equipment are determined through full-scale fire testing to internationally recognized test protocols. The flux densities differ sufficiently among manufacturers so that one cannot enforce a single generic criterion on all manufacturers. Full-scale testing continues to be justified.

This chapter reviews the salient features of water mist fire protection systems. It discusses the general extinguishing mechanisms and the influence of fuel type and compartment conditions on effectiveness. The chapter provides details on the components, types of systems, calculation methods for single- and twin-fluid systems, pump selection and application of positive displacement pumps, and maintenance issues.

For related topics, see the following chapters in Section 16: Chapter 1, "Principles of Automatic Sprinkler System Performance"; Chapter 2, "Automatic Sprinklers"; and Chapter 3, "Automatic Sprinkler Systems."

APPLICATIONS OF WATER MIST SYSTEMS

Before discussing the details and general principles of water mist systems, it is instructive to review several applications of water mist systems. Some of the applications have been studied in detail by various technical groups seeking to develop consensus fire test protocols to set design criteria. Others were developed through ad hoc testing by a group interested in solving a specific problem. The following examples represent the proving ground for water mist fire suppression systems technology.

Machinery Spaces

Fires in machinery compartments involve diesel fuel and lubricating or hydraulic oil spills, ignited by hot engine parts, overheated bearings, or electrical arcing. Pool or spray hydrocarbon fires can be fast developing, very hot, and have the potential to cripple or destroy a ship. International shipping safety regulations, developed by the International Maritime Organization (IMO) and as written in the rules of SOLAS (Safety of Life at Sea), have for many years required that machinery spaces on large vessels be equipped with either CO_2 or halon fire suppression systems. With the phase-out of halon and increased awareness of the safety hazard that CO_2 represents, there is strong interest in finding an alternative fire suppression agent for machinery compartments on ships. Further incentive for improved suppression systems for machinery spaces comes from IMO regulation enacted in the 1990s that required all ships capable of carrying more than 36 passengers to be equipped with automatic sprinkler systems by 1997. Where the necessary pumps and water supplies must be provided for general sprinklering of the ship, the use of a water-based suppression system in lieu of a gaseous agent in the machinery space becomes economically viable. The requirement to retrofit existing ships with sprinkler systems raised concerns, however, about creating stability problems due to adding weight of piping or large volumes of water to the superstructure of a ship. Those potential problems could be addressed by water mist fire suppression systems that promise to use small-diameter piping and deliver minimum quantities of water.

The potential to use finely divided water sprays to suppress hydrocarbon pool and spray fires has been known for some time, at least since the 1950s.[1,2] Since 1990, a number of companies have developed water mist systems for marine machinery compartments, in which the primary fire hazard involves hydrocarbon spray or pool fires. The International Maritime Organization (IMO) test protocols and amendments dating from 1994 and 1996 established the baseline for machinery space water mist fire suppression systems (IMO MSC/Circular 668: Alternative Arrangements for Halon Fire Extinguishing Systems in Machinery Spaces and Pump-rooms).[3,4] The tests address liquid fuel fires in machinery compartments of 500 m^3, main diesel machinery in spaces up to 3000 m^3, and in larger-volume diesel machinery spaces on oil tankers and container ships. These test protocols are described in NFPA 750. There are 13 test scenarios involving shielded pool and spray fires of different size around a mockup of a diesel engine. There is a void space under the diesel mockup intended to simulate a bilge space with a shielded fire. There is also a 2 m by 2 m ventilation opening in the lower quarter of the test compartment. In order to pass the IMO test protocol a water mist system must extinguish all 13 of the test fires, from the largest 6 MW spray fire to the smallest pool fire (500 kW) within 15 minutes. The test fires involve both low- and high-flashpoint hydrocarbon fuels. One test involves a small wood crib and heptane igniter. Since 1999, the International Maritime Organization has issued test standard IMO MSC/Circular 913[5] for local application systems to protect specific equipment in large machinery spaces. In 2005, IMO produced MSC/Circular 1165,[6] which sets criteria for water mist systems for very large machinery spaces, for example, up to 3300 cubic meters. IMO MSC/Circular 1165 includes most of the fire tests used in MSC/Circular 668 but eliminates the need to extinguish the very smallest fire.

Experience has shown that extinguishing large fires in a compartment with limited ventilation is relatively easy.[7–9] A large fire consumes oxygen and generates enough heat to convert water droplets to water vapor, reducing the oxygen concentration in the compartment. The fire extinguishes itself due to oxygen starvation. Small fires are more difficult (take longer) to extinguish, because they do not consume the available oxygen fast enough (relative to the inflow through the ventilation opening), nor do they generate enough heat to evaporate much of the water mist.[7] For these reasons the IMO machinery compartment tests become increasingly difficult to pass as the compartment becomes larger and the fires become smaller. The IMO test protocol requires full extinguishment of all fires. Systems that have passed the IMO machinery space test protocol are permitted to utilize combinations of total flooding ceiling nozzles and screening nozzles over the ventilation opening, as well as the addition of a surfactant to the water supply. To a certain extent the successful system designs may be customized to pass the IMO test specifically. Some systems may be dependent on controlling the ventilation through the specific ventilation opening. If the actual application does not have such a well-defined ventilation opening, it is unknown whether the system would still achieve the same results. Furthermore, the IMO test structure

does not include the clutter of overhead piping, cable trays, and ducts found in real machinery spaces. The extent to which the additional obstructions might increase extinguishment times is not evaluated by the test protocol.

The IMO regulations also require the installation of local application fire suppression systems on certain machinery space equipment, in particular, large diesel engines. The IMO MSC/Circular 913, Local Application test protocol[5] defines the performance requirements. For ships that utilize carbon dioxide for the engine room suppression system, the requirement to install the water-based local application system represents an additional cost. For passenger ships that utilize water mist to comply with the IMO requirements, the water supply and pumping capacity are already provided. The local application system represents only a small cost increase.

Both FM Global Research and Underwriters Laboratories (UL) have developed their own versions of the IMO test series. The FM Global Research and UL test programs differ from the IMO tests in certain ways. The FM Global Research and UL test protocols, for example, relax the requirement to extinguish the smallest pan fire in the bilge. The relaxation recognizes the level of control achieved by the suppression system—the small shielded fire can be approached and extinguished by hand.

Water mist systems have been installed in land-based machinery spaces in Alaska's North Slope. There are differences between machinery spaces on land and on ships. On ships, the concept of a single 2 m by 2 m ventilation opening is valid because of the nature of compartmentation on ships. In land-based facilities, the ventilation openings may be distributed differently. The designer must understand the conditions and the performance objectives of each test protocol in order to make an appropriate adaptation to a real installation.

Machinery compartment water mist systems can be characterized as follows:

- *Safety objectives.* Replace halon or CO_2 extinguishing agents. Extinguish all fires involving spilled or sprayed diesel fuel or hydraulic oils and provide cooling of hot gases using a limited amount of water. Fire sizes range between 0.5 and 10.0 MW. Extinguishment times must be within 15 minutes (IMO) or 30 to 60 minutes (UL or FM Global Research).
- *Mechanisms.* Mechanisms include convective cooling of flame, hot gases, and fuel; steam displacement of oxygen and dilution of air-fuel vapor mixtures; and blocking convective and radiant heat transfer to surfaces of unburned fuels and surrounding objects. The ability to ensure optimum conditions for any of the extinguishing mechanisms decreases as compartment size, ventilation, fuel complexity, and number of obstructions increase.
- *System features.* Deluge systems with open nozzles in grid at ceiling and sometimes at intermediate levels are used for flooding the total compartment with water mist. Local application systems around equipment also utilize open nozzles. Nozzles may be high- or low-pressure jet, twin-fluid, or impingement types and may be combined with other suppression systems (e.g., bilge foam systems) where control is beyond the capability of mist alone. A separate detection system is used for activation. Water supply is preferably fresh water, but systems are designed to permit switching to seawater after fresh-water supplies are depleted. Maritime regulations (IMO) require a minimum 30 minute water supply.
- *Industry acceptance.* Water mist systems are accepted worldwide by the International Maritime Organization (IMO) as a replacement for halon or CO_2 in marine machinery spaces. Maritime insurance societies such as Det Norske Veritas and Lloyd's inspect and commission the systems. For passenger cruise ships, which must be sprinklered throughout, water mist is frequently used to comply with Solas requirements for the machinery space. For cargo shipping, carbon dioxide systems are more widely used. The petroleum resource industries worldwide are using water mist systems in machinery spaces such as process modules at production sites.

BP Alaska, Phillips Petroleum, and ARCO Alaska have installed water mist systems in machinery modules on Alaska's North Slope as a replacement for halon 1301 systems. The designs of these land-based machinery space systems are based on IMO, FM Global Research, or UL protocols for machinery spaces.

Turbine Enclosures

Turbine enclosures are a type of machinery space. Unlike general machinery spaces, which may contain many potential fire sources, the source of fire in a turbine enclosure is limited to the turbine and its fuel lines. Large diesel or gas-driven turbines are standard equipment in offshore drilling platforms. Fuel line breaks may lead to spray fires or three-dimensional spill fires with pool fires in a bilge area under the turbine. The rotating turbine blades are susceptible to serious damage if the surrounding casing is cooled rapidly and contracts. For that reason, it was in the past considered dangerous to apply water to turbine fires, at least until the machine had stopped rotating. The turbines are enclosed in ventilation-controlled compartments. Halon 1301 and CO_2 total flooding systems have been the preferred method of providing automatic fire suppression for turbine enclosures.

Wighus et al.[7] confirmed the ability of a water mist fire suppression system to extinguish fires in a turbine enclosure. Subsequent test protocols have been developed by FM Global Research to address concerns about the use of water spray on hot turbines. The FM Global Research fire test protocol for turbines in enclosures incorporates a test to measure the rate of cooling of a thick metal plate. The test results in convective heat transfer coefficients for different segments of the heated plate. The heat transfer coefficients can then be used in a finite element analysis of the turbine casing to evaluate clearances between casing and turbine blades. As turbines are typically installed inside enclosures, the test protocols have been developed for enclosed conditions. A number of water mist equipment manufacturers have obtained FM Global Research listings for water mist systems in turbine enclosures up to 260 m^3. Other turbine enclosure test protocols exist in Europe and Australia. The manufacturers have adopted various strategies in order to pass the cooling test in the FM Global Research test protocol. These include orienting the nozzles to project the spray horizontally, parallel with the axis

of the turbine, to minimize direct-spray impingement on the casing, or cycling the spray on and off for short intervals.

The turbine enclosure water mist system can be characterized as follows:

- *Safety objectives.* The safety objectives are to rapidly extinguish a fire involving spilled or sprayed diesel fuel on or under an operating diesel turbine, using a limited amount of water, and without damaging the turbine blades through thermal shock; provide cooling of hot gases in the compartment; and replace halon 1301 or CO_2.
- *Mechanisms.* Mechanisms include convective cooling of flame, hot gases, and fuel; steam displacement of oxygen and dilution of air/fuel vapor mixtures; blocking convective and radiant heat transfer to surfaces of unburned fuels and other objects; and cooling hot metal surfaces.
- *System features.* These include total compartment flooding systems with open nozzles on a preengineered piping system. Both low-pressure and high-pressure systems utilize stored water and compressed gas to deliver the water to the nozzles. Nozzle locations and orientation are important to overall performance. Cycling (on/off cycles) are sometimes used to minimize the cooling rate of the turbine casing. A separate heat or optical detection system is used to control release of the system and to activate interlocks. Water storage volume is based on either the FM Global Research minimum requirement for 10 minutes' duration or the NFPA 750 requirement for two complete discharges for preengineered systems (20 minutes).
- *Industry acceptance.* Norwegian and Australian petroleum industry operators and regulators accept water mist as an alternative to halon or CO_2 in turbine enclosures on offshore platforms. The Alaska North Slope oil field regulators also accept the use of water mist in land-based turbine enclosures. Most turbine manufacturers accept the use of water mist around their turbines provided they have passed the FM Global plate cooling test.

Marine Accommodation, Public Spaces, and Service Areas

The IMO maritime regulations that require installation of sprinkler systems on passenger-carrying ships have stimulated interest in developing water-based suppression systems that require less water than standard sprinklers, can use smaller-diameter piping, and be compatible with the water supplies, detection, and control systems on a ship. To that end, considerable effort has gone into developing water mist systems that operate in the same manner as sprinkler systems.

Test protocols have been developed by IMO to evaluate the use of water mist in crew's quarters and ship corridors.[10–12] Testing to date has focused on small cabins (i.e., 12 m^2 for crew's quarters, and 25 m^2 for luxury cabins). Unlike the water mist systems intended for application to Class B (hydrocarbon fuel) fires, the crew's quarters fire scenario involves Class A combustibles. Whereas large droplets are a disadvantage for hydrocarbon fires, they are beneficial to the extinguishment of Class A combustibles due to wetting of unburned fuel. Mist intended for suppression of Class A combustibles can have more large droplets than sprays intended for liquid fuel fires.

Water mist systems incorporating thermally released nozzles were recognized under IMO as equivalent to sprinklers for application in crew's quarters and passenger cabins.[10] Additional tests have been developed by IMO for the more severe fuel loading associated with shopping and service areas on ships.[11–14] The fire tests developed by IMO for the Class A hazards on ships have become the basis for generalized systems intended for land-based "light and ordinary hazard" and "residential" occupancies.[15,16]

The light and ordinary hazard occupancy applications of water mist systems can be characterized as follows:

- *Safety objectives.* The safety objectives are to save lives by suppressing and controlling fires in Class A combustibles and to prevent fire spread from the compartment of origin into adjacent compartments.
- *Mechanisms.* Mechanisms include wetting of wood, paper, cloth, and plastic fuels in furnishings and wall coverings; some steam displacement of oxygen; convective cooling of flame, hot gases, and fuel; and blocking convective and radiant heat transfer to surfaces of unburned fuels and other objects, thereby preventing flashover.
- *System features.* The system is similar to wet-pipe sprinkler systems with normally closed, fast-response, thermally activated nozzles. The nozzles produce a higher percentage of finer drops than standard sprinklers.
- *Industry acceptance.* As of 2006, almost all cruise ships are protected with marine water mist systems tested under the IMO test protocols for accommodation, public spaces, and service areas. The systems are recognized by most national coast guard authorities and marine classification societies.

Hotels, Heritage Buildings, and Galleries

Nonmarine applications of water mist systems include hotels, heritage buildings, and art galleries. The IMO test protocols for accommodation, public spaces, and service areas provide the design basis for many of these systems. Rooms with corridors on cruise ships are similar to rooms with corridors in land-based hotels. Since 2000, two hotels in the United Kingdom have been retrofitted with high-pressure water mist sprinkler systems for the purpose of increasing life safety. High-pressure water mist systems were selected because of the advantages of using small-diameter tubing and a small waterflow requirement compared to standard sprinklers. The water mist systems were cost competitive with standard sprinklers.

Water mist systems have been installed to protect remote heritage buildings in Norway and Finland. The 1000-year-old wood stave churches are located in remote areas with minimal or no water supply. There was a need to provide an automatic detection and suppression system that could protect the structures with a minimum amount of water and without damaging the icons painted with water-soluble paint on the wood walls. A water mist system was developed using nozzles at ceiling height to achieve flashover suppression by delivering enough water to take the heat out of the hot gas layer but not to wet the walls.[17,18] Supplementary nozzles with higher flow rates were mounted at floor level to extinguish the accelerant fires. Testing was performed in Norway to validate the concept, and

Norwegian authorities responsible for preservation of national treasures were pleased to have a means of protecting the structures.[19] The National Gallery of Art in Washington, DC, has installed a preaction, high-pressure water mist system in a series of galleries. The galleries are primarily period rooms with combustible walls or ceilings. A fire in these galleries would threaten all other areas of the gallery with smoke and fire damage. The combustible walls and ceilings were not considered to be irreplaceable because the woodwork could be recreated if damaged by water. The objective was to provide fire protection with minimal water use, so that other areas of the gallery would not be flooded or damaged. Water mist nozzles were selected to project spray horizontally along the underside of the ceiling in the concealed spaces above the ceiling and in wall cavities. The nozzles are thermally activated, although the fire pump unit does not start unless there is an alarm signal from at least two smoke detectors.

Water mist systems for hotels and heritage buildings can be characterized as follows:

- *Safety objectives.* For hotels, the objective is life safety, although property protection is also important. For remote heritage buildings and galleries, the objective is primarily property protection and heritage preservation.
- *Mechanisms.* Mechanisms used include cooling of hot gases near the ceiling to minimize the occurrence of flashover and direct wetting of Class A combustibles.
- *System features.* For hotels and galleries, high-pressure pump water supplies are used for a minimum 30 minute duration. For remote heritage buildings, compressed gas–driven systems with 10 minutes' stored water are used. Open nozzles on deluge systems for flashover suppression, thermally activated (automatic) nozzles on preaction systems for gallery protection, and automatic nozzles on wet-pipe systems for hotels are used. Preaction and deluge systems would also include the use of a supplemental fire or smoke detection system and interconnected alarm panel.
- *Industry acceptance.* Acceptance by authorities having jurisdiction (AHJ) in Europe is based on collaborative development work involving AHJ, design engineers, and manufacturers. Acceptance is growing rapidly in North America.

Electrical Equipment Rooms, Computer Rooms, and Wet Benches

Water mist has been viewed as a possible alternative to halon 1301 for use in electrical equipment rooms. Potential applications include telecommunications central office facilities, control rooms, and computer rooms. Developments in these areas are limited. There is strong interest worldwide in the use of water mist systems in control rooms, particularly since several European authorities mandated the removal of all halon systems. Consensus on a general design approach and performance objectives for water mist on fires in electronic equipment has not yet been reached.

Testing has been performed by the U.S. Navy and by manufacturers to demonstrate that water mist may be used on high-voltage electrical equipment if precautions are taken with regard to stand-off distances.[20] Electrical charge does not transmit through an atomized spray. Water mist may be used in switchboard compartments for 10 minutes or more before leakage currents reach dangerous levels.[21]

Although FM Global has shown support for the use of water mist for telecommunications central offices, general acceptance by end users has been slow in North America. Similarly, the use of water mist as a halon replacement for computer rooms has been mixed. The fundamental issue has to do with comparing the performance of total flooding gaseous clean agents that can penetrate into electronic cabinets with water mist that cannot extinguish fire inside a cabinet, at least not in a total compartment flooding mode.

One water mist manufacturer markets a water mist system intended to capture smoke in a computer room subfloor and direct it into tubes where it can be scrubbed of acidic gases. This computer room "smoke scrubbing" subfloor system has been approved by FM Global for the protection of computer room subfloors, not as a general computer room fire protection system. For general fire protection in the computer room above the subfloor, standard water mist nozzles are distributed according to light hazard spacing rules. In general, water mist may provide the level of protection afforded by sprinklers against Class A fire hazards in a computer room but with discharge of smaller volumes of water. The objective of extinguishing a small fire inside an electrical cabinet without causing extensive wetting of sensitive electronics can be better achieved with gaseous clean agents.

It should be stated that the subfloor "smoke scrubbing" takes place inside a 100-mm-diameter tube where thorough mixing and washout are possible. The system captures smoke from the subfloor in 100-mm-diameter tubes. A water mist nozzle placed inside the tube creates a positive differential pressure downstream of the nozzle and a negative differential pressure upstream of the nozzle relative to the pressure in the subfloor. In the positive-pressure end, nitrogen and very fine mist are pushed out of holes in the pipe into the subfloor. In the negative-pressure end of the pipe, air and smoke from the subfloor are drawn into the pipe. Nitrogen rises into the computer cabinets above the subfloor where it extinguishes small telltale fires inside a computer cabinet. For the smoke that is drawn into the scrubbing tube, the vigorous mixing causes soluble corrosive gases such as HCl to be washed out.

In contrast, it is not true that water mist has a general smoke-scrubbing benefit when injected into a smoky fire compartment from ceiling nozzles. Unfortunately, some water mist manufacturers make the general claim that water mist provides a smoke-scrubbing benefit, making it suitable for use in electronic spaces. This erroneous claim of generalized smoke-scrubbing benefit is promoted for electronic spaces, art galleries, highway tunnels, and buildings in general. In a study conducted for the U.S. Navy, Mawhinney et al. measured the optical density of smoke before and after passing through water mist screens.[22] The study noted that optical densities decreased as a result of the water mist but not enough to materially improve visibility. Furthermore, nonsoluble toxic gases in the smoke are not washed out, so the toxicity of smoke is not reduced by the water mist. Recently, an Austrian group claimed that water mist provided

scrubbing benefits for fires in a highway tunnel—the perceived benefits include improved visibility and increased "breathability."[23] Such claims are not supported by experimentation and may lead to a dangerous misunderstanding of the benefits of water mist.

Wet benches are used for the manufacture of electronic computer chips. They are traditionally protected by carbon dioxide systems. The hazard includes confined spaces under the wet bench, vats of flammable liquid on the polypropylene surface of the work bench, and the collector hoods. Two water mist manufacturing companies have developed water mist systems for installation in wet benches. FM Global Research developed a test protocol for evaluation of the system.[24] The system consists of open nozzles in zones connected to a water storage cylinder connected to a cylinder of compressed gas. It is activated by optical detectors. Because of the high corrosivity of the etching acids used in the process, corrosion-resistant pipe and fittings are needed. One company manufactured a twin-fluid nozzle out of the equivalent of Teflon plastic to meet the corrosion-resistance requirement.

Water mist systems for electronic equipment, computer rooms, and wet benches can be characterized as follows:

- *Safety objective.* The safety objective is to provide property protection by extinguishing small fires and removing acid gases from smoke generated in subfloor areas.
- *Mechanisms.* Mechanisms include direct wetting of Class A combustibles in electrical wiring and normal combustible items found in computer rooms and washing out of soluble acid gases in subfloor smoke.
- *System features.* For computer rooms and electrical equipment rooms, closed nozzles equivalent to sprinklers are used. For subfloor smoke scrubbing, a custom-designed grid of large-diameter tubes for distribution and collection of the combined nitrogen/fine mist gas is used. Small water storage cylinders and cylinders of nitrogen gas provide a 10 minute operation of the subfloor system.
- *Industry acceptance.* Acceptance by authorities having jurisdiction in Europe is based on collaborative development work involving AHJ, design engineers, and manufacturers of water mist equipment. Consensus on test protocols and design criteria for water mist systems for computer rooms has not yet been reached. Wet bench systems have approval by FM Global.

Tunnels

Tunnels are likely to be an important direction of development for water mist fire protection systems in the next 10 years. Fire testing has been performed to evaluate the use of water mist against electrical cable fires in tunnels.[25] After a decade of serious highway and rail tunnel fires in Europe that resulted in heavy loss of life and financial losses totaling in the billions of dollars, the tunnel authorities in Europe have begun to lessen their reluctance to employ active water-based fire suppression systems in tunnels.[26,27]

In North America and Europe the fire protection strategies for highway tunnels have been based on providing ventilation to remove smoke and hot gases, using spall-resistant concrete, and providing traffic control and evacuation exits at certain distances along the tunnel. Water-based fire suppression systems were until recently viewed as undesirable, possibly because of incomplete risk evaluations. The body of opinion on which the designers of fire safety systems for tunnels have relied was reflected in NFPA 502, *Standard for Road Tunnels, Bridges, and Other Limited Access Highways*.[28] That standard also provided estimated fire sizes for different types of vehicles for use as design fires for designing ventilation systems and protective linings. Remarks in the Appendix to NFPA 502 gave dire warnings against the use of sprinklers or suppression systems.

A series of full-scale fire tests conducted in Norway in 2003 presented a challenge for the traditional design assumptions for fire safety in tunnels. The Runehamar Tunnel[29] fire tests demonstrated that a typical HGV lorry transporting furniture or foam mattresses could create a fire ranging from 75 to 200 MW. NFPA 502 suggested design fire size for a HGV is 30 MW. Ventilation systems designed on the basis of an assumed 30 MW fire are going to be ineffective against 150 MW fires. This fivefold underestimate in the size of the design fire for ventilation system design suggests that water-based suppression systems are in fact necessary in order to reduce the impact of fire in a tunnel to a level that the ventilation systems or other safety features can handle.

Since 2003 the tunnel fire safety authorities in Europe have realized that water-based active fire suppression systems may be essential to ensure the assumed (public expectation) minimum level of life safety in road tunnels. This change in attitude has motivated significant spending on the part of manufacturers of water mist fire suppression systems in full-scale testing. In the last 5 years, systems including high expansion foam, compressed air foam (CAF), and water mist have been tested. Fire testing of water mist systems has been and continues to be carried out at the Runehamar test tunnel in Norway, the IF tunnel research facility also in Norway,[30] the Hagerbach tunnel research facility in Switzerland,[31] and the San Pedro de Anes tunnel safety research facility in Spain.[32] Recently, contracts have been let to begin installation of water mist systems in several highway tunnels in Europe. One result of the extensive full-scale fire testing conducted to satisfy tunnel authorities will be some standardization of the performance objectives for the suppression system, against standard design fires, versus against very severe heavy goods vehicle fires such as identified in the Runehamar testing. Due to a lack of consensus among tunnel authorities in different countries as to how to set realistic performance objectives for a tunnel fire suppression system, there may be significant differences in the design features of systems developed by different manufacturers. The benefits of water mist in highway tunnels include cooling the gases to reduce the thermal threat to people, prevention of fire propagation beyond the first one or two vehicles involved, and reduced buoyant smoke spread. Reduced buoyancy makes it easier for existing ventilation equipment to function and for fire fighters to force smoke back into a tunnel as they try to approach the fire area. It should be noted that water mist applied generally from ceiling nozzles does not provide a smoke-scrubbing benefit. Although some soot is washed out of the smoke, the visibility does not improve sufficiently to improve existing conditions, and nonsoluble toxic gases such as CO are not re-

moved.[33] Water mist can be used to cool tunnel ventilation fans so that they survive longer and continue to remove smoke from the tunnel.

Tunnels can be very long with limited space for equipment such as pumps and water reservoirs. The challenge of providing adequate flow and pressure of water to the mid-sections of a tunnel that might be 10 km or more in length presents a unique opportunity for water mist systems, which use smaller-diameter piping than traditional water-based suppression systems. Extensive full-scale fire testing of water mist systems in highway tunnels in the last 5 years has shown that water mist can provide satisfactory protection of life and property against even catastrophic fires in heavy goods vehicles. Cost-effective engineering designs to achieve the required waterflow rates at the three most remote zones in the tunnel have been realized.

Water mist systems for tunnels can be characterized as follows:

- *Safety objectives.* For electrical cable tunnels, the primary objective is property protection, although life safety is an issue for workers in the tunnel. For railway tunnels, both life safety and property protection are important**.** For highway tunnels, the property protection objective is to limit thermal damage to the tunnel lining to the area of a single burning vehicle and to prevent propagation of fire to adjacent vehicles. Reduced temperatures and smoke buoyancy will increase the effectiveness of ventilation systems in tunnels and make it easier for the fire fighters to enter the tunnel to fight the fire and aid rescue.
- *Mechanisms.* Mechanisms include direct wetting of Class A combustibles in electrical wiring or commodities carried in vehicles, cooling of hot gases; reduced smoke buoyancy, hence, smoke spread; and direct cooling of gases entering the smoke exhaust system to prolong functionality of equipment.
- *System features.* Features include generally high-pressure water mist systems with stainless steel tubing and several positive displacement pump stations, special detection systems, zoning of systems fixed to the tunnel, or systems fixed to a moving vehicle.
- *Industry acceptance.* Acceptance by local authorities having jurisdiction is on the basis of special fire testing directed by end users.

Aircraft Passenger Compartments

Starting in 1985, the Civil Aviation Administration (CAA) in the United Kingdom and the Federal Aviation Administration (FAA) in the United States, with the involvement of Transport Canada, Airbus, Boeing, and other aviation industry agencies, developed a fine water spray fire control system for aircraft passenger compartments.[34] The objective of this international research and development effort was to find a way to decrease the number of fatalities in air crashes that involve fuel spill fires (i.e., the postcrash fire scenario). The Manchester, United Kingdom, air crash of 1984 was the particular incident that sparked this interest. In that incident, the fatalities were not caused by the crash but by the fire from spilled fuel that engulfed the fuselage and spread into the passenger compartment. Aircraft are not at present equipped with fixed systems to protect against a postcrash fire.

The testing program verified that the aircraft passenger compartment water mist system met or exceeded the researchers' objectives for the postcrash fire scenario.[35] Having determined the details of the design, a cost-benefit study was conducted. The study concluded that the cost of outfitting a fleet of aircraft with passenger compartment water mist systems would be too high relative to the number of lives that would be saved to justify mandatory requirements for their installation.[34] As a result, both industry and regulatory partners in the aviation industry decided not to make it mandatory to install such systems on existing or new aircraft. Instead, focus has shifted to the problem of developing water mist systems for onboard cargo compartment fires during flight.

The aircraft passenger cabin water spray system can be characterized as follows:

- *Safety objective.* The primary safety objective is saving lives by protecting an aircraft passenger compartment from a postcrash, external fire threat and extending the survivable evacuation time.
- *Mechanisms.* Mechanisms include blocking convective and radiant heat transfer, cooling of hot fire gases, and wetting of fuels (plastic and cloth).
- *System features.* The system features zoned piping, automatic thermal activation of each zone, 3 minute supply of stored water in pressurized cylinders, single discharge, with limited duration of protection adequate for a well-defined performance objective.
- *Industry acceptance.* Developed through collaboration between aviation industry and regulatory authorities, the system has not been made mandatory on the basis of an unfavorable cost-benefit study.

SUMMARY OF WATER MIST SYSTEM FEATURES

From the preceding descriptions, it is evident that there are wide variations in the objectives, fire scenarios, system details, and levels of acceptance for water mist fire suppression systems. These can be summarized as follows:

Objectives

1. Protect lives and property in a compartment from external fire threat.
2. Control fire temperatures in a compartment to prevent flashover and fire spread to adjacent compartments.
3. Extinguish Class A and Class B fires.
4. Use water to provide protection where there was no previous protection (aircraft passenger compartments).
5. Use water where halon or CO_2 was previously used (Class B fires in machinery rooms).
6. Provide freedom from sprinkler system design constraints (e.g., allow use of smaller pipe sizes) with equivalent level of safety.

Fire Scenarios

1. Large external pool fire threatening to spread into a compartment

2. Liquid hydrocarbon fuels with high- and low-flashpoint liquids, in spray, spill, and pool fires, outdoors and in compartments
3. Class A combustibles (furniture, bedding, books on fixed shelving) in small compartments
4. Machinery compartments, underventilated liquid fuel fires
5. Large machinery compartments with obstructions, well-ventilated conditions, and small to large fire sizes
6. Tunnels with very large fuel loads of wood and plastic commodities on heavy goods vehicles or passenger vehicles

System Details

1. Low-pressure to high-pressure systems: 5 to 140 bar (75 to 2000 psi)
2. Single- and twin-fluid systems
3. Normally open nozzles, deluge-type systems, with separate detection system for activation
4. Normally closed, thermally activated nozzles
5. Continuous discharge
6. Repeated short discharges (cycling)
7. Declining pressure systems (gas driven)
8. Constant pressure systems (pump driven)

Levels of Acceptance

1. IMO full-scale fire test protocols, to be conducted by national laboratories, have been in place since 1996. Systems that meet the fire performance criteria in the IMO test protocols will be acceptable to national and international maritime authorities. Water mist is widely used on passenger ships, less so on commercial cargo ships.
2. FM Global Research approved a preengineered system for turbine enclosures in a compartment of fixed maximum dimensions. The performance evaluation includes not only the suppression effectiveness but also the performance of the detection system, effects of water on the equipment being protected, the performance of the detection/actuation equipment, flow duration, and sensitivity to partial dysfunction.
3. The components of water mist systems, including nozzles, pumps, actuators, gas cylinders, pressure control equipment, detection system panel, control valves, and so on, must meet IMO component testing criteria or be listed by Underwriters Laboratories Inc. (UL 2167) or FM Global Research (FM 5560 Test Protocols) for use in water mist systems.
4. Acceptance of water mist systems in land-based applications continues to grow. Authorities having jurisdiction are accepting more and more systems for industrial process modules, highway tunnels, hotels, and heritage buildings.
5. NFPA 750 describes what must be taken into account in full-scale fire test evaluations of water mist systems but defers to testing agencies to conduct those tests. If tests conducted by a credible laboratory demonstrate that the proposed design will meet the performance objectives, then it is expected that authorities having jurisdiction will accept the design.

Having reviewed the types of water mist systems that have achieved a level of recognition, the fundamental principles involved in extinguishing fires with water mist can be addressed. Ultimately, an understanding of the first principles governing the performance of water mist systems will allow the designer to adapt the range of misting technologies to the range of fire scenarios to meet a variety of system objectives.

GENERAL PRINCIPLES OF WATER MIST SYSTEMS

This section describes the general principles of water mist fire suppression systems technology and includes extinguishing mechanisms, spray characteristics, generic design elements, and methods of generating water mist. Extinguishing mechanisms are discussed first, as they are the basis on which the importance of specific spray characteristics can be appreciated. Technical details relating to spray characteristics are presented next. General principles governing the performance of water mist systems are outlined, and methods of generating water mist are described.

Extinguishing Mechanisms

A basic description of how water mist extinguishes fires was provided as early as 1955 by Braidech[1] and confirmed by Rasbash et al.[2] To quote Braidech:

> The extinguishing action of sprays of finely divided water applied to commonly encountered fires appears to be due predominantly to dilution of the air (oxygen) supply in the zone of burning with vapor (steam) resulting from evaporation of water droplets in the heated area surrounding the fire. The cooling effects of the water may also be important factors in extinguishment in many cases. In order to obtain extinguishment, the water droplets comprising the spray must be relatively small, and the amount of water applied must be adequate in relation to the specific fire.

Research conducted more than four decades later has not altered the accuracy of this description. The recent work has, however, suggested other processes that are involved and has identified the mechanisms that are most important for the design of effective fire suppression systems.

Figures 16.8.1 and 16.8.2 illustrate the mechanisms involved in extinguishing fire with mist. The mechanisms that act together to extinguish fire can be described as three primary and two secondary mechanisms.[36] The primary mechanisms are (1) heat extraction, (2) oxygen displacement, and (3) blocking of radiant heat. Wighus[7] and Hanauska and Back[37] described the mechanisms as "gas-phase cooling and steam inerting," making no reference to radiant heat attenuation. Although all three mechanisms are involved to some degree in every extinguishment, in tests conducted at the National Research Council, some fires were extinguished predominantly through heat extraction (cooling) and others predominantly through displacement of oxygen. The difference depends on whether the fire was poorly or well ventilated and on the properties of the fuel. The benefit of radiation attenuation in a compartment is evi-

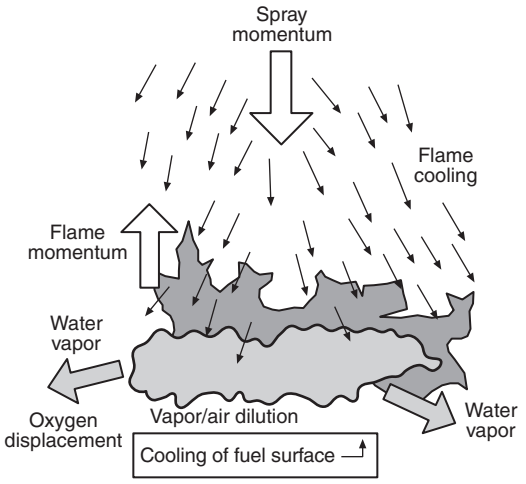

FIGURE 16.8.1 Interaction of Mist with Pool Fire Flame, Showing the Extinguishing Mechanisms

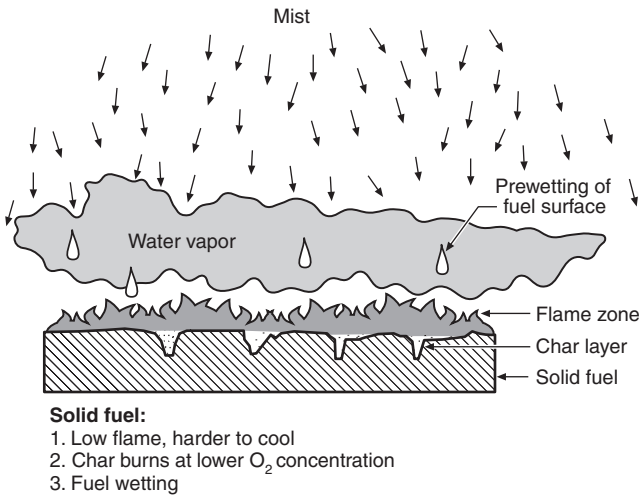

FIGURE 16.8.2 Flame on a Solid Fuel with Charring and Mist

dent in reduced thermal feedback to burning and unburned fuel surfaces. In the National Research Council of Canada (NRCC) experiments, however, radiation attenuation could not be identified as the dominant mechanism of extinguishment.

There are two secondary mechanisms that play a role in extinguishment, but it is difficult to quantify their importance. These are (1) vapor/air dilution, and (2) kinetic effects. The dilution of vapor/air mixtures by the mixing of water vapor and entrained air in the flammable vapor zone above a fuel surface can be deduced to have some effect on pool fires. Also, the velocity of the flame front in a flammable gas mixture may be inhibited (or accelerated) by the presence of small water droplets dispersed in a volume of flame, and this phenomenon may play a role in the extinguishment of spray fires and in inhibiting deflagrations.[38]

For engineering design of reliable water mist fire suppression systems, it may be sufficient to understand the three dominant mechanisms (i.e., heat extraction, oxygen displacement, and radiation attenuation). For scientific purposes, computer modelers need to consider all extinguishing mechanisms in order to develop algorithms to simulate the extinction of fire by mist. An ideal computer model would account for flame and fuel cooling, oxygen reduction, concentration changes in vapor/air mixtures at the fuel surface, reduced radiant feedback from flame to fuel surface, and possible kinetic effects caused by the interaction of mist with a moving flame front. Computational fluid dynamics (CFD) modeling to that level of detail is, at this time, in its early stages of development.[39–42] Recently zone models have been developed that predict extinguishing time based on oxygen depletion and cooling.[43] The mechanisms of extinguishment are described in detail in the sections that follow. Table 16.8.1 summarizes the points to be discussed.

Heat Extraction (Cooling). When water is applied to a fire, heat is absorbed in three areas: (1) from the hot gases and flames, (2) from the fuel, and (3) from the objects and surfaces in the vicinity of the fire. Cooling of the fuel and nearby objects contributes to reducing fire spread, but it does not necessarily require fine drop sizes. In fact, wetting and cooling of solid fuels are easier to achieve by using larger droplets (400 microns) and delivering more water than can usually be delivered as water mist.

Compared with coarser sprays, finely divided water sprays enhance the speed at which the spray extracts heat from the hot gases and flame. Reducing the drop size increases the surface area of the water mass and thereby increases the rate of heat transfer. The conversion of water droplets to steam absorbs heat. If sufficient heat is withdrawn, the gas-phase temperature of the flame can be dropped to a level that is below that necessary to sustain the combustion reaction, and flame will be extinguished. Theoretical considerations suggest that the combustion reaction in a diffusion flame will cease if the flame temperature drops below approximately 1600°K (1327°C).[1,2,36]

As for what constitutes "sufficient" heat absorption, various authors note that it is not necessary to absorb all of the heat given off by the fire at the rate of burning. Absorbing 30 to 60 percent may be enough to cause burning to stop.[44] An estimate of the minimum evaporation rate to extinguish a fire of a given heat release rate (HRR) is of little practical value, however, because extinguishment usually involves more than just flame cooling. The concurrent effect of oxygen reduction could mean the fire could be extinguished with only a fraction of the theoretical minimum required for flame cooling.

For liquid fuel fires, the evaporation of mist cools the flame, which, in turn, reduces the radiant heat flux to the surface of the fuel, resulting in a reduction in the evolution of flammable vapors. The combination of reduced flame temperature and reduced evolution of vapors results in a reduced burning rate and, in some cases, complete extinction. Fires in liquid fuels with flashpoints (FPs) above normal ambient temperatures, for example, diesel fuel (FP ~ 60°C), can be extinguished with relative ease by flame cooling and reduced radiation to the surface. Fires in liquid fuels with flashpoints below normal

TABLE 16.8.1 Mechanisms of Extinguishment by Water Mist and Their Application

Mechanism	*Principle of Application*
Primary	
Heat extraction	The drop size distribution, momentum, and mass flow rate delivered to the fire, after losses to interior surfaces and obstructions, must be sufficient to absorb a critical percentage of the heat released by the fire.
Oxygen displacement	Designed to: 1. Enclose fire to contain evaporated water 2. Use nozzle dynamics to force water vapor into the base of the fire
Radiant heat attenuation: 1. To unburned surfaces 2. To burning surfaces	Mist must: 1. Surround the fire 2. Penetrate the flame
Secondary	
Vapor/air dilution: 1. By water vapor 2. By entrained air	Significant for liquid fuel pool or spray fires. Must have enclosure or control of dynamic spray properties to distribute diluent over the fuel surface. Nozzle design may influence air entrainment, hence, dilution.
Kinetic effects: 1. Reduce flame velocity 2. Accelerate combustion reactions	Difficult to predict or control. Applies to deflagration control by reducing velocity of the flame front, hence, explosion overpressure. Unpredictable: mist may suppress or invigorate combustion.

ambient temperatures, for example, heptane (C_7H_{16}, FP ~ –4°C), are much harder to extinguish by cooling alone because temperatures cannot be reduced enough to reduce the vapor/air mixture above the surface of the fuel to below the lean flammability limit.[45] Any hot object or fragment of flame can cause reignition.

The cooling of flames above solid fuels also reduces the radiant heat flux to the fuel surface and the rate of pyrolysis of the fuel. As illustrated in Figure 16.8.2, however, with charring substances, the combustion reaction occurs within the carbon-rich porous zone that forms on the fuel surface.[46] Cooling of the diffusion flame above an established char zone may not suppress radiant feedback within the crevices of the char. Either water mist must be applied early in the fire, before a deep char zone has developed, or water droplets must penetrate the char zone and reach the actual interface between burning and unburned fuel. On the other hand, the flame height and plume velocities for glowing combustion are relatively low, so that the larger drop sizes in a spray may not be evaporated and will wet the fuel surface.

Extinguishment of solid fuels such as Class A combustibles, therefore, depends on the geometry of the fuel arrangement and the depth of the char layer. Exposed surfaces facing the source of the spray might be extinguished, whereas shielded surfaces (such as within a wood crib) will be almost impossible to extinguish by cooling alone.

Oxygen Displacement. Braidech et al.[1] concluded correctly in 1955 that the suppression effect of water mist "appears to be due predominantly to dilution of the air (oxygen) supply in the zone of burning with vapor (steam)." That is to say, oxygen displacement appears to play a stronger role than flame cooling. Water droplets expand approximately 1900-fold upon evaporation (at 95°C, 1 atm pressure). If evaporation occurs rapidly, the water vapor displaces the air in the vicinity of the drop. Injection of a finely divided water spray into a hot compartment results in rapid evaporation, expansion, and displacement of the air in the compartment by steam. If the amount of oxygen available for combustion is reduced below a critical level, the fire burns inefficiently and will be easier to extinguish by cooling.

The average temperature of the gases in the compartment limits the dilution of oxygen by water vapor in a suppression scenario.[42] As illustrated in Figure 16.8.3, the absolute concentration of water vapor that can be held in air at 60°C is 20 percent by volume—that is high enough to reduce the oxygen concentration in a compartment to about 16.8 percent, which begins to affect combustion. But at 45°C, the amount of water vapor in saturated air falls below 10 percent, which would only reduce the oxygen concentration to about 19 percent, which is not enough to extinguish the fire. This fact helps explain why water mist is more effective at extinguishing large fires than small fires in a given compartment. The higher the compartment temperature, the more water vapor dilutes the oxygen. It also explains why cycling sprays on and off, in closed compartments, reduces extinguishing time compared to systems with continuous discharge. More water is evaporated because of the increase in compartment temperature during the "off" stage of the cycle. Water mist is likely to act as gaseous extinguishing agent if the average compartment temperature is between 60 and 70°C. In a cooler compartment, the effectiveness of oxygen depletion is reduced. Flame and fuel cooling and wetting become the primary mechanisms of extinguishment.

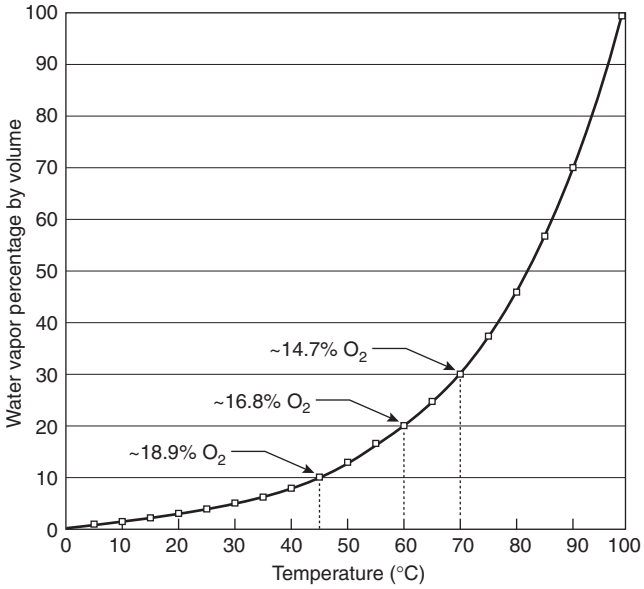

FIGURE 16.8.3 Relationship Between Gas Temperature and Volume Concentration of Water Vapor in Saturated Air. Approximate resulting oxygen concentration is indicated.

The Braidech et al.[1] study, as with most studies of the extinguishment of fires with water mist, concentrates on hydrocarbon pool fires with a few tests on wood cribs. Recent tests by Wighus et al.,[7,44] Mawhinney,[47] and Hanauska and Back[37] on diesel and heptane pool and spray fires confirmed that oxygen displacement ("steam inerting") was the dominant mechanism by which water mist extinguished the flames, both in compartments and in open-area pool fires. The confinement of heat allowed the water vapor concentration to build up so that hidden and shielded fires could be extinguished. Hanauska and Back[37] used a very fine spray with low momentum and flow rate to extinguish heptane pool and spray fires, after 30 to 50 seconds of mist application, in a 28 m^3 compartment. Fires in such enclosures can be extinguished with about one-tenth the mass flux of water needed for pool fires in open areas.[7,44] In open-area fire tests at National Research Council Canada (NRCC), extinguishment of pool fires could not be achieved unless the spray was oriented and applied with enough force to push water vapor created in the outer regions of a flame onto the fuel surface. The open-area fires required high-momentum sprays, properly oriented with respect to the plume direction. This fact suggests that the water vapor concentration at the fuel surface can be increased by either confining the fire in an enclosure or by using spray momentum to push the water vapor against the surface. In the NRCC plenum tests,[48] turbulent mixing alone did not bring about extinction if there was no component of the spray velocity directed toward the fuel surface.

The minimum amount of free oxygen needed to support combustion varies with the type of fuel. In general, hydrocarbon gases and vapors cease burning at oxygen concentrations below 13 percent, whereas charring solid fuels may burn with oxygen concentrations as low as 7 percent.[46] This explains why it is easier to extinguish hydrocarbon pool fires (diesel and heptane) than wood crib fires; the reduction in oxygen needed to extinguish a hydrocarbon flame is easy to obtain compared to that needed to arrest combustion in burning wood.

Figure 16.8.3 also explains why it is easier to extinguish large fires than small fires. The terms *small* and *large* refer to the size of the fire relative to the size of the enclosure. The observation is explained by the fact that a small fire has little effect on the average oxygen concentration in the enclosure (initially, at least), whereas the effect of a large fire on oxygen concentration is quickly evident. Compared to a small fire, a large fire generates more heat and creates a higher compartment temperature that in turn supports a higher absolute concentration of water vapor and reduces the average oxygen concentration more rapidly. To be useful in a compartment that cannot tolerate the damage that could be done by a small fire, perhaps due to flame impinging directly on a critical piece of equipment, careful thought must be given as to when or if it is necessary to extinguish small fires early.

Radiant Heat Blocking. Blocking radiant heat plays a role in stopping the fire from spreading to unignited fuel surfaces and reduces the vaporization or pyrolysis rate at the fuel surface. On a macro scale, radiation attenuation provided by water mist protects objects and personnel in a space from radiant heat damage, whether or not extinguishment occurs.

Theoretical work on radiation attenuation by water sprays[49,50] indicates that the attenuation of radiation depends on drop diameter and mass density of the droplets. As the concentration of drops with diameters smaller than 50 microns increases, the degree of attenuation of radiant heat increases.[49] This is one reason why water mists, having high concentrations of very fine drops, prove to be very effective at reducing radiant heat transfer. One question that arises is how much of the reduction in radiation to surfaces is due to the reduced size of the flame and what proportion is due to actual attenuation of radiant heat due to the presence of mist. Theoretical considerations suggest that mist or steam that enters the space between a flame and the fuel surface will reduce the radiant heat flux to that surface.[38] This is difficult to measure, but it is hypothesized that radiant heat from the flame could be absorbed by unevaporated droplets and steam, which reradiate at the lower temperature of the droplets or vapor. With some liquids, such as diesel fuel (FP ~ 60°C), this reduction in the heat flux to the fuel surface may reduce the vaporization rate of the liquid fuel and contribute to the extinguishment. Reducing energy transfer to the fuel surface reduces the rate of generation of volatile vapors.

Radiant heat attenuation between flame and fuel surface is important for computer modeling of fire suppression using computational fluid dynamics (CFD). In developing a CFD model of fire suppression using water mist, An et al.[51] calculated the heat release rate of a liquid pool fire, taking into account the coefficient of absorption of water vapor in each control volume. A reduction of radiant heat transfer to the fuel pan was predicted to measurably reduce the vaporization rate, hence, the heat release rate of the burning vapors. More experiments are needed to compare measurements of heat flux in this zone to predictions of radiant heat attenuation obtained using the CFD models.

Vapor/Air Mixture Dilution. Air and water vapor entrained in a water spray may dilute the vapor/air mixture to below the lean flammability limit. With diesel fuels (FP ~ 60°C), cooling of the flame reduces the thermal energy to the fuel surface, which in turn reduces the rate of evaporation. Coupled with a dilution of the vapors by the addition of entrained air, the vapor/air concentration falls below the lean flammability limit. In contrast, it is much harder to reduce a heptane/air mixture to below its lean flammability limit because of the low-flashpoint temperature (–4°C) and high vapor pressure of heptane. Dilution of pyrolized vapors emitted from solid fuels may also contribute to extinction and is referred to as a secondary mechanism because it is difficult to see how dilution alone could result in extinguishment. It requires uniform mixing of mist and entrained air throughout the space between the flame and the fuel surface to dilute all of the vapor/air mixture within the vaporization region. Mixing at fuel surfaces is often turbulent and nonuniform, so it is likely that there will always be some region of the vapor/air cloud that is in the flammable range.

For purposes of designing suppression systems, it is not yet feasible to quantify the relationship among the flammability limits of different fuels, the fuel vaporization rates, spray evaporation rate, and the mass flow rates of water mist and entrained air. A knowledge of dilution effects can, however, be used to explain differences in the effectiveness of water mist on different fuels as, for example, diesel and heptane. It should in principle be possible to calculate dilution effects on gas concentrations using computer field models based on computational fluid dynamics.

Kinetic Effects of Mist on Flames. A liquid pool fire is sometimes intensified by the application of water spray. A flare-up often occurs during the first moments of contact with the water mist, and it is evident in some fire tests that the burning rate is increased for longer periods. The general flare-up at the instant of application of water spray on liquid fuel fires is familiar to fire fighters. In many cases, the flare-up is followed by a quick knockdown and extinguishment of the flames. If the spray dynamics are insufficient to bring about extinguishment, the fire will continue to burn violently in spite of the mist.

The momentary intensification of the fire has been attributed by some authors to the effect of droplets striking the fuel surface and causing splashing and increased vaporization rate. Kokkala[52] referred to a "flame ball" that occurred when a sprinkler spray hit a hot, high-boiling-point liquid and explosively vaporized. In a study performed at WPI, the intensification of high-flashpoint oil fires on application of water spray was attributed largely to the disturbance of the fuel surface.[53] The same phenomenon was noted by Mawhinney[48] during suppression tests in which a fine water mist was applied from below a diesel pan fire in a direction concurrent with the fire plume, such that very few droplets could reach the surface of the diesel fuel. The visual evidence, supported by thermocouple readings, was that the flame within the plenum became violently turbulent and appeared to intensify during the time of application of the mist. One possible explanation for the observed intensification is that the turbulence acted to introduce more air into the combustion zone and thereby increased the burning rate of the fuel.

Mawhinney et al.,[36] at NRCC, measured the heat release rate of open-area heptane and diesel pan fires during the application of water mist. Figure 16.8.4 shows the measurements of heat release rate (HRR) during the suppression of a diesel pool fire and a heptane pool fire, respectively, using the same downward-oriented water spray in both cases. The HRR curves under suppressed conditions are plotted with the curves for unsuppressed fires in the same pans. In the case of diesel fuel, there is a brief spike in the HRR, followed by complete extinguishment within 60 seconds once the system is activated. For the heptane fire, a brief spike also occurred, followed by a partial suppression of the fire, and then by a continued increase in the burning rate of the heptane. The water spray failed to extinguish the fire, and turbulent flaming continued until the fuel was consumed. Over a portion of the burning time, the HRR of the fire with mist exceeded the HRR for the unsuppressed fire although, as expected, the overall burning time was reduced by the interval of intensified combustion. It is possible that the combustion process benefited from the additional air brought into the flame zone by the turbulent spray.

Jones and Thomas[38] report intensification of the rate of combustion in the use of water mists to quench gaseous explosions. The mist suppresses the maximum overpressure in an enclosed gaseous ignition, but the peak pressure may be attained sooner than for an unsuppressed explosion. Furthermore, the authors report that it is "never immediately obvious whether application of a water spray will quell or invigorate an explosion."

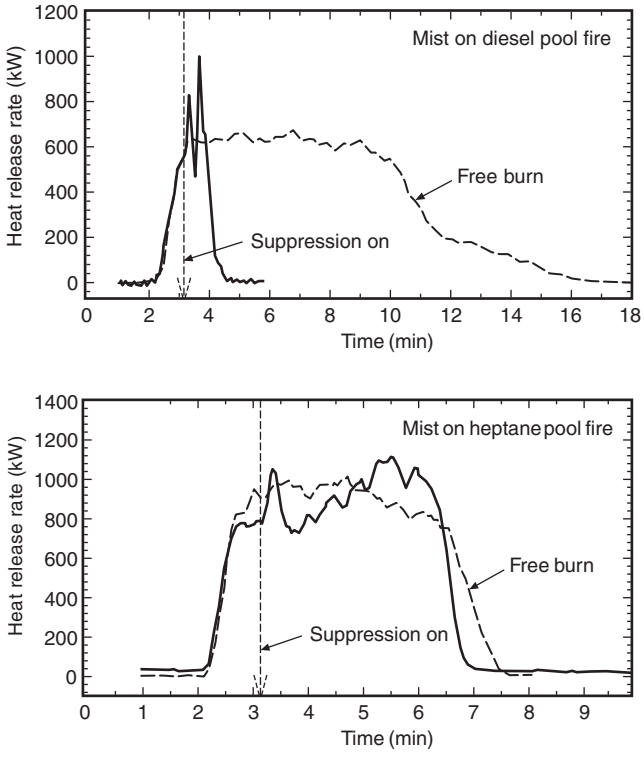

FIGURE 16.8.4 Momentary and Sustained Increases in the Heat Release Rate of Diesel and Heptane Pool Fires with Application of Water Mist

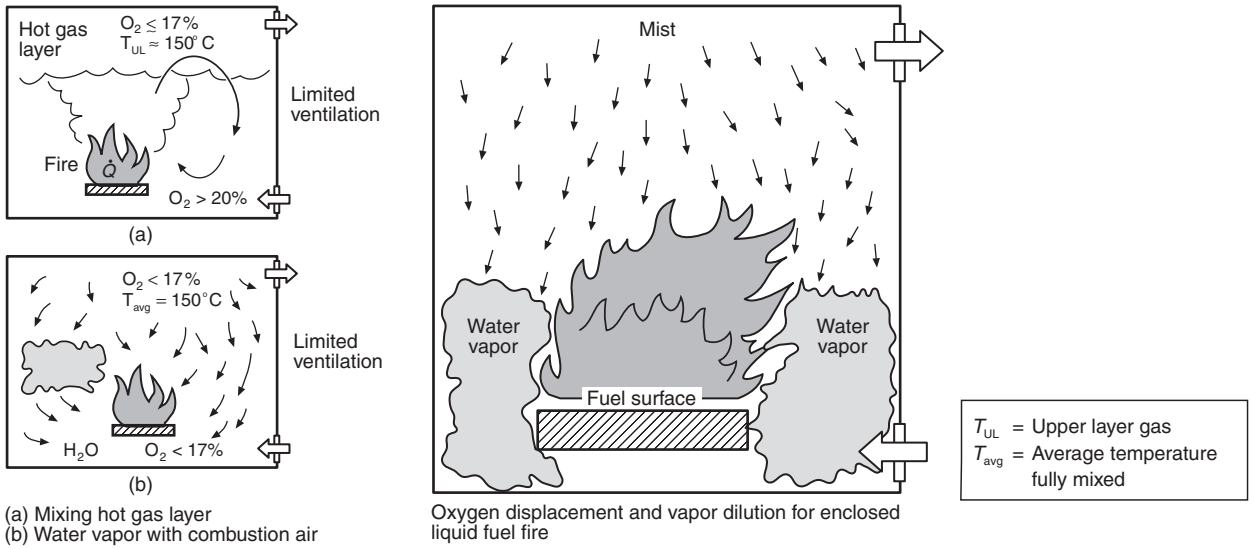

FIGURE 16.8.5 Enclosure Effects

The conflicting influences of cooling, inerting, dilution, and enhanced turbulence and fuel mixing lead to a degree of unpredictability in the effects of water mist on gas-phase burning.

There is reason to be concerned that a water mist system that is unable to extinguish a liquid fuel pool or spray fire could instead increase the heat release rate of the fire. Further research is needed to investigate the conditions under which flare-up or flame invigoration occurs.

Enclosure Effects. Enclosure effects enhance the performance of water mist systems. The enhanced performance can be attributed to restricted ventilation and heat entrapment. A fire in a small compartment reduces the average oxygen concentration in the compartment by several percentage points within the first few minutes of growth. Thus, a fire that is large enough to quickly reduce the average oxygen concentration in a compartment could be considered to be poorly ventilated. The addition of a small amount of water mist and resulting increase in water vapor further reduce the oxygen available to support combustion. Thus, an underventilated fire in an enclosure is "easier" to extinguish than a well-ventilated unenclosed fire.

Figure 16.8.5 illustrates how enclosure effects contribute to fire suppression with water mist. Heat from the fire trapped in the compartment evaporates the finest portion of the mist, so that the expanding water vapor pushes the air out of the compartment. Then oxygen-depleted, hot fire gases at the ceiling of the compartment are cooled by the mist and pushed down to floor level, mixing water vapor, oxygen-depleted air, and water drops with the fire. The combined effects of reduced combustion efficiency and flame cooling usually result in extinguishment. With enclosure effects, it is possible to extinguish even shielded fires with low-momentum sprays in heavily obstructed compartments. Where enclosure effects can be relied on, the flux density required for extinguishment can be as much as 10 times lower than that required for unconfined, well-ventilated fires.[7,44]

A phenomenon associated with enclosure effects can lead to very rapid pressure change between the fire compartment and the surrounding spaces. Water mist injected by a deluge system uniformly through the hot gas layer causes a rapid cooling of the gas layer. The accompanying volume change of the cooled gases creates a negative pressure inside the compartment relative to surrounding spaces. This is illustrated in Figure 16.8.6.[54] Depending on the temperature and depth of the hot layer, the rapid cooling results in an instantaneous volume reduction and

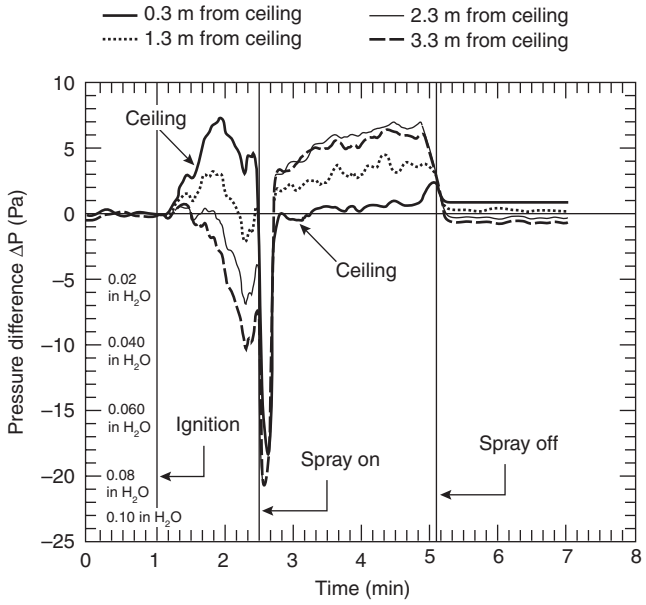

FIGURE 16.8.6 Generation of a Negative-Pressure Pulse in an Enclosure After the Injection of Water Mist into a Hot Gas Layer

negative pressure change that can suck in the windows or walls of a tight enclosure. The potential damage to a compartment is minimized by early release of the water mist system. If there is a delay in activation of the mist system, such as may occur with manual release of a local application system, the negative-pressure spike may be severe enough to damage the compartment ceiling, walls, windows, or doors.

In the case of an unconfined and, therefore, well-ventilated fire there are no enclosure effects to create conditions favorable to extinguishment. Water mist can achieve extinguishment only if the spray has strong enough momentum to push water droplets and vapor into the flame to the fuel surface. Thus, the absence of enclosure effects creates the need for a local application system. Local application systems typically have different spray characteristics, higher flow rates, and closer nozzle spacing than total-compartment application systems. Nozzle dynamics must compensate for the lack of confinement of vitiated gases, heat, and water vapor.

Time to Extinguishment. The time needed to extinguish a fire with water mist varies with the fuel type, compartment geometry, drop size distribution, momentum, and application rate of the water mist. Water mist extinguishes liquid fuel pool fires in 10 to 20 seconds, using small amounts of water. The top part of Figure 16.8.4, for example, shows a 600-kW, unenclosed diesel pool fire that was extinguished in less than 60 seconds by water mist. Such successes occur in circumstances in which all suppression properties act together (i.e., oxygen displacement, flame cooling, radiant heat blocking, and vapor dilution).

Rapid extinguishment is not characteristic of all water mist fire suppression systems, however. There are circumstances in which it can take several minutes to extinguish a fire without it being considered a failure. For example, the IMO machinery space test protocol requires extinguishment within 15 minutes. One example is where flame cooling cannot extinguish the fire immediately but, after several minutes, the buildup of water vapor in the compartment (an enclosure effect) combines with flame cooling to bring about extinguishment. With combustibles that form a char layer (e.g., fabric, wood, plastics, or electrical wiring), the fire may not be extinguished immediately. Fuel wetting begins to reduce the size of the fire and it is eventually extinguished. As long as the mist limits the heat release rate, causes the fire to progressively diminish in intensity, and cools the compartment, the level of fire control can be considered adequate.[55]

The relationships among fire size, compartment volume, and time to extinguishment are well described in work by Back et al.[56] Figure 16.8.7[56] shows test results for a series of machinery room fire tests conducted for the U.S. Coast Guard. The data were analyzed to develop a prediction for time to extinguishment as a function of fire size in different size compartments.[56] Fires were extinguished solely through the mechanism of oxygen depletion. It is evident from Figure 16.8.7 that smaller fires take longer to extinguish than larger fires and that increasing the compartment volume increases the time to extinguishment. For each size of compartment shown, there is a fire that is too small to extinguish (i.e., an "unextinguishable fire"). The size of the unextinguishable fire is a function of the size of the compartment. The relationship illustrates that there is a practical limit to what can be achieved through extinguishment by total flooding alone. That limit is reached when the unextinguishable fire is either too large to be extinguished by hand or when it is likely to do unacceptably severe damage to the contents of the space.

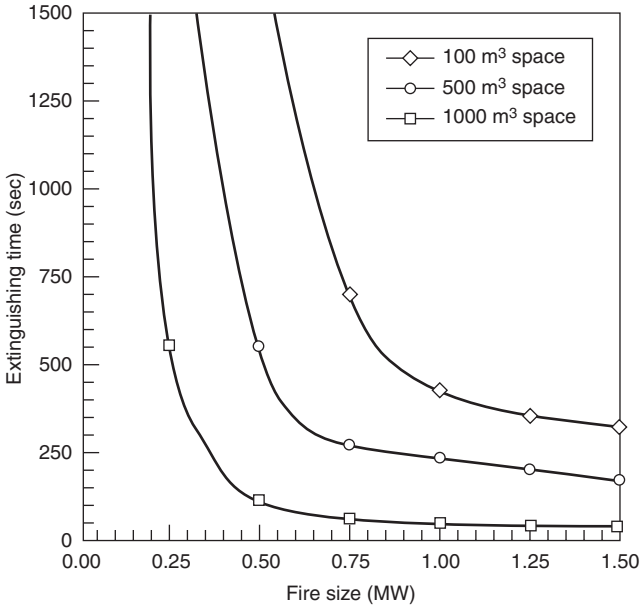

FIGURE 16.8.7 Relationship Between Fire Size, Enclosure Volume, and Time to Extinguishment of Fires in an IMO Machinery Room Test Enclosure

If the damage expected to be caused by the unextinguishable fire is unacceptably high, the system design must convert to a combination of total flooding and local application. It means that it is not sufficient to rely solely on the oxygen depletion mechanism of extinguishment. The other extinguishing mechanisms permitted by direct local application of spray must be unleashed.

Duration of Discharge. There are reasons to flow water from a system for a longer period of time than the minimum extinguishing time. First, extinguishment times vary even under controlled test conditions, and conditions in real compartments cannot be closely controlled. Second, with liquid fuel fires, reignition may occur if hot surfaces are not sufficiently cooled or if there is a remnant of flame in a shielded area. In principle, the flow should be sustained until it is confirmed that all fire has been extinguished and reignition will not occur. Such confirmation is difficult to obtain in real fire conditions. Practically, it is tempting to assign an arbitrary minimum flow duration, based on conservative assumptions about the probability of fire being extinguished. NFPA 750 recommends that the water supply be sized based on a 30 minute minimum flow duration. An exception is provided for preengineered systems, for which the minimum duration must be sufficient for two complete discharges. The length of one complete discharge is determined by the full-scale testing on which the listing was based. A second exception allows a fire protection engineer to use standard methods of fire

hazard analysis to determine the appropriate design duration. The author's experience has been that a careful fire hazard analysis for a specific application invariably results in a decision to enforce the 30 minute minimum duration.

Spray Characteristics

The term *water mist* implies a very fine water spray that remains suspended in air for an extended period of time. The term reflects one of the qualities of a spray (i.e., the drop sizes are small) relative to rain or to sprinkler sprays, for example. This one characteristic of drop size is not the only characteristic of a spray that must be controlled in order to generate an effective fire suppression medium. There are three other characteristics that influence its effectiveness as an extinguishing agent: (1) the density of the spray (mass of suspended water per unit volume of space), (2) the velocity with which it is delivered to the seat of the fire, and (3) the quality of the water itself (which may contain dissolved additives to enhance suppression effectiveness). The following discussion includes all four characteristics of a water mist for fire suppression purposes:

1. Drop size distribution
2. Flux density
3. Spray momentum
4. Additives

Drop Size Distribution. It is difficult to discuss water mist without measuring and analyzing its most notable feature, the fact that it is made up of very small water drops. At the time of this writing, except for computer modeling, the drop size distribution of the spray cannot be used explicitly as a variable in the design of a water mist system. That stage awaits the results of further research work. The value in knowing the drop size distribution (and other characteristics) of a water spray lies in the fact that it relates directly to system performance: how spray is affected by obstructions, the dynamics of the spray interaction with the fire, and how extinguishment occurs. For computer modeling of the dynamics of suppression with water mist, a quantitative measure of the drop size characteristics of the spray is essential.

The term *drop size distribution* refers to the range of drop sizes contained in a representative sample of a spray or mist. There is a distribution of small and large drops, which varies with location in the spray as well as with time. For a continuous discharge, the distribution of drop sizes changes with distance from the source as drops collide, evaporate, or hit surfaces and fall out. For a short-duration discharge, the distribution measured at a point in space changes with time as the larger drops pass through quickly, leaving increasingly finer drops, which move at lower velocity.

There are a number of ways to present data about drop size distributions of sprays.[42,57,58] It is customary in some fields to refer to the size of particles in a spray by a single drop size parameter, such as a "Sauter Mean Diameter (SMD)" or "Volumetric Median Diameter (VMD)." Such terms reveal little about the *range* of drop sizes in a spray, however. It is important to know about the presence of larger-diameter drops in a spray to avoid splashing on the surface of a liquid fuel, for example, or perhaps to know about the potential to achieve fuel wetting.

NFPA 750 has adopted the cumulative percent volume (CPV) versus diameter curve to represent the distribution of drop sizes in a water mist. Reasons for this choice are that (1) the cumulative percent volume plot visually reveals the range of sizes, and (2) the volume distribution converts readily to mass distribution, which is the most relevant term for analyzing heat transfer and evaporation rates using computer modeling. Figure 16.8.8 illustrates cumulative percent volume curves, measured 3 ft (0.9 m) from the nozzle, for several nozzles used in water mist systems.[22] The weighted average CPV curves were obtained using the method described in NFPA 750.

Commercial software conforming to ASTM E799, *Standard Practice for Determining Data Criteria and Processing for Liquid Drop Size Analysis,* for particle size measurement,[57] provides output in several formats, one of which is the cumulative percent volume versus diameter curve. For comparison with other sprays, the "S" shape of the curve can be roughly

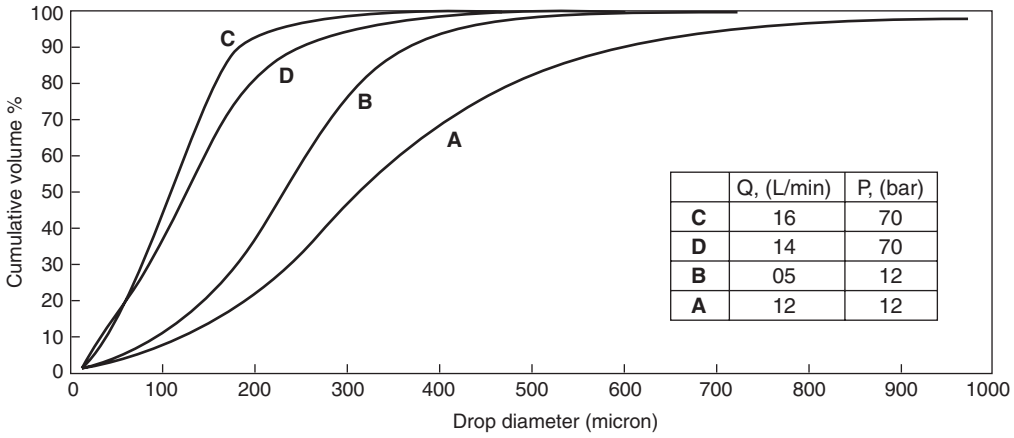

FIGURE 16.8.8 Statistically Weighted Cumulative Percent Volume Versus Drop Size Distribution Plots for Two Low-Pressure (A and B) and Two High-Pressure (C and D) Water Mist Nozzles

described using only three representative diameters: Dv0.1, Dv0.5, and Dv0.9. These parameters appear as standard output from a particle size analyzer conforming to ASTM E799. For a spray with a Dv0.9 of 400 microns, it means that "90 percent of the volume of a sample of the spray, at the sampling location, is contained in drops with diameters less than 400 microns." The cumulative percent volume distribution versus diameter curves can also be expressed as a mathematical function, which can be used in computer modeling of water spray/fire plume interactions.[42,58,59]

A method of obtaining a statistically representative measure of drop size distribution is described in the Appendix of NFPA 750. It is intended that the listing agency conduct drop size distribution measurements as part of component testing. The listing agency would then use the initial distribution readings as a baseline for ongoing checking for consistency in manufactured nozzles. The drop size distribution is measured 1 m from the nozzle, where the spray is expected to have the average properties of the spray elsewhere in the compartment. At that distance the cone is close to its maximum diameter, the entrained air has acquired a velocity, and the velocities of large- and small-diameter drops equalize.

This weighting approach, as described in NFPA 750, is necessary because individual readings may vary widely. If listing laboratories checked drop size distributions of manufacturers' nozzles annually, based on single point readings, they could see large variations that suggest changes in manufacturing quality, where in fact the variation could be due to the randomness of single point measurements. In contrast, a statistically blended curve will be more reproducible over time. Figure 16.8.8 shows statistically weighted cumulative percent volume distribution curves for two low-pressure and two high-pressure commercially available water mist nozzles.

Early research with fine water sprays was motivated by interest in using small drop sizes to enhance evaporation and heat extraction, using small volumes of water.[1,2] The research focused primarily on liquid fuel pool fires, for which the desired benefits are achievable with sprays that have most of the mass contained in drops of diameters of 400 microns or less.[48] Recent interest in using water mist for applications involving solid fuels, however, suggests that sprays with drop sizes greater than 400 microns need to be included. Drop sizes larger than 400 microns provide for fuel wetting, an important mechanism in extinguishing fires in solid fuels and charring substances. For that reason, the definition of water mist in NFPA 750 includes sprays for which 99 percent of the volume of the spray is contained in droplets less than 1000 microns in diameter ($Dv0.99 < 1000\ \mu$). Water mist systems, therefore, are applicable to a wide range of fire scenarios, including both liquid and solid fuels.

Classification of Water Sprays by Drop Size Distribution. The definition of water mist in NFPA 750 is so broad that some important differences in the qualities of sprays are disguised. It includes, for example, all water sprays used in NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection,* sprays produced by standard sprinklers operating at high pressure, and light mists suitable for greenhouse misting and HVAC humidification systems. In addition, the sprays referred to here are much coarser than what a meteorologist or physicist would view as a true mist.

The drop size distribution that will be most effective in one fire scenario will not necessarily be the best for a second scenario. There is no "one size fits all." The type of fuel (solid or liquid), the compartment dimensions, the velocity at which the mist is delivered, and the performance objective (e.g., temperature control versus extinguishment) collectively determine the most appropriate drop size distribution for a given application.

As a means of allowing distinctions to be made among coarser and finer sprays across the 1000 micron spectrum of the NFPA 750 definition of water mist, this chapter adopts a classification system that subdivides water mist into Class 1, 2, or 3 mists, according to their representative cumulative percent volume (CPV) versus diameter distribution curve (Figure 16.8.9).

This classification is introduced as a utilitarian necessity. It facilitates talking and thinking about sprays of significantly different character without referring to single-point parameters such as Sauter Mean diameter, volumetric, or numeric mean diameters. If a spray is reported as having a volumetric median diameter of 500 microns or a Sauter Mean diameter of 400 microns, the information is incomplete. Those single-point parameters do not tell us about the range of drop sizes in the spray or the steepness of the curve. Furthermore, it is difficult to say whether a 100-micron difference in volumetric mean diameter is significant in any way with respect to suppression effectiveness. The classifications of Classes 1, 2, and 3 set broad bands that describe the range of drop sizes and the relative steepness of the CPV curve. The classifications permit immediate visualization of the range of drop sizes in a spray.

The NFPA 750 committee agreed to delete reference to the spray classification system that was originally published in the Appendix of NFPA 750 in 1996 for the reason that some authorities having jurisdiction and specifying engineers imposed an interpretation on the system that Class 1 mists were superior in some way to Classes 2 and 3 mists. This misinterpretation of the meaning of spray drop size characteristics was used by some manufacturers to unjustifiably denigrate the products of their competitors. This misinterpretation of Classes 1, 2, and 3 sprays was damaging to some parties and to the promulgation of sensible engineering for water mist system design in general.

On the basis that the description of sprays as Class 1, 2, or 3 is of practical value to fire protection engineers working with water sprays, the classification system is described here. The boundaries defining the three classifications are shown in Figure 16.8.9.

A spray for which the $Dv0.9 \leq 200$ microns is a Class 1 mist, that is, $({}^{1}Dv0.9) \leq 200$. This category includes the finest water mists. In general, one expects that the fineness of a spray is obtained at the expense of mass flow rate and spray velocity. As shown in Figure 16.8.8, however, there are a number of commercial water mist nozzles that produce Class 1 sprays at the same mass flow rate as Class 3 sprays and with a higher initial velocity.[22] Class 1 sprays can be generated at low pressures or high pressures with twin-fluid, single-fluid, pressure jet, and impingement nozzles and flashing of superheated water.

Again with reference to Figure 16.8.9, the CPV curve for a Class 2 mist falls in the range $200 < ({}^{2}Dv0.9) \leq 400$ microns.

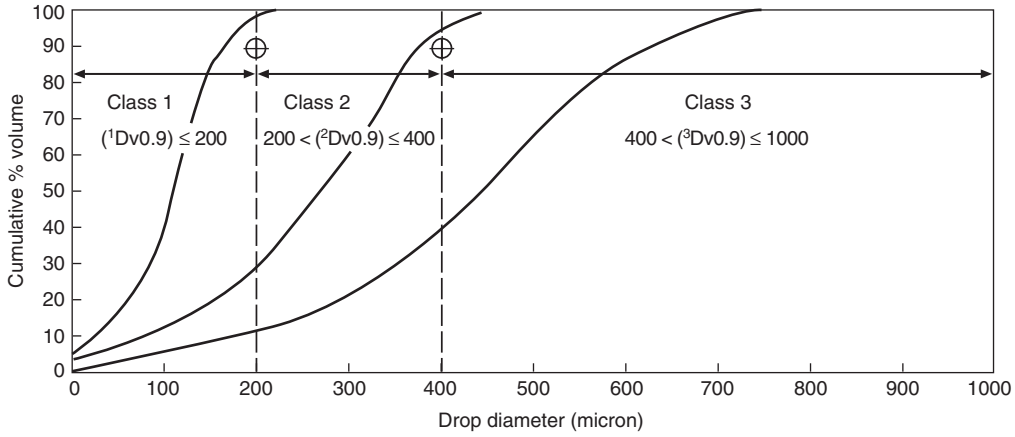

FIGURE 16.8.9 Classification of Drop Size Distributions—Classes 1, 2, and 3

Such sprays can be generated by low- and intermediate-pressure, pressure-jet nozzles; twin-fluid nozzles; and impingement nozzles.

A Class 3 mist has a CPV curve that lies in the range $400 < ({}^{3}Dv0.9) \leq 1000$ microns. Such sprays are typically generated by impingement nozzles of various sorts, including low- and intermediate-pressure, small-orifice nozzles. High mass flow rates are possible.

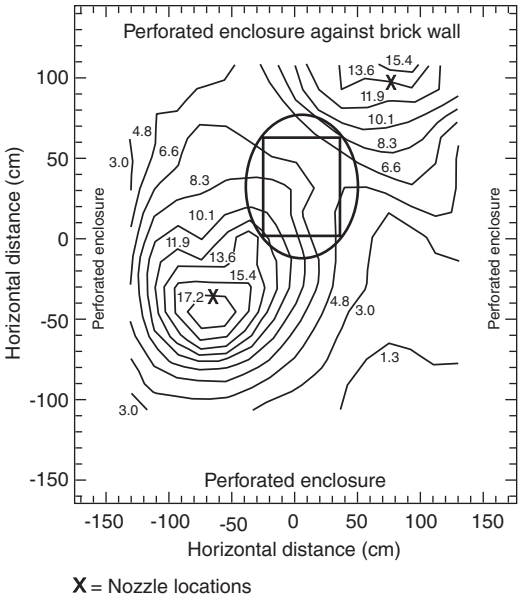
The relationship between drop size distribution and extinguishing capacity of a water mist is complex. In general, Class 1 and Class 2 mists are successful at extinguishing liquid fuel pool fires and spray fires without agitation of liquid pool surfaces. Class 3 sprays also extinguished pool fires. Class A fires can be extinguished with Class 1 mists if the velocity is high, the burning is surficial, or enclosure effects enhance the degree of oxygen reduction. This evidence confirms that drop size distribution alone does not determine the ability of a spray to extinguish a given fire. Factors such as fuel properties, enclosure effects, spray flux density, and spray velocity (momentum) are all involved in determining whether a fire will be extinguished. For this reason, NFPA 750 could not assign an optimum drop size distribution as a universal design variable for water mist systems for a specific hazard. Unlike with standard sprinklers, the flux density that successfully achieves the performance criteria of a fire test will vary depending on the drop size distribution, spray velocity, and mass flow rate of the nozzle.

Flux Density. The ability of water mist to extinguish a fire depends only partly on having the appropriate drop size and spray velocity. It also requires that the mass of water spray that interacts with the fire be sufficient to absorb a critical portion of the heat given off by the fire. Spray flux density is, therefore, an important characteristic of water mist for fire suppression systems. It can be expressed in *volume units* of gpm/ft^3 (L/min/m^3), although it is more practical to measure it as *area units* of gpm/ft^2 (L/min/m^2).

Expression of spray density in volume units is useful for the limited case of a total-flooding system in a compartment with no obstructions and nozzles with uniform distribution within their spray cones. With few exceptions, the flux density distribution of mist within a single spray cone is nonhomogeneous. When mixed with overlapping spray cones, air movement caused by the fire plume and the nozzles themselves and the deposition of mist on obstructions results in an unpredictable volume concentration of spray at any point in the compartment. It is, therefore, difficult to establish a meaningful correlation between volume concentration of mist and extinguishing effectiveness.

On the other hand, the average flux density in area units of gpm/ft^2 (L/min/m^2) can be measured easily using a grid of collection cups to measure the volume of liquid collected per unit of area per unit time. It is possible to relate success or failure to extinguish a fire to the flux density measured at that point (under nonfire conditions). It is, therefore, more useful to express flux density in area units, as a design variable, than to express it in volume units. Both representations are poor approximations of the actual flux density during extinguishment, however. That number is likely to vary dynamically with fire conditions and spray velocity and, therefore, can at best be used only as a rough design guide.

The density distributions from spray nozzles are far from uniform. Figure 16.8.10 shows an example of the flux density distribution on a plane 9.9 ft (3.0 m) below two SSC ¾ 7G5 nozzles, spaced 6.6 ft (2.0 m) apart, discharging 9.2 gpm (35 L/min) each.[60] These nozzles have been proposed for a "waterfog" system in a hydraulic equipment compartment on British (Royal Navy) submarines. At 100 psi (6.8 bar), the nozzles produce a Class 2 spray. The area covered by the spray cone at the level of collection was about 5 ft (1.5 m) square, for an area of 25 ft^2 (2.25 m^2). The nominal flux density for this array is calculated as the nozzle discharge divided by the coverage area of the spray cone at the plane of interest. In this case, the nominal flux density was 0.37 gpm/ft^2 (15.1 L/min/m^2). The measured flux density ranged from 0.42 gpm/ft^2 (17.2 L/min/m^2) directly below the nozzle, to 0.07 gpm/ft^2 (3 L/min/m^2) at the outer edge, and about 0.16 gpm/ft^2 (6.6 L/min/m^2) midway between the two nozzles. Thus, within a distance of less than 3.3 ft (1 m), the flux density distribution from these two nozzles ranged from 0.2 to 1.1 times the nominal flux density.



L/min / m²	gpm / ft²
17.2	4.2
15.4	3.8
13.6	3.3
11.9	2.9
10.1	2.5
8.3	2.0
6.6	1.6
4.8	1.2
3.0	0.7

FIGURE 16.8.10 Actual Flux Density Measured 9.9 ft (3.0 m) Below Two SSC ¾ 7G5 Nozzles, Spaced 6.6 ft (2.0 m) Apart, Discharging at a Nominal Flux Density of 0.37 gpm/ft^2 (15.1 L/min/m^2)

The extinguishing effectiveness of these two nozzles on heptane and diesel fuel pan fires varied with fire location.[60] Directly beneath the nozzles, where both flux density and spray direction (momentum) were sufficient to overpower the fire plume, all fires were extinguished in less than 10 seconds. Placed midway between the nozzles, the diesel fires took longer to extinguish, and some heptane fires were not extinguished. Midway between nozzles, the overlapping spray cones create a zone of turbulence in which spray goes in all directions. The flux density of 0.16 gpm/ft^2 (6.6 L/min/m^2) would likely have been sufficient had the spray momentum been better aimed against the fire plume. The strong heptane fire plume could rise through the mist and deflect the rest of the spray cone.[59]

These results illustrate that the extinguishing effectiveness of water mist can only be related to actual, not nominal, flux density. Many nozzles concentrate a high percentage of the water spray into the center of the cone area. This occurs because a negative pressure develops in the inner core of a hollow-cone spray, which draws droplets from the outer fringes into the center. Further distortion of actual from nominal flux densities occurs because of obstructions. Obstructions scrub water mist from suspension, drastically reducing the flux density. Obstructions also deflect the spray randomly, reducing its momentum and rendering it less effective.

Spray Momentum. The difference between success and failure of a fire suppression test can often be attributed to variations in spray *momentum.* Three factors that constitute the momentum of the spray are (1) the spray velocity, (2) its direction relative to the fire plume, and (3) the mass of the water droplets transported into the flame or onto the fuel surface. Velocity is a vector quantity, which has both magnitude and direction. The more control that can be exercised over momentum, the greater the ability to control total water requirements, time to extinguishment, water damage, and overall system reliability.

The extinguishing capacity of water mist is the result of a complex interaction of fuel properties, enclosure effects, drop size distribution, flux density, and spray momentum. Of course, the velocity cannot be too great or liquid fuels could be displaced, worsening fire conditions. The efficiency of a spray generation method is highest when the maximum amount of the spray has the desired directional properties relative to the fire plume. Control over momentum, then, depends not only on the nozzle characteristics but also on the degree to which nozzles can be strategically positioned around the fire.

One very important aspect of the selection of a mist generation method is the degree of control it allows over the directionality of the spray produced. If oriented strategically, narrow-cone-angle sprays direct more of their flow toward the fire source than wide-angle-spray cones. This was demonstrated in a series of tests conducted by NIST[61] and at NRCC, involving fires in computer cabinets.[62] The fire was located between two parallel printed circuit boards in an array of circuit boards, as illustrated in Figure 16.8.11. The fires were extinguished only when the spray direction was close to parallel to the circuit boards. A single, wide-spray-angle nozzle mounted in an open space above the circuit boards could only extinguish fires in a narrow band on either side of the vertical axis of the cone, in which the spray could enter the narrow spaces between the circuit boards.[62] As the horizontal component of the spray increased toward the edges of the array, the spray could not penetrate the space between the circuit boards. Increasing the nozzle pressure and mass flow rate did not widen the effective zone: it simply increased its depth. When the wide-angle nozzle was replaced with a series of closely spaced, narrow-spray-angle nozzles, the effective zone was widened to include the entire cabinet. By converting from a "fan-shaped" distribution of spray to a linear distribution of parallel sprays, it became possible to extinguish fires between any of the circuit boards with very little water.

The experiment described here illustrates that controlling the directionality of the spray can be more important than controlling the drop size distribution or mass flow rate. Drop size distributions can vary by 100 microns (Dv0.9) or more and be apparently equally effective. Most water supply systems deliver more water than is needed for the minimum performance of a single nozzle, so there is no penalty for being overdesigned on flow rate. There is little to be gained by designing to narrow tolerances on those parameters. On the other hand, small modifications to the direction of application of the spray can mean the difference between success or failure to extinguish.

Additives. The chemical nature of the water supplied to the nozzles influences the performance of water mist as a fire suppressant. Experiments at NRCC demonstrated that the extinguishing effectiveness of a water mist was enhanced by addition of sodium chloride to the water.[48] Mist made with seawater (2.5% by weight sodium chloride solution) extinguished diesel fuel pan fires at lower flux densities, and 40 to 50 percent faster,

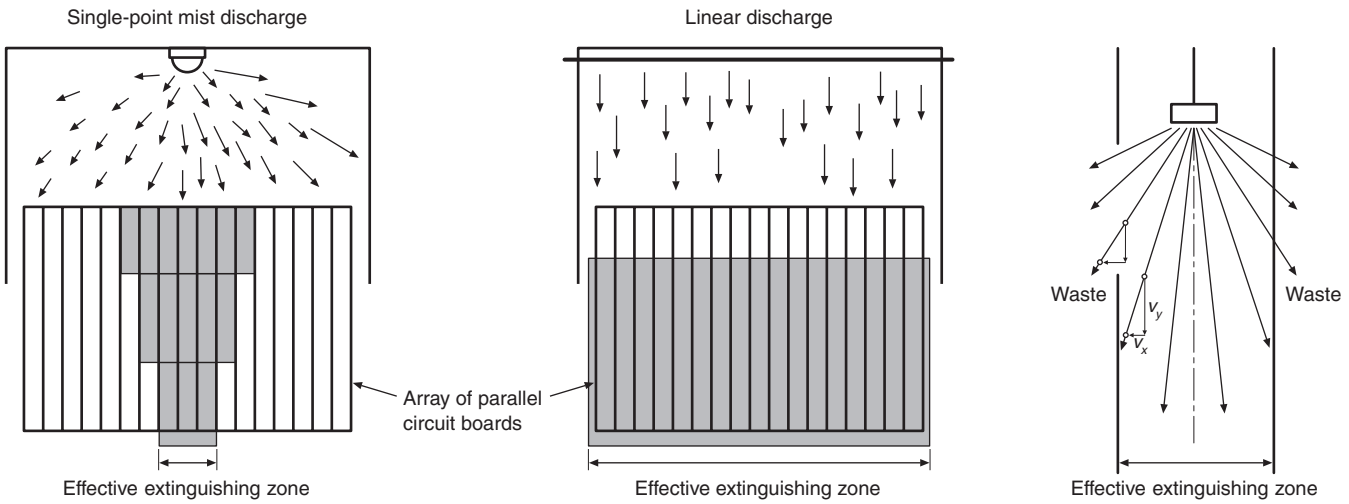


FIGURE 16.8.11 Effect of Controlling Spray Directionality or Momentum in Extinguishing Fires in Printed Circuit Boards

than mist made with fresh water. In addition, the seawater mist was less influenced by obstructions than fresh-water mist. One possible explanation for the improved performance is that dissolved alkali salts crystallize in the flame zone as drops evaporate. The salt crystals are small enough to be in the optimum effectiveness range of dry chemical extinguishing agents,[63] many of which are alkali salts. This hypothesis suggests that other alkali salts, which are better dry chemical fire suppressants than sodium chloride, could significantly improve the extinguishing effectiveness of water mist. Various products are already sold on the basis of their ability to enhance suppression effectiveness of water sprays.

The addition of a low percentage of a film-forming agent (e.g., 0.3% AFFF) greatly improves the effectiveness of water mist on hydrocarbon pool fires. This is particularly useful for suppressing spill fires in bilge areas that are sheltered from the water spray.

The chemicals that could be added to the water supply for a water mist system include antifreeze, film-forming agents, Class A or B foaming agents, surfactants, or emulsifiers to increase penetration of water into solid fuels, fire-retardant salts, biocides to prevent algae growth in stored water, and so on. The benefit provided by the additive may be offset by the introduction of secondary problems, for example, such as increased corrosivity or increased toxicity. The tolerance of equipment for increased corrosivity must be evaluated by the property owner/insurer on the basis of degree of corrosivity and the acceptable level of loss. Toxicity concerns, on the other hand, invoke government regulation. At the time of the aviation industry studies on aircraft passenger cabin water mist systems,[35] the U.S. surgeon general expressed concerns about the effects of inhalation of fine water spray on people. Those concerns were raised also by the U.S. Environmental Protection Agency (EPA) when water mist was being evaluated under the Significant New Alternatives Policy Program (SNAP) as a halon replacement. In response to the EPA concerns, the Halon Alternatives Research Committee (HARC), with the participation of the NFPA 750 committee, convened a health panel of medical experts to review data on this potential hazard.

The HARC Health Panel Report[64] concluded that water mist supplied by water, equivalent in quality to potable water (i.e., containing no additives other than those used in drinking water), or by natural seawater, poses no health risk to persons exposed to it, either under circumstances of a fire or due to nonfire actuation. The EPA found the panel's findings were credible and adopted its conclusions as the basis to a ruling. The resultant U.S. Federal Register regulation[65] recognizes that water mist systems supplied by potable water or natural seawater are "acceptable without restriction," as both a halon 1301 substitute in occupied spaces and as a streaming agent to replace halon 1211.

Water mist systems with additives are of interest for applications such as the engine compartments of vehicles and in machinery spaces. The EPA has accepted the use of water mist combined with a small percentage of a surfactant (water mist/Surfactant Blend A) for such applications in unoccupied areas.[65] Recent tests of surfactants used to improve suppression effectiveness by DuPont confirmed that their particular additive is not harmful to health.[66] Other additives, such as antifreeze, foaming agents, and fire-retardant salts, will be limited to unoccupied spaces unless the proponent provides EPA with the results of a medical peer review panel study addressing the toxicity question.

DESIGN OF WATER MIST SYSTEMS

The present level of understanding of the interaction of water mist with fire, obstructions, ventilation conditions, and compartment features is not sufficient to permit design of water mist systems by "first principles." Ideally, a first principles design would assume that there was a fixed relationship between the fire scenario, compartment geometry, ventilation, and application rate of water mist with a given drop size distribution. This relationship would hold regardless of the specific details of individual

manufacturers' equipment. Such an ideal relationship has not been established for water mist systems. There is considerable variation in the design parameters associated with the systems of different manufacturers, even when they have supposedly optimized their systems to the same fire test protocol.[67] In the absence of a large empirical database of design criteria and of a set of general principles that applies to all water mist hardware, NFPA 750 requires that all water mist system designs be linked to formal fire tests. Testing has shown that the performance of water mist systems is dependent on the specific manufacturer's equipment, particularly the nozzle design. One manufacturer might pass a fire test program at a particular flow rate and nozzle spacing. Another might operate at a lower pressure but have a higher flow rate and closer nozzle spacing to pass the same test. If one calculates the average flux density for the two systems, they may differ by a factor of three![67] Consequently, it is not yet possible to see convergence between manufacturers' systems toward generic design criteria such as a consistent nominal flux density for a particular fire scenario. The criteria are dependent on the manufacturer's choice of equipment. It appears that barely perceptible differences in atomization, spray cone angle, and velocity influence the performance of the system. The only way to be sure that a particular manufacturer's water mist system will work in a given application is to conduct fire tests with the manufacturer's equipment.

If a water mist system is listed for an application, the system design criteria and performance objectives have been validated through fire tests conducted by a recognized testing laboratory. Table 16.8.2 shows a list of fire test protocols recognized in North America and Europe. Test protocols are intended to test the limits of performance of systems against a realistic range of conditions, including worst-case scenarios, and to establish agreed-on and measurable performance objectives. Considerable thought and experience go into achieving consensus on the test scenarios. In North America, end users of water mist technology tend to rely on third-party listings by Factory Mutual Research Corporation (FM Global Research) or Underwriters Laboratories (UL) to confirm suitability. In Europe end users are likely to accept the results of ad hoc or specially designed fire testing. It is always important that the test program put sufficient effort into looking for failure conditions, limits of applicability, and breadth of criteria for judging acceptability. Ad hoc tests will be very specific to an application. There are many ad hoc water mist test efforts that form the basis of design for water mist systems. Examples include local application systems;[68] high-voltage cable tunnels; railway tunnels;[69,70] heritage properties, libraries, and archival storage on fixed shelving,[71,72] electronic equipment rooms,[73] computer room underfloor areas;[74] aircraft cargo bays;[75] and outdoor transformers.[76] Many of the ad hoc test programs have the potential to become formal or consensus test protocols.

NFPA 750 describes a number of fire test protocols in detail. It should be noted that the criteria by which systems are deemed acceptable are decided by consensus of a committee. Successful performance does not necessarily mean extinguishment of the fire. For example, the IMO tests for accommodation spaces and public spaces on ships require only that the fire be controlled for a period of 10 minutes. At the end of 10 minutes, the fire is manually extinguished and a damage assessment made. Fire extent and damage to the test materials must be within certain limits. During that 10 minutes, the fire continues to burn, and if the water mist system is shut off, the fire will regrow. The IMO machinery space protocol, on the other hand, does require extinguishment of all fires, including small, hidden bilge fires. Both FM Global Research and UL have their own versions of the original IMO machinery space tests. They have listed systems without requiring extinguishment of the smallest shielded pan fire. Unfortunately, it is not certain that the designer and the end user will understand the significance of such differences for the application at hand.

It is not advisable to rely on a generalized listing without checking that the performance promised by the listing meets the end user's actual needs. The fire protection engineer must confirm that the application is similar to the conditions of the test protocol. He or she must also check that the performance criteria used to judge pass or fail in the test protocol are compatible with the end user's needs in the actual installation. In some cases the performance requirements of the listing may be lower than what the end user really needs. Measures to upgrade performance will be required. To determine exactly what upgrade measures might be required to raise the level of performance without doing further testing the designer will have to apply first principles of fire science.

A second problem with the current approach is that a simplified test protocol can never capture the details of all possible field conditions. For example, the IMO Machinery Space test compartment contains only a mockup of a large engine; it does not contain any of the ducts, cable trays, and overhead piping that may clutter a real machinery space. Yet the design spacing determined in the mockup is applied rigorously in all applications. Furthermore, the manufacturers may be able to fine-tune their systems to meet the narrow performance criteria of the test protocol. The tolerance for differences between the test arrangement and real spaces is not known. Rather than achieving better performance through more efficient mist nozzles, we may simply be peeling away the safety margin. Once installed in a real machinery compartment with more overhead clutter or different ventilation opening than the test setup, one manufacturer's system may be within a hair's breadth of losing control. Another manufacturer's system may be more tolerant of variances. It would be reassuring if we were not so entirely dependent on the formalized "design by fire testing" approach.

METHODS OF GENERATING WATER MIST

Methods to generate water mist range from simple to elaborate. Some of the more elaborate methods include high-speed spinning discs, ultrasonic vibrations, flashing and recondensation of superheated liquids, rapid release of dissolved gases, and explosives. For fire suppression purposes, the choice of method is narrowed by the fact that the mass flow rates and velocities needed to be effective are beyond the capacity of some methods. The methods that are practical for fire suppression systems are those that break up water into drops smaller than 1000 microns at mass flow rates and spray velocities

appropriate for full-scale fire scenarios, which can be protected against plugging and which reliably sustain that flow as long as required. The economics of providing the stored energy, or installing special pumps and piping systems, are also determinants in selection of a mist-generating technology for a given application.

Water mist nozzle designs involve one of three basic principles: (1) impingement of a jet of water on a deflector (impingement), (2) expulsion of a high-velocity jet from an orifice (pressure jet), or (3) use of compressed air or nitrogen to shear water into fine spray (twin-fluid or air-atomizing nozzles). All three methods have been used by manufacturers of spray nozzles. The innovations being made by manufacturers interested in fire suppression are intended to improve efficiency or to optimize some spray characteristics such as mass flow rate, spray velocity, drop size, or cone shape. NFPA 750 distinguishes among the pressure regimes at which mist-generating technologies operate by introducing terms for low-, intermediate-, and high-pressure systems. Low-pressure systems operate at pressures of 175 psi (12 bar) or less; intermediate-pressure systems involve pressures greater than 175 psi (12 bar) but less than 500 psi (34 bar); and high-pressure systems operate at pressures of 500 psi (34 bar) or greater. The operating range of low-pressure systems is similar to standard fire protection systems, such as sprinklers and standpipes. The requirements for pipe, fittings, valves, pumps, or hydraulic calculations can be met by conventional materials and installation practices. Pipe, fittings, and valves for intermediate-pressure systems are also commonly available, although there may be no listed centrifugal fire pumps that produce pressures in the range of 500 psi (34 bar). Therefore, there are some aspects of intermediate-pressure systems that lie outside of standard fire protection engineering experience. Special requirements are invoked with high-pressure systems for pipe, fittings, pumps, valves, pressure regulators, cylinders, and tanks. The technology of high-pressure systems, although new to fire protection engineering practice, is well developed in other industries, such as the hydraulics and offshore petroleum drilling industries.

The method of generating mist does not uniquely determine suppression capability. Matching the spray characteristics of drop size distribution, flux density, and spray momentum to the fire hazard is more important. The choice of mist-generating method does influence factors such as the cost-effectiveness and reliability of a system.

Impingement Nozzles

Impingement nozzles operate on the principle of a solid jet of water striking a deflector and breaking up into small drops. They include standard sprinklers, nozzles used in traditional (see NFPA 15) water spray and deluge systems, and nozzles used for a myriad of industrial applications. The jet velocity and the shape of the impingement surface determine the cone angle, drop size distribution, flux uniformity, and spray momentum. Figure 16.8.12 shows several types of impingement-style nozzles used in water mist systems.

Impingement nozzles operating at low pressures are simple in design and, therefore, cost less to construct than nozzles that require more precise machining. In 1992, NRCC[77] measured the

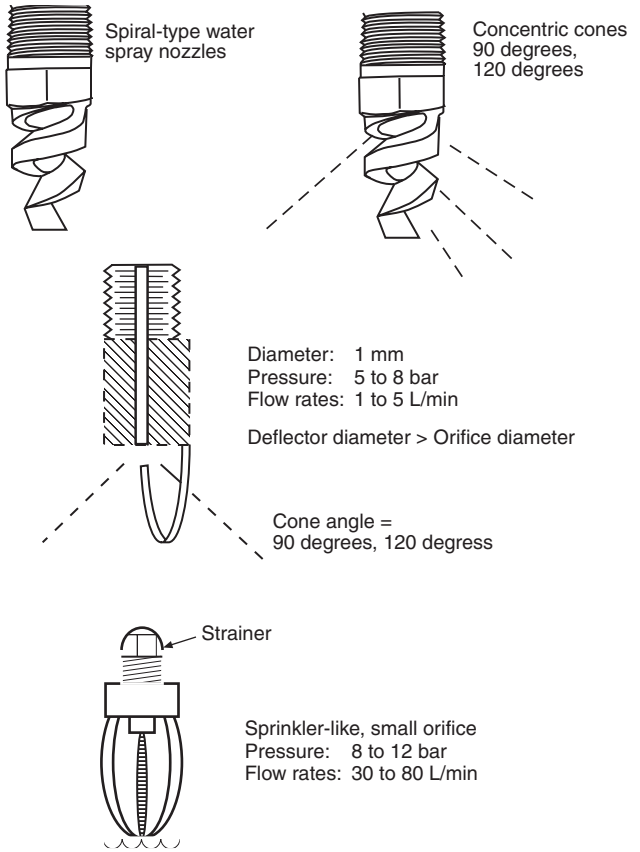

FIGURE 16.8.12 Several Types of Impingement Nozzles for Fine Sprays

spray characteristics of several commercially available impingement nozzles, including sprinkler-type deflector plates, spiral deflectors, and pin-type deflectors, operating at pressures less than 175 psi (12 bar). These nozzles produced Classes 2 and 3 sprays, with cone angles between 60 degrees and 120 degrees. The size and shape of the deflector determined the cone angle. The tests revealed that impingement nozzles have a limited axial spray projection distance because of the energy lost as the jet strikes the deflector. A slight tilt in the deflector plate will skew the spray distribution in one direction. Deflector supports can cause shadow effects, and irregularities in the impingement surface can magnify to large variation in the spray distribution patterns. These sprays controlled or extinguished fires, not only with Class A combustibles, but also in liquid fuel fires in enclosures, where enclosure effects made spray momentum less critical. Overall, the reduced forward spray momentum and irregular flux distribution, which were typical of the impingement nozzles tested, were limitations on their potential use in a water mist system for large machinery spaces.

The relationship between nozzle pressure and discharge rate for impingement nozzles is reliably calculated using the expression familiar to sprinkler system designers: where q is the discharge rate, P is the gauge pressure at the orifice, and k is a coefficient characterizing the nozzle.

Impinging Jets

The term *impinging jets* is used to describe a type of water mist nozzle that creates mist by forcing two thin jets of water to collide after exiting the orifice. Machining of the very small orifices must be very accurate to achieve correct alignment for collision of the jets. A German company has an impinging jet that creates a Class 2 mist at approximately 5 L/min at 175 psi (12 bar) operating pressure. It is an intermediate-pressure nozzle. The nozzle is used in turbine enclosure systems. It was tested in a cable tunnel fire scenario in New Zealand and performed very well.[25]

Pressure Jet Nozzles

Pressure jet nozzles work by pushing a jet of water through a relatively small-diameter orifice at a high velocity. As the jet leaves the orifice, complex physical events occur, involving the fluid viscosity and the jet diameter and velocity relative to the air.[58] The breakup of the thin jet of water into droplets begins within a few millimeters of the orifice. Figure 16.8.13 illustrates several pressure jet nozzles. The disintegration of the jet into droplets can be enhanced by inserting swirl devices in a chamber inside the nozzle to impart a rotation to the jet as it emerges from the orifice. If water is pushed through a narrow slot instead of a circular orifice, the jet takes the form of a sheet, which becomes unstable and disintegrates into droplets.

Individual pressure jet orifices can be assembled in groups on a single base or at intervals along a pipe (linear arrangement). Where several pressure jets are assembled in close proximity on a single base, the combined effect of all jets entrains air into the composite spray cone. The diameter of the fully developed composite cone is not a simple function of initial jet velocity and direction. The trajectory of drops from the individual jets is influenced by the pressure regime within the spray cone, which depends on the manner in which air is drawn toward the nozzle and entrained into the cone. With some nozzles, the spray cone may not become fully developed if free air movement to the back of the nozzle is restricted.

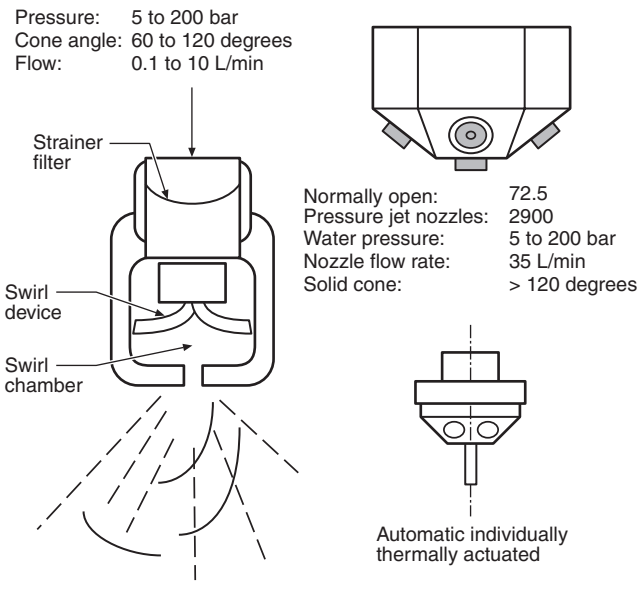

FIGURE 16.8.13 Pressure Jet Nozzles

Pressure jet nozzles operate over a wide range of pressures from 75 to 4000 psi (12 to 272 bar). Pressure jet nozzles require higher operating pressures than impingement nozzles. Up to a limit, the drop size distribution becomes finer as pressure increases. Often there is an upper limit, at which further increase in pressure has little effect on the drop size distribution. There may be incremental increase in mass flow rate or momentum but with no significant improvement in the coverage area of the spray cone. The listing agency will provide information about the operating pressure range needed to produce the desired spray qualities.

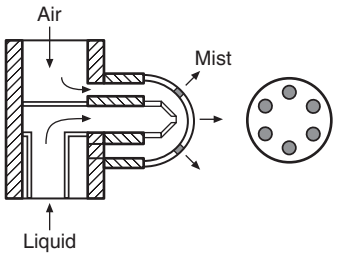
The relationship between pressure and flow from multiorifice pressure jet nozzles follows the simple formula used for single-orifice nozzles, such as sprinklers. Again, the listing agency must provide information on how to calculate discharge rates as a function of pressure from pressure jet nozzles.

Twin-Fluid Nozzles

Twin-fluid nozzles are also referred to as air-atomizing nozzles. They combine compressed gas with a water stream to shear the water into fine droplets. The resulting mist can be directed through one or more orifices to shape a conical spray of any desired cone angle. Twin-fluid nozzles allow for efficient control over drop size distribution, cone angle, spray momentum, and discharge rate. Nozzle manufacturers have produced twin-fluid nozzles for a wide variety of industrial applications, including spray painting, agricultural spraying, and humidification systems. One company markets a twin-fluid nozzle based on a design developed by British Petroleum (BP) Ventures in the 1980s. This nozzle operates with compressed gas and water pressures in the 65- to 90-psi (4.5- to 6.2-bar) range. For fire protection systems (which may require many nozzles), it is an advantage to minimize the total required flow rate of compressed gas. Although typical industrial twin-fluid nozzles operate at air-to-liquid mass ratios (ALR mass) of 0.20 or greater, this particular water mist nozzle operates with ALR mass values of 0.05 to 0.10. Figure 16.8.14 illustrates the mixing arrangement for two types of twin-fluid nozzles.

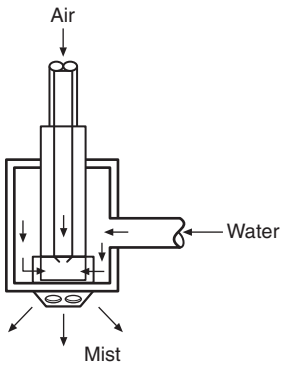
The relationship between water discharge and atomizing medium (air) discharge from a twin-fluid nozzle cannot be characterized by the expression used for simple orifice nozzles. Because the air and water lines are joined (inside the nozzle), the pressure in one line works against the pressure in the other line. As air pressure increases, the airflow increases, which, in turn, forces a reduction in the waterflow and modifies the water system pressure. Conversely, if the water pressure is increased, it reduces the airflow.

Figure 16.8.15 shows a plot of atomizing medium and waterflow rates for a commercial twin-fluid nozzle. The term *air to liquid ratio* (ALR) is used to describe the balance of atomizing medium and liquid demand across the nozzle. To adjust a system in the field and to determine air and water discharge rates from manufacturers' data sheets, it is convenient to use the air-to-liquid pressure ratio, ALR_p. For comparing



Typical commercial air atomizing nozzle

Cone angle:	72 degrees
Nozzle flow rate:	5.3 gpm
Air/liquid ratio (mass):	0.27
Water pressure:	65 psi
Air pressure:	75 psi



Securiplex

Cone angle:	90 degrees, 120 degrees
Nozzle flow rate:	5 to 25 L/min
Air/liquid ratio (mass):	0.10
Water pressure:	4 to 5 bar
Air pressure:	5 to 7 bar

FIGURE 16.8.14 Two Designs for Twin-Fluid Nozzles

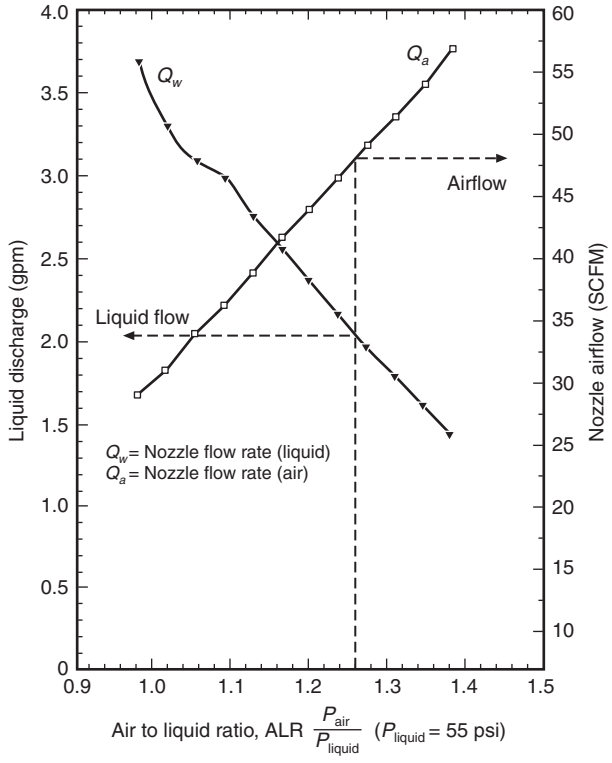


FIGURE 16.8.15 Air- and Waterflow Rates in Twin-Fluid Nozzles

the efficiencies of different nozzles and performing pneumatic system calculations to determine pipe sizes, pressure regulator settings, and the total quantity of compressed gas required for a system, it is better to work with an air-to-liquid ratio expressed in terms of mass flow rates, ALR_m. It is interesting to note that FM Global Loss Prevention Data Sheet 4-2, Water Mist Systems,[74] simply recommends calculating the pneumatic and the hydraulic piping separately to show that the nominal required flow can be delivered at an acceptable minimum pressure. The approach is simpler than the method described previously, and for some types of nozzles it may be sufficiently accurate for practical purposes. A functional discharge test of the installed system will be needed, however, as a final check on the system design.

$$ALR_p = \frac{P_a}{P_w} \qquad ALR_m = \frac{M_a}{M_w}$$

where

ALR_p = Air-to-liquid pressure ratio

ALR_m = Air-to-liquid mass ratio

P_a = Air pressure, gauge, psi (bar)

M_a = Mass of air per unit time, lb/min (kg/sec)

P_w = Water pressure, gauge, psi (bar)

M_w = Mass of water per unit time, lb/min (kg/sec)

The nozzle manufacturer should identify the range of air-to-liquid ratios (pressure and mass) over which the nozzle achieves the optimum spray characteristics. The total compressed gas demand of many nozzles in an open-nozzle system can be costly, so it is desirable to minimize the demand for atomizing medium. An efficient operating point for a twin-fluid nozzle is one that produces the desired spray characteristics at as low an ALR_m as possible (e.g., between 0.05 and 0.10).

Innovations in Mist Generation

The term *innovation* as used here applies to nozzles that incorporate unusual features to improve efficiency or to optimize some characteristic of the spray or that produce spray by a different physical mechanism than those described previously.

Combined Nitrogen and Water Discharge. One company has developed a two-stroke piston pump unit that is driven by compressed nitrogen. It has advantages for applications where electrical power for pumps may be unavailable. It is referred to as a GPU unit and has been listed for machinery spaces, turbine enclosures, and light hazard applications. At each stroke of the piston pump, either water or nitrogen gas is pushed into the piping. It is not clear how to do hydraulic calculations for a distribution system using this system. As the unit discharges air or nitrogen gas in one stroke and water on the next stroke, the flow of mixed gas and water in the piping system has unknown properties with respect to friction loss.

It may be undesirable to use the GPU system for nozzles at different elevations, as the balance of gas and water delivered from the nozzles is unpredictable. It is recommended to conduct a full discharge test of the system to ensure that the quantity of compressed gas is sufficient for the required duration of protection.

Linear Sprays. Water mist is usually delivered from nozzles with a 360° circular spray cone. Nozzles are distributed in a grid at ceiling level. This delivery pattern is typical of sprinkler systems and is suitable for most applications. Some applications, however, require that water mist be delivered to protect a well-defined geometry. Spray that is discharged in any direction other than that dictated by the fuel arrangement would be wasted. Fixed shelving in rows, cable trays, or electronic cabinets with parallel circuit boards are examples of applications in which circular distribution patterns lead to inefficient application of water. Placing small pressure jet orifices at close intervals along a tube creates a linear spray. The nozzle then is actually a length of tube with discharge orifices spaced along its entire length. The K-factor for such an elongated nozzle is different than for a conventional nozzle with orifices situated around a circular metal base. The discharge characteristic of a linear system is a function of the flow rate per orifice, the number of orifices per meter, the total length of each line, and whether water is supplied from one end or both ends.

Flashing of Superheated Water. The "flashing of superheated liquid" phenomenon is usually associated with gaseous fire suppression agents, but it occurs with water as well. A superheated liquid is one that is maintained by pressure in its liquid state at a temperature above its boiling point. When released suddenly from the pressurized container, the liquid partly flashes to vapor and partly disintegrates into spray by the shearing effect of rapidly expanding bubbles.[78–80] The pressure in the closed container is determined by the vapor pressure of the liquid at the given temperature. For water, standard steam tables indicate that at 348°F (176°C) the gauge pressure inside the container will be 118 psi (8 bar). This self-generated pressure is enough to discharge the water from the cylinder. The storage cylinder can be further pressurized by addition of compressed nitrogen, if necessary.

Once released to atmospheric pressure through a simple orifice, superheated water boils instantaneously. Tiny gas bubbles form, expand, and then explode in a powerful release of energy that fractures still-liquid water to small droplets. The rapid release of energy propels the mist throughout the compartment. The percentage of the water that flashes to vapor can be estimated from standard steam tables and could be as high as 14 percent at 348°F (176°C). The flashed water vapor promptly cools and condenses, forming an opaque fog of aerosol-sized (20 micron) water drops. These ultra-fine drops are the result of condensation, not the physical breakup of liquid water by mechanical energy. Within the cloud of white fog, the portion of the liquid that does not flash to vapor is distributed as a "rainout" of Class 1 mist ($^1Dv0.9 \leq$ 200 microns).[62,80]

The rapid generation of mist by the flashing process has been demonstrated to be effective in quenching dust explosions. For hydrocarbon pool fires in enclosures, tests conducted at NRCC[62] showed that the spray was no more effective than other Class 1 sprays. Research into the possible application of this technology continues.

Nano-Mist[81] is an ultra-fine mist with very uniform drop size distribution with a volumetric mean droplet diameter in the 10 micron range. The technology combines an ultrasonic transducer assembly and a process technology for aerosolization, extraction, and transport of mist. The throughput capacity of the mist generator is in the range of 0.25 Lpm (0.06 gpm). The opaque cloud of low-momentum mist can achieve suspended mass of water droplets in excess of 240 g/m^3 (0.015 lb/ft^3). No conventional water mist nozzle approaches that level of suspended water droplets. The Nano-Mist can be transported through smooth ducts to confined areas. In a series of tests conducted for the U.S. Navy to develop a hybrid system (nitrogen plus water mist),[82] Nano-Mist was tested in a mock computer-room subfloor (false deck) against telltale fires.[81] Various combinations of inert gas (nitrogen) and water mist were used to extinguish the test fires. The concentration of nitrogen needed to inert the space and extinguish the fires was first determined. Then water mist was added to the nitrogen. The water mist reduced the concentration of nitrogen needed to extinguish the fires by as much as 40 percent.[83] However, water mist itself could not extinguish the concealed fires in the subfloor. The Nano-Mist, however, was able to extinguish the telltale fires itself without addition of any nitrogen.

The Nano-Mist technology appears to be able to achieve the suspended mass of water droplets needed to bring about extinguishment of hydrocarbon fires if it can be delivered to the seat of the fire. As it is a low-momentum mist, it needs to be transported to the flame region by controlled air movement. Research and development work continues, seeking to increase the rate of generation of the mist to flow rates needed for large spaces, to improve the means of transporting the cloud to the flame area, and to reduce the cost of the ultrasonic generators.

Automatic, Nonautomatic, and Hybrid Nozzles

NFPA 750 introduces the terms *automatic, nonautomatic,* and *hybrid nozzles* to distinguish among three types of nozzles that are already on the market.

Automatic Nozzles. Automatic nozzles operate independently of other nozzles by means of a detection/activation device built into each nozzle. A heat-activated link or bulb is built into the nozzle that, when exposed to heat, releases and allows discharge from that single nozzle in exactly the same manner as a sprinkler. Automatic water mist nozzles use fast-response glass bulb elements, some of 2.5 mm diameter or less. The temperature ratings of the automatic nozzles are selected according to the

application. Automatic water mist nozzles may also be referred to as "water mist sprinklers," as they are used in exactly the same manner as standard sprinklers.

Nonautomatic Nozzles. Nonautomatic nozzles are open nozzles used in deluge-type systems. Water mist systems intended for total compartment flooding are designed to discharge mist from all nozzles in the compartment. A separate detection system is required to detect the fire and release the system. Some local application systems in marine machinery space systems are permitted to be released manually. Once the main control valve is opened, water discharges from all nozzles. Nonautomatic nozzles for use in machinery spaces or aggressive environments are often equipped with blow-off caps to keep moisture and grime from getting into the nozzle orifices and piping. Release of water into the piping system creates enough force to dislodge the blow-off caps, allowing water to discharge freely.

Hybrid Nozzles. The term *hybrid nozzle* was introduced in NFPA 750 to recognize nozzles that were designed with a thermal element so that they would release if exposed to fire in the same manner as an automatic nozzle but which could also be released by a signal from a separate detection system. Hybrid nozzle hardware was developed for experimental work in the 1990s but has not been commercialized or undergone formal component testing associated with the official fire test protocols. It should be noted that the means of generation of Nano-Mist does not involve a nozzle as defined by NFPA 750. The ultrasonic generator, chamber, and associated delivery tubing might be viewed as a hybrid conception.

Choice of Mist-Generation Method

Full-scale fire testing has shown that it is not possible to say categorically that one mist-generation method is better than another with respect to fire suppression. Manufacturers working in different pressure ranges and employing different nozzle designs have all passed the IMO and FM Global Research machinery space and turbine enclosure tests. In general it can be stated that there is a tendency to favor higher rather than lower operating pressures. Nozzles that were at one time thought of as low-pressure nozzles require 185 psi (12.8 bar) minimum nozzle pressure. This means that the normal system operating pressure will be at a higher pressure, putting the system functionally in the intermediate-pressure range (12 to 34 bar). Only the twin-fluid system operates entirely in the low-pressure range for water pressure—the compressed gas provides the additional energy needed to produce a suitable spray. For manufacturers, the choice of mist-generation method for their product line is largely dictated by availability of unpatented technology and the ability to be cost competitive. The designer of water mist systems should be free to choose a mist-generation method according to the engineering merits and the cost of each.

Ultimately the best choice of mist-generation method will be determined by the following:

- Evidence of acceptable performance in a recognized fire test protocol relevant to the application
- Number of nozzles required at the manufacturer's spacing, hence, pipe and fitting materials and labor costs
- Total water demand—storage requirements, potential water damage, and environmental regulations for water retention
- Pump details—suction supply, pump capacity, power requirements, and emergency backup power
- Reliability considerations taking into account the ability to maintain water supply quality, compressed gas cylinder management, electrical circuit supervision, details of specific equipment, and degree of effort involved in scheduled maintenance tasks
- Cost

Reliability Considerations

Water mist systems incorporate a number of features that traditionally have been avoided in water-based fire protection systems. The use of small orifices increases the risk of nozzle plugging. The use of higher operating pressures than traditional sprinkler or water spray systems increases the risk of piping system failure. Control systems rely on electrical release of solenoid valves on compressed gas cylinders or on sectional control valves—a failure of the electrical control circuit will cause failure of the entire system. The use of positive displacement pumps to meet a variable system demand involves programming control logic in a programmable controller. Design procedures to calculate the correct storage volumes of compressed gas and water to deliver water to the nozzles at the specified pressure for the minimum discharge duration have not been fully developed. Design criteria for such systems are based on empirical testing. The use of multiple small storage reservoirs of water instead of a single large tank introduces concerns about maintaining the quality of stored water. The features unique to water mist systems introduce many potential failure modes. Measures must be taken in the design process and in ongoing maintenance to counter each identified failure possibility. Table 16.8.3 tabulates recommended countermeasures to improve system reliability.

DESIGN CALCULATIONS FOR WATER MIST SYSTEMS

Calculation Fundamentals

The calculation procedures for water mist systems range from fundamental methods for single-fluid, low-pressure systems to somewhat more complex methods for twin-fluid and high-pressure systems.

As for any engineered hydraulic system, the designer must select pipe sizes, confirm flows and pressures at discharge points, and determine total flow and pressure requirements for the system in order to select pumps and size storage reservoirs. Such calculations are done routinely for sprinkler systems and water spray systems. Water mist systems introduce problems

TABLE 16.8.3 Potential Failure Concerns and Suggested Countermeasures to Improve Reliability in Water Mist Systems

Potential Failure Concern	*Suggested Countermeasures to Improve Reliability*
Plugging of small orifices in nozzles and small-diameter passages in valves	• Set water quality standards = potable water. • Require screens or filters or both on inlet to storage tanks and on the outlet if algae growth could occur. • Treat stored water to prevent bacterial activity—either chlorination or bromination of UV light. Avoid chlorination where stainless steel tubing is used. • Provide screens on each individual nozzle. • Use corrosion resistant liners in water storage vessels. • Monitor water quality quarterly as part of regular maintenance. Drain and refill stored water cylinders semiannually. • Use corrosion-resistant pipe and fittings; mandate cleaning and flushing measures as installation practice and acceptance testing. • Use blow-off caps to prevent external grime from getting into open nozzles.
Start-up problems with positive displacement (PD) pumps (overcurrent trip)	• Modify NFPA 20 to specify controller design appropriate for PD pumps. • Conform to NFPA 20 with respect to duplicate power supplies and overcurrent protection.
Normally closed valves: Failure of electrical solenoid valves to release compressed gas or open sectional control valves	• Mandate emergency backup power supplies, apply process industry reliability standards, and ensure component testing as part of listing. • Duplicate release capability with hydraulic or pneumatic and manual release features. • Perform regular maintenance to check functionality of solenoid valves.
Normally open valves: Failure to identify a closed valve due to use of nonindicating type valves.	• Mandate use of open/closed indicators on all control valves. • Develop supervisory circuits and scheduled maintenance tasks to confirm water supply valves are open.
Inadequate capacity of stored gas to sustain discharge for the minimum duration	• Mandate calculation procedures to determine required capacity of compressed gas. • Confirm capacity of gas storage vessels by discharge test through system piping or test orifice with equivalent K-factor.
Accident while handling compressed gas cylinders	• Mandate safe handling and storage practices for compressed gas cylinders. • Secure support frames; provide minimum width of access aisle.
Loss of pressure in compressed gas cylinders due to slow leak	• Mandate electrical supervision of gas pressurized piping. • Mandate microleakage control on cylinder headers.
Failure of pressure regulator	• Require component testing of regulators and control valves as part of listing.
Install incorrect size of replacement cylinder	• Post specifications for all replacement cylinders on support rack.
Failure of stored water supply due to: — error in design calculation — loss of water from tank — deterioration in quality (algae growth) — tank corrosion	• Confirm correct capacity of water storage vessels by full discharge test through system piping or test orifice with equivalent K-factor. • Provide duplicate capacity of stored water. • Mandate supervision of water level or visual indicators. • Establish monthly, semiannual, and annual maintenance procedures to monitor water quality.
Failure of detection system for deluge and preaction systems	• Confirm functionality of all detectors, control panel, and interlocks at acceptance test.
Failure of interlocks to shut down ventilation and operate other ancillary devices	• Design and commission detection system to NFPA 72 and conduct regular maintenance as per industry standards.

that are not commonly encountered in calculations for sprinkler systems, however. For example, high-pressure systems may involve positive displacement pumps or stored pressure reservoirs with continuously declining pressure during the discharge. Twin-fluid systems involve the use of pressure-regulating and solenoid valves on both liquid and compressed gas lines. This section reviews some of the special calculation problems encountered in design of water mist systems.

Calculations Involving the Hazen-Williams Equation

NFPA 750 defines a low-pressure water mist system as one that operates at 175 psi (11.9 bar) or less. The operating range of low-pressure systems is similar to standard fire protection systems, such as sprinklers (see NFPA 13, *Standard for the Installation of Sprinkler Systems*), standpipes (see NFPA 14, *Standard for the Installation of Standpipe and Hose Systems*), and water spray systems (see NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection*). The requirements for pipe, fittings, valves, pumps, and hydraulic calculations, then, can be met by conventional materials and design practices. Based on this assumed similarity with sprinkler piping, NFPA 750 accepts the use of the Hazen-Williams equation to calculate pressure losses in piping provided that fluid velocity never exceeds 25 ft/sec (7.6 m/sec) (Table 16.8.4).

Values of the friction loss coefficient, *C,* used in the Hazen-Williams equation, are accurate only if the flow velocity is close to that at which the value of *C* was measured.[84] It is a matter of judgment as to what velocity is "too high" for the Hazen-Williams equation. American Water Works Association (AWWA) data, quoted in Titus,[84] list *C* factors measured at a velocity of 3 ft/sec (0.9 m/sec), yet it is standard practice in sprinkler calculations to accept velocities in sprinkler piping between 10 and 20 ft/sec (3.05 and 6.1 m/sec). Similarly, the tables of equivalent lengths for fittings and valves, used by sprinkler system designers, are based on fittings and valve types typical of sprinkler systems. Water mist systems may incorporate different types of fittings and valves, for which the Hazen-Williams–based equivalent length values commonly accepted for sprinkler piping will be incorrect.

Calculations Involving the Darcy-Weisbach Equation

The Hazen-Williams (H-W) equation contains no terms that allow one to change the temperature, density, or viscosity of the liquid. It assumes that the water contains no additives and is close to 60°F (15.6°C). The Darcy-Weisbach (D-W) equation does allow for variation in fluid properties, and for that reason it is widely used by mechanical engineers designing fluid systems.

TABLE 16.8.4 Hazen-Williams Equation for Calculation of Pressure Loss Due to Friction

U.S. Customary Units	*SI Units*
$p = \frac{4.52\,Q^{1.85}}{C^{1.85}d^{4.87}}$	$p_m = 6.05\left(\frac{Q_m^{1.85}}{C^{1.85}d_m^{4.87}}\right)10^5$
p = Frictional resistance, psi per foot of pipe	p_m = Friction resistance, bars per m of pipe
Q = Flow, gpm	Q_m = Flow, L/min
C = Friction loss coefficient	C = Friction loss coefficient
d = Actual internal diameter, in.	d_m = Actual internal diameter, mm

It also allows input of more detail to account for differences in pipe materials from standard sprinkler pipe and fittings. For water mist systems, if viscosity or water temperature departs significantly from typical sprinkler system water supply conditions, the Darcy-Weisbach equation should be used. NFPA 750 requires the use of D-W equation if fluid velocity exceeds 25 ft/sec (7.6 m/sec). The limiting velocity was selected after review of calculations comparing the agreement between H-W and D-W calculations and measured head losses in 1- to 3-in. (25- to 80-mm) diameter black steel pipe, over a range of velocities.[85] Table 16.8.5 shows the Darcy-Weisbach and related equations for use in calculating friction loss in pipe and tubing.

Most of the parameters in the Darcy-Weisbach equation will be known by the designer, such as the diameters and lengths of pipe (including equivalent lengths for fittings) and the density of the fluid. Density may vary according to water source (seawater or potable water) and the possible presence of additives such as wetting agents, fire retardant salts, or antifreeze. The flow rates (Q) will be determined by the nozzle characteristics, such as the K-factor. The unknown value f (friction factor) must be derived through a three-step process as follows:

1. Equation 2 in Table 16.8.5 is used to calculate the Reynolds number (Re).
2. Equation 3 in Table 16.8.5 is used to calculate the relative roughness factor

TABLE 16.8.5 Darcy-Weisbach and Associated Equations for Pressure Loss in Piping

U.S. Customary Units	*SI Units*
Darcy-Weisbach Equation: $\Delta p = 0.000216\,\frac{fL\rho Q^2}{d^5}$	Darcy-Weisbach Equation: $\Delta p_m = 2.252\,\frac{fL_m\rho_m Q_m^2}{d_m^5}$
Reynolds Number: $\mathrm{Re} = 50.6\,\frac{Q\rho}{d\mu}$	Reynolds Number: $\mathrm{Re} = 21.22\,\frac{Q_m\rho_m}{d_m\mu}$
Relative Roughness: $\textit{Relative roughness} = \frac{\varepsilon}{D}$	Relative Roughness: $\textit{Relative roughness} = \frac{\varepsilon_m}{d_m}$
Δp = Frictional loss, psi gauge	Δp_m = Frictional loss, bars gauge
f = Friction factor, psi/ft	f = Friction factor, bars/m

ρ = Weight density of fluid, lb/ft^3	μ = Absolute (dynamic) viscosity, centipoise (cP)
Q = Flow, gpm	Q = Flow, L/min
d = Internal pipe diameter, in.	d_m = Internal pipe diameter, mm
ε = Pipe wall roughness, ft	ρ = Weight density of fluid, kg/m^3
D = Internal pipe diameter, ft	ε = Pipe wall roughness, mm
μ = Absolute (dynamic) viscosity, centipoise (cP)	

3. The Moody diagram (Figure 16.8.16) is used to obtain a value for the friction factor

Tables 16.8.6 and 16.8.7 provide values of water density dynamic viscosity and absolute roughness for use in solving equations 2 and 3. Once the Reynolds number and the relative roughness are determined, the values are located in the Moody diagram (see Figure 16.8.16). The intersection point for the Re and values is located on the diagram. A horizontal line is projected from the intersection point to the left axis of the Moody diagram, which provides a value for the friction factor

The value of f and other known parameters are then used in the equation in Table 16.8.5 to calculate a total pressure loss over each length of pipe. The value of f changes as flow quantities accumulate along the pipe length and as pipe diameters change across the system. From this point on the hydraulic calculation procedures are comparable to standard sprinkler calculations—discharges and pressure losses are accumulated over the entire piping network to provide an estimate of the total waterflow rate and pressure required at the water source (pump). Computerized calculation procedures based on the Darcy-Weisbach equations are available.

The equivalent length tables available in many NFPA standards are based on the Hazen-Williams equation and should be checked before being used with the Darcy-Weisbach equation. The head losses incurred across valves and fittings not found in standard tables may be calculated using resistance coefficients (K) and equivalent lengths and flow coefficients, C_v.[86] Valve manufacturers should provide C_v values with data sheets on their valves.

Calculations for Declining Pressure Systems

Systems that utilize stored energy from compressed gas cylinders will operate in one of two ways. Low-pressure systems use a pressure regulator to sustain a constant pressure in the system 7piping. High-pressure systems do not regulate the pressure—all the gas is directed into the piping system, which instantly sees a high pressure that then decays steadily. In either case, the driving pressure in the compressed gas cylinders decreases throughout the discharge. The end of discharge is determined when the compressed gas can no longer deliver the minimum pressure to meet the minimum design flow condition.

For single-fluid systems, calculations to determine pipe sizing are the same as for any constant-pressure system. The engineering question of greater interest is how to determine the number of compressed gas cylinders needed to meet the flow/pressure/duration requirements of the water mist system. For the most part, systems utilizing compressed gas as a driving force are preengineered systems. The manufacturer has determined in

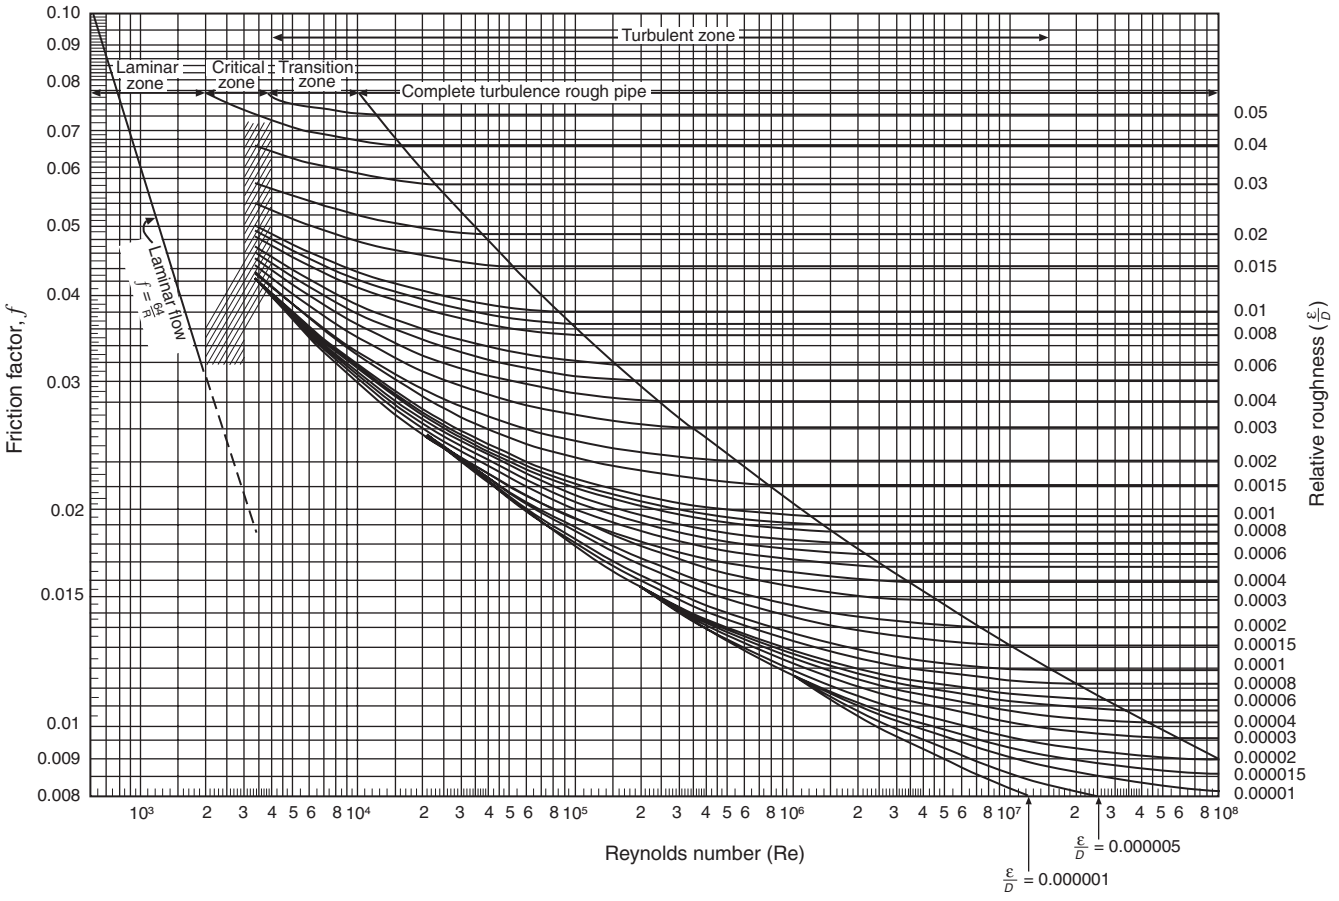

FIGURE 16.8.16 Moody Diagram

TABLE 16.8.6 Approximate Values of μ, Absolute (dynamic) Viscosity, and ρ for Clean Water, over the Temperature Range 40 to 100°F (4.4 to 37.8°C)

Temperature (°F)	*Temperature (°C)*	*Weight Density of Water (lb/ft³) p*	*Weight Density of Water (kg/m³) p_m*	*Absolute (dynamic) Viscosity, μ (centipoise)*
40	4.4	62.42	999.9	1.50
50	10.0	62.38	999.7	1.30
60	15.6	62.34	998.8	1.10

100	37.8	62.00	993.6	0.66

previous trials how many cylinders are needed to meet the design flow and the choice has been validated by the listing tests. However, if the number of nozzles increases and the piping layout is changed to adapt to an actual space, the compressed gas demand must be calculated. The designer is interested in knowing the length of time each nozzle will discharge in the pressure range needed for producing the design spray characteristics, the settings for pressure regulators, and how much water must be stored.

Practical calculation procedures for predetermining quantities of compressed gas cylinders for compressed gas–driven systems are not yet available. Manufacturers generally work out the gas requirements from basic assumptions about the volume of gas in a cylinder at a given pressure, the ideal gas law, and trial and error. If it is not possible to check design adequacy by reviewing the designer's calculations, there is no better means of confirming adequacy of compressed gas supply than a full system discharge test.

Figure 16.8.17A shows the results of pressure measurements taken at the hydraulically most remote nozzle in a twin-fluid system. The measurements were taken as part of the final acceptance test for the system. The system was designed to deliver six discharges of 50 second duration each. The manufacturer's specification for minimum nozzle operating pressure, for both water and compressed gas lines, was 66 psi (4.6 bar). The test plot shows that the system completed five discharge episodes at the desired pressure range, but the sixth discharge could not achieve the minimum operating pressure. The compressed gas supply was exhausted before the design duration was achieved. Adding one cylinder to the compressed gas bank extended the discharge to the minimum required duration.

In this case the manufacturer's method of estimating compressed gas requirements was inaccurate. The problem could be due to unavoidable imbalances in the system piping, so that more compressed gas than necessary was flowing through nozzles closest to the source. Thus, the characteristics of the pip-

TABLE 16.8.7 Recommended Values of Absolute Roughness or Effective Height of Pipe Wall Irregularities, for Use in Relative Roughness Equation

Pipe Material (new)	*Design Value of ε (ft)*	*Design Value of ε (mm)*
Copper, copper nickel, drawn tubing	0.000005	0.0015

Galvanized iron	0.000500	0.1500

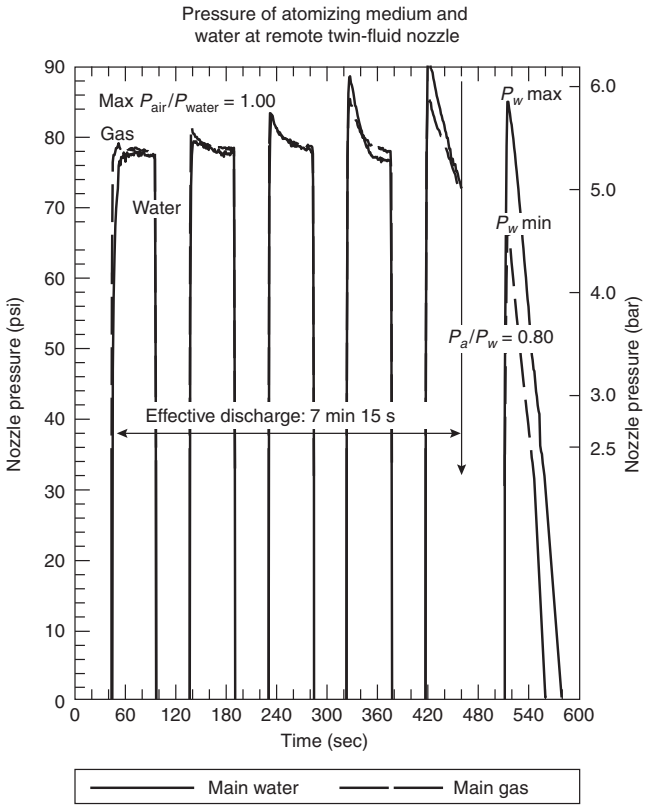

FIGURE 16.8.17A Discharge Test Results for a Twin-Fluid Water Mist System. Test objective was to confirm that the compressed gas supply was sufficient to sustain pressure greater than minimum 4.6 bar (66 psig) for 30 minutes. Pressures measured at remote twin-fluid nozzle.

ing system will directly affect the rate at which compressed gas supply is depleted. Since there were no calculations to confirm the adequacy of gas supply, the full discharge test was the only means of verification. In contrast, Figure 16.8.17B[87] shows the results of a full system discharge test of a gas-driven pump unit. The objective of the test was to ensure the adequacy of the compressed gas supply to achieve a 30 minute discharge duration, with the final system pressure not less than the end-of-discharge pressure in the FM approval test, which was 15 bar (215 psi).

Compressed gas cylinders are used on a variety of preengineered water mist systems. For all of these systems, the manufacturer is responsible for ensuring that the compressed gas supply is adequate for the design performance. Because industry practice is still founded in trial and error, it is highly advisable to verify design adequacy by means of a full system discharge test. The noise, sputter, and poor visibility in the compartment make it difficult to identify the end of discharge by visual observation. There must be actual measurements of nozzle pressure—the end of discharge is clearly identified when the nozzle pressure falls below its minimum operating pressure.

If circumstances do not permit a full system discharge for acceptance testing, the absence of a verifying calculation procedure is a serious problem. Such systems should be equipped with a test connection that simulates the system K-factor.

Calculations for Twin-Fluid Systems

Twin-fluid systems require sources of pressurized water and compressed gas in order for the nozzles to produce spray as required for fire suppression. The two "fluids" are delivered to the nozzles through two independent piping systems. The designer must calculate the pressure losses in each piping system in order to ensure that nozzles perform as intended and to determine the minimum storage quantities and pressure for each agent. The quantities of water and of compressed gas ("air") discharged at each nozzle depend on the air-to-liquid ratio (ALR) characteristics of the nozzle. If the air pressure is too high, it could prevent water from entering the nozzle. If the water pressure is too high, not enough air will enter the nozzle and the spray quality will deteriorate. Both air- and waterflow rates are very sensitive to the balance between their respective pressures. For that reason, summing the nominal flow rates of air and water is not the correct way to determine the required quantities of stored water or gas. Twin-fluid systems require special calculation procedures in order to ensure adequate nozzle performance, select pipe sizes, and determine agent storage requirements.

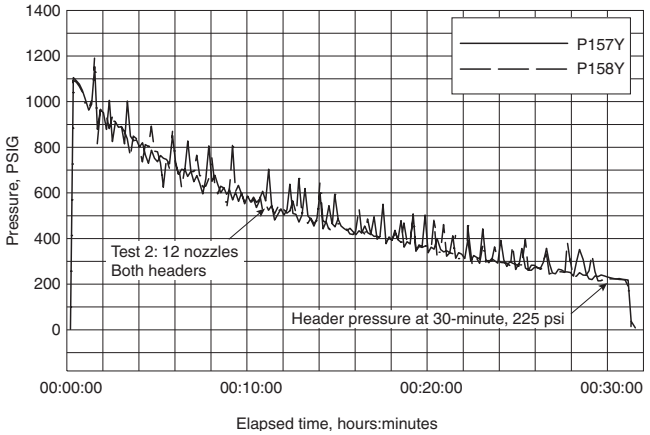

FIGURE 16.8.17B Results of Acceptance Test of a Decaying Pressure, Gas-Driven Pump System over a 30 Minute Discharge Period. Test objective was to confirm that the compressed gas supply was sufficient to sustain pressure greater than minimum 15 bar (215 psi) for 30 minutes. Pressures measured at pump discharge header.

One approach to the problem is to perform both the hydraulic and the pneumatic calculations simultaneously, checking to ensure that the gauge pressures, and pressure differences between liquid and compressed gas, at each nozzle, fall within a specified range. The listing information for a twin-fluid nozzle identifies the maximum and minimum operating pressures for both liquid and atomizing media. The designer's task is to select preliminary pipe sizes on both piping systems and then to work methodically through two sets of calculations, comparing the conditions at each nozzle. The H-W equation can be used for the water distribution piping. The calculations for the compressed gas line should follow standard engineering practice as described in references.[88] At any point, if the pressure/flow conditions exceed or fall outside of the desired operating range, an adjustment to the piping system should be made. After several iterations, it is possible to arrive at a reasonable estimate of total system demand.

The key step in the calculation procedure involves confirming that the ALR_m, that is, the mass ratio of the water discharge and the atomizing media discharge, at each nozzle, is within an acceptable range. That is,

$$ALR_m \text{ (min)} < ALR_m \text{ (actual)} < ALR_m \text{ (max)}$$

Figure 16.8.18 illustrates one model for this calculation procedure. Values for the water pressure and flow rate and air pressure and flow rate, at the most hydraulically remote nozzle, are set based on the manufacturer's recommended values. Flow rates must be converted from volumetric to mass units, for example, gpm to lb/min (L/min to kg/min), and SCFM to lb/min (m^3/min to kg/min). The ALR_m value (ALR_1 in Figure 16.8.18) is calculated. Then, for the given flow rates through the pipes supplying the most remote nozzle, the total pressure losses in each leg are calculated using the appropriate equations and added to the beginning pressures. The new pressures at the upstream nozzle (Pw_2 and Pa_2 in Figure 16.8.18) are used, with the manufacturer's nozzle data, as shown in Figure 16.8.15, to determine the new flow rates, Qw_2 and Qa_2. These values are converted to mass units to calculate ALR_{m2}. If ALR_{m2} is not within the acceptable range, then one of the pipe diameters should be increased or decreased and the calculation repeated. If it is within the acceptable range, the flows are accumulated and the calculation proceeds to the next nozzle until all nozzles have been included.

It is expected that manufacturers of twin-fluid systems will develop computerized methods for performing hydraulic and pneumatic calculations in combined piping systems. As noted earlier, FM Global accepts calculating the hydraulic and pneumatic piping independently.[74]

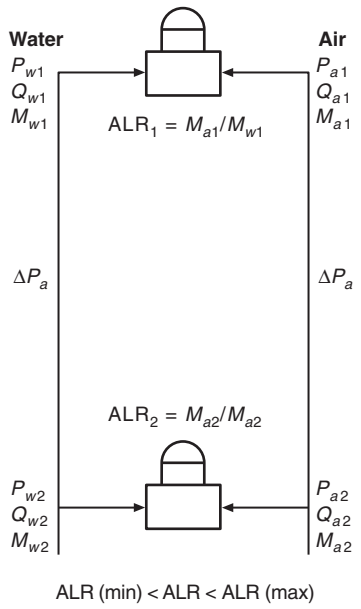

FIGURE 16.8.18 Simplified Air-to-Liquid Ratio Model

Calculations for High-Pressure Pump Systems

Water mist systems for large spaces or where a long duration of flow is needed require the use of pumps rather than compressed gas cylinders. For high-pressure systems, positive displacement (PD) pumps are normally used. Positive displacement refers to the fact that at each rotation of a gear or a piston, a fixed quantity of water is displaced. Although it is possible to use centrifugal pumps to generate high pressures, either by operating at very high speeds or by adding pumps in stages, it is more cost-effective to use PD pumps. The output pressure of a PD pump is limited only by the power of the motor and the strength of materials used. Centrifugal pump systems automatically vary both the pressure and discharge according to the demand of the fire suppression system. In contrast, PD pumps put out a constant Q but at varying pressure. Herein lies the engineering challenge: the hydraulic demand for a water mist system is seldom constant. Demand varies depending on the number of nozzles that open, as is the case when automatic nozzles are thermally released. It is also the case when several deluge systems of different sizes are supplied by a single pump source. The pump system must be able to supply both the largest and the smallest system demands. Calculations are needed to match the pump supply curve to the range of system demands and to develop a control program to manage the system.

The key to design involving PD pumps is to incorporate a pressure unloading valve, or unloader valve, with each pump. Figure 16.8.19 is an ISO symbol diagram showing a PD water mist pump assembly with unloader valves on each pump. The diagram shows two PD pumps driven by a single electric motor using direct-drive couplings at each end of the drive shaft.

An unloader valve incorporates a spring-operated valve and a check valve. When the system pressure exceeds the setting on the spring, the valve bypasses all output from the pump(s) that cannot be discharged by the system. The designer selects a pump with a specified volumetric output (L/min) at the set motor speed. The pump is coupled with an unloader valve that can "unload" up to the full output capacity of the pump. One approach is to design with one or more pumps to provide the desired Q output (equal to the maximum system demand) and a single large-capacity unloader valve. Several water mist pump manufacturers' systems are designed on this basis. In this case, the "pump curve" appears as shown in Figure 16.8.20, where the maximum pressure of the system is determined by the setting of the single unloader or pressure relief valve.

Another approach is to divide the total system demand among a number of small pumps, each with its own unloader valve and

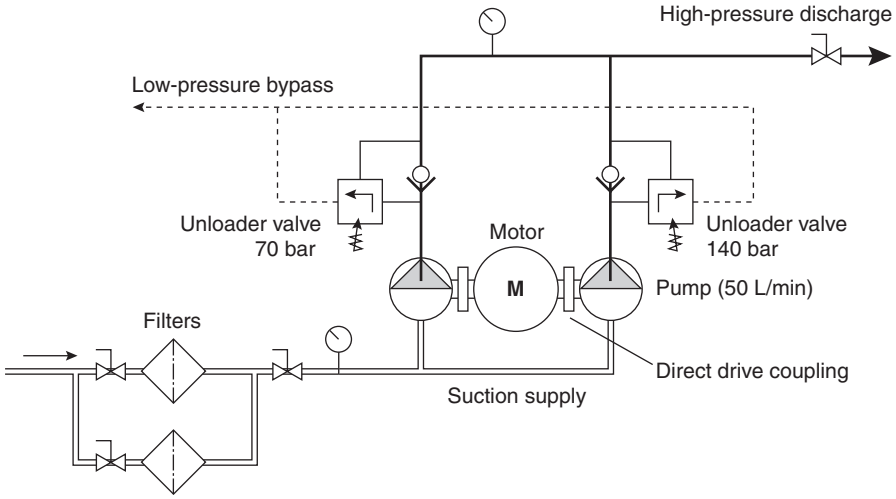

FIGURE 16.8.19 ISO Symbol Diagram of a High-Pressure Pump Assembly with Unloader Valves on Each Pump

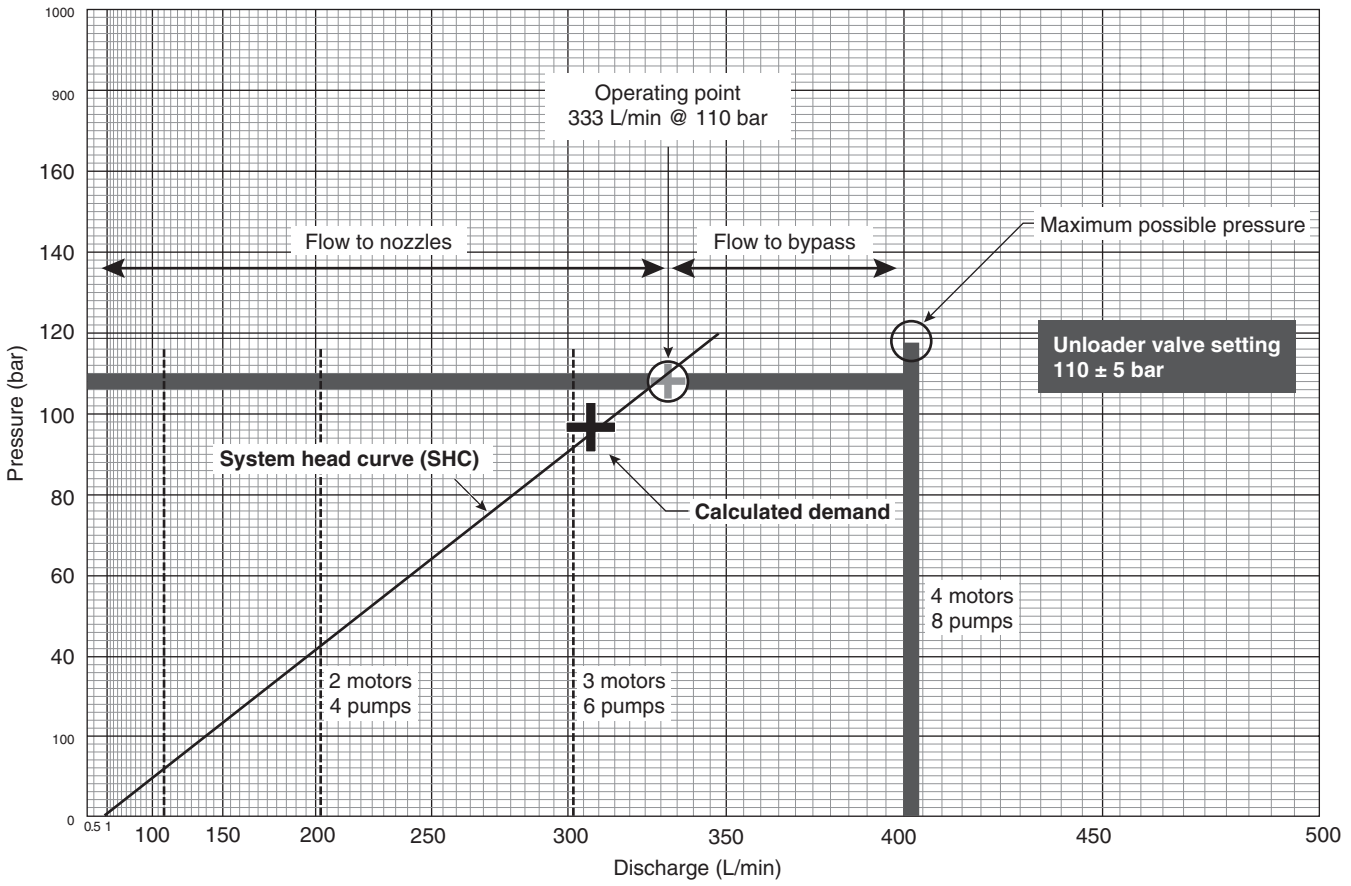

FIGURE 16.8.20 Composite Pump Curve for an 8 Pump Assembly with Single or Multiple Unloader Valves Set at 110 Bar

unique setting, and then bring different numbers of pumps on line as needed to match the demand. If one unloader valve is set at one-half the setting of the other unloader valve, the pump curve has a stepped appearance, as shown in Figure 16.8.21.

Suppliers of high-pressure water mist pumps and pump assemblies use both of these strategies. A German company uses a motor driving a single-piston pump of 120 L/min volumetric output at 1800 rpm as its basic unit. To meet larger demands several motor/pump combinations are connected in parallel to a common header. An unloader valve is connected to the common header—it is sized to pass the total output of all pumps connected to the header, for example, 120, 240, 360 L/min or more. Figure 16.8.20 illustrates the resulting pump curve. One difficulty presented by using a single large-capacity unloader valve is that, with small flows such as with a single water mist sprinkler flowing, the unloader valve may "chatter," causing uneven flow to the single nozzle. The arrangement is adequate for deluge-type water mist systems for which a relatively large flow rate is required, but it is less suitable for sprinkler-type water mist systems with automatic nozzles, in which only one or several nozzles will be opened. It should also be noted that settings on unloader valves may vary by 5 bar or more (75 psi) above or below the set pressure. It is imperative to test the installed equipment to determine the as-built capacity of the combination of pump(s) and unloader(s).

A European manufacturer of high-pressure water mist systems uses a different strategy. A piston pump with a volumetric output of about 50 L/min at 1800 rpm is used as the basic unit. A single electric motor may drive from one to four such pumps. Each pump is equipped with its own unloader valve, and each unloader valve can be set to different pressure. This approach allows the pump assembly to provide small flows at very high pressure and larger flows at a lower pressure, usually one-half the pressure of the lower flow regime. Figure 16.8.21 shows the two-step pump curve for the arrangement.

Each piston pump has an output of 13 gpm (50 L/min) discharge capacity at 1800 rpm. Assume, for example, that the largest demand on a system is 19.8 gpm (75 L/min), and the smallest demand is one nozzle at, say, 5.3 gpm (20 L/min). Both pumps would be required to meet the largest demand, at 70-bar pressure and some flow going to waste. The smallest demand of a single nozzle is less than the output of one pump. The unloader set at 70 bar will send all of its flow to the bypass, and the unloader set at 140 bar will allow 20 L/min to flow to the nozzle and the unused 30 L/min to bypass to waste. Even though the constant Q output of a single pump at 13 gpm (50 L/min) exceeds the smallest demand, the unloader valves allow partial output flows.

Table 16.8.8 displays the equations needed to design a PD pump system. Equation 1 calculates the power required of a motor to achieve a specified pressure/flow condition. Equation 2

TABLE 16.8.8 Basic Equations to Be Used in Design of PD Pump Assemblies

Pump Equations—Metric Units

$$kw = \frac{Ql \times H}{600 \times Em \times Ed} \quad \text{Eq. 1}$$

$$H_{max} = \frac{kW \times 600 \times Em \times Ed}{Ql} \quad \text{Eq. 2}$$

$$\text{Amp} = \frac{kW \times 1000}{Em \times Pf \times V \times \sqrt{N}} \quad \text{Eq. 3}$$

kW = Motor power, kW
Ql = Discharge flow, L/min
H = Discharge pressure, bar
600 = Coefficient of 598.8 ~ 600
Em = Efficiency of motor (0.88 to 0.92)
Ed = Efficiency of drive gear (<0.85)
Amp = Full load amp draw
Pf = Power factor (~0.85 depends on motor)
V = Volts
N = Number of phases in supply ($N = 3$)

Pump Equations—U.S. Units

$$bHp = \frac{Qg \times P \times 2.31}{3960 \times Em \times Ed} \quad \text{Eq. 4}$$

$$P_{max} = \frac{bHP \times 3960 \times Em \times Ed}{Qg \times 2.31} \quad \text{Eq. 5}$$

$$\text{Amp} = \frac{bHP \times 746}{Em \times Pf \times V \times \sqrt{N}} \quad \text{Eq. 6}$$

bHP = Brake horsepower
Qg = Discharge flow, gal/min
P = Discharge pressure, psi gauge
3960 = Coefficient for U.S. units
Em = Efficiency of motor (0.88 to 0.92)
Ed = Efficiency of drive gear (<0.85)
Amp = Full load amp draw
Pf = Power factor (~0.85 depends on motor)
V = Volts
N = Number of phases in supply ($N = 3$)

calculates the maximum pressure that could be achieved using a specific motor with a specific PD pump. Equation 3 is used to calculate the full-load amp draw in order to size the electrical supply. All electrical equations assume 60 Hz frequency power.

Some very large water mist systems, such as those installed on cruise ships and in the oil and gas processing industry, make use of multiple assemblies of motors and PD pumps capable of providing specific flow rates to different zones. A controller is programmed to start a specified number of electric motors depending on which system is activated. Each system of nozzles will have its unique hydraulic characteristic, referred to as a system head curve (SHC). The SHC for any system is obtained by performing hydraulic calculations on the piping system to determine the total head losses at a given discharge rate. When the water supply is activated, the actual operating point can be determined by plotting the system head curve (SHC) for the piping system on the plot of pump curves. In Figure 16.8.21, which is a Cartesian plot, the SHC has an actual curve shape. When plotted on $N = 1.85$ hydraulic graph paper, as in Figure 16.8.20, the SHC is a straight line. For a complex assembly of multiple pumps and unloader-valve settings, the hydraulic plot looks like Figure 16.8.22.[89]

Figure 16.8.22 shows a plot of an assembly that includes 6 motors and 24 pumps. The assembly was designed to meet the different demands of many separate water mist systems in machinery modules of different sizes. The composite pump curve is determined by summing the number of motors, the number of pumps per motor, the volumetric capacity of each pump, and the settings on the unloader valves on individual pumps. The demand for each water mist system must be calculated separately and plotted on the graph. The SHC represented by the constant K line (dashed line) for the calculated point is projected to where it intersects the supply curve. This determines the operating point for the system and how many motors and pumps will be needed. A programmable controller is used to start the correct number of motors for a given water mist system demand. When a separate detection system calls for release of a water mist system in a given machinery module, the controller starts the number of motors needed to meet the precalculated demand. Figure 16.8.22 was used for acceptance testing to confirm that the PD pump system design for a large facility in Alaska was correct.[89]

As recommended by NFPA 750, when conditions permit, a full system discharge should be performed with recordings of critical pressures throughout the duration of the test. In the case shown, the actual measured operating point was above the calculated value, indicating either an error in the calculation or a significant difference between design and as-built piping. There

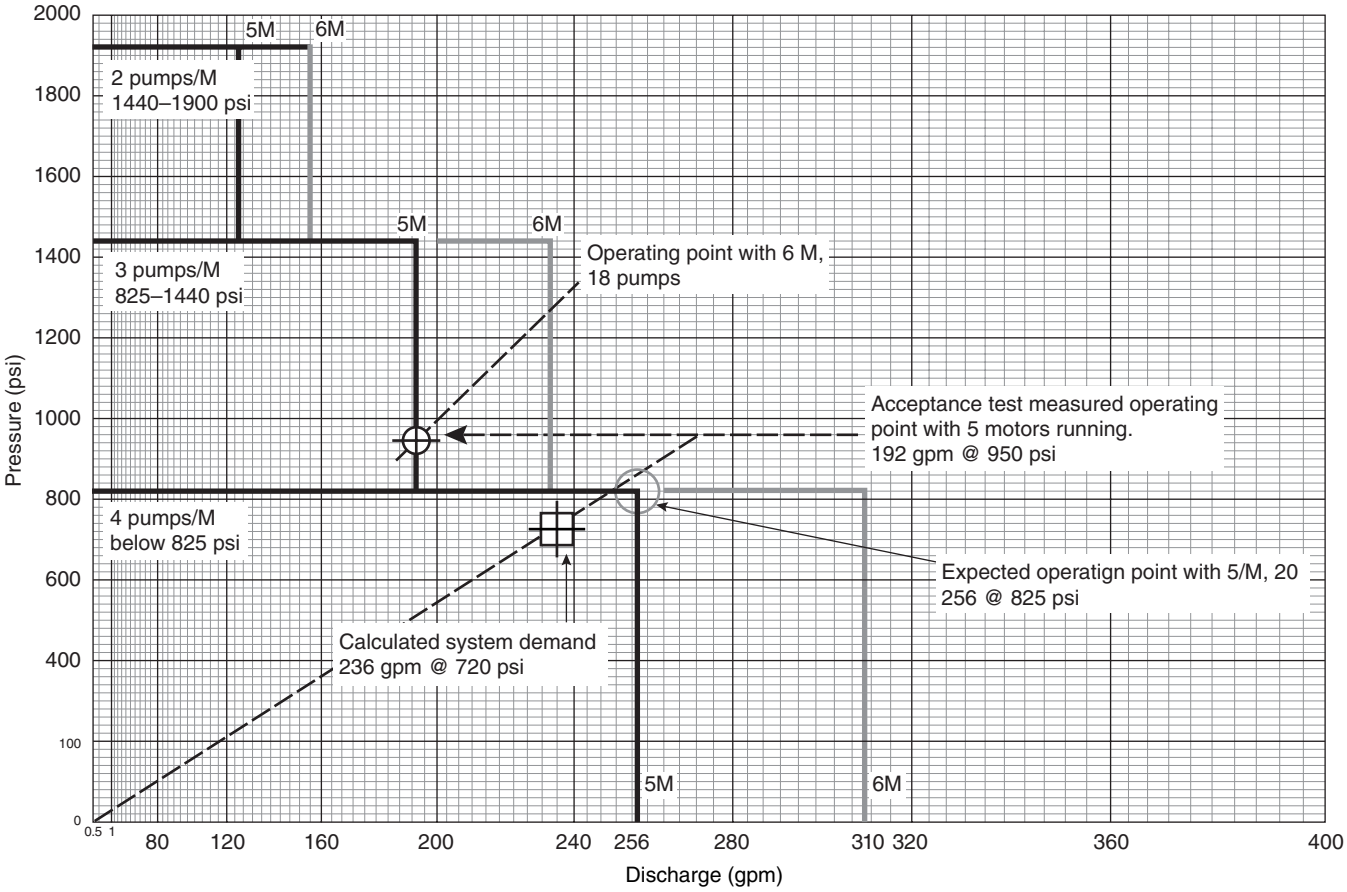

FIGURE 16.8.22 Hydraulic Diagram for Acceptance Test of a Water Mist System. Measured operating point indicates piping system is more restricted than calculated. Solution was to program system to operate six rather than five motors.

is a tendency to interpret a higher pressure on a system as corresponding to a higher discharge from the system. That interpretation only applies for a demand curve (i.e., a system head curve), for which a pressure increase corresponds to an increase in discharge. But a discharge pressure measured as part of a pump test represents the operating point of the system, where the demand curve intersects the supply curve. For a supply curve, a higher than expected pressure corresponds to a lower discharge rate. This principle applies for both centrifugal and PD pumps. Therefore, the operating point plotted in Figure 16.8.22 lies on the vertical portion of the pump curve above the lowest pressure setting of the fourth unloader, for which the total flow rate is *less than* the design flow rater for the system. In this case plotting the results of the full-system discharge test on the hydraulic graph sheet revealed the problem. After confirming that the hydraulic calculations were correct, the possible remedial actions were to (a) investigate the piping system to find and remove any restrictions, and (b) change the control program to start six motors instead of five motors for this system. In the particular case, the control program was changed to start another motor to increase the flow to at least the minimum design flow rate.

SYSTEM TYPES

NFPA 750 has introduced descriptive terms that classify water mist systems according to four basic characteristics of their design. The four parameters used as the basis of description are (1) system operation method, (2) operating pressure, (3) application, and (4) nozzle type. The reasons for classifying systems according to these four classifications are presented in the following sections.

System Operation Method

Systems may be described as deluge, dry-pipe, preaction, or wet-pipe systems. These descriptions are the same as those used for automatic sprinkler systems.

Deluge Systems. Deluge systems utilize open nozzles spaced throughout a compartment or around an object to be protected. Water is held out of the piping system by a *deluge* valve, which can be automatically released on a signal from a control panel. The system requires a separate fire detection system, which provides the signal to the control panel to release the water. Manual release features are always provided as well. When the deluge valve opens, water fills the piping system and discharges from all water mist nozzles simultaneously. The deluge system operation is widely used for machinery compartments and other applications where it is necessary to completely surround a fire with mist.

Dry-Pipe Systems. Dry-pipe systems utilize normally closed automatic nozzles on a closed piping system. The piping is pressurized with compressed gas. Some low-pressure water mist systems may use a differential-type dry-pipe valve held closed by the gas pressure. Such systems are then exactly equivalent to a standard dry-pipe sprinkler system. In the case of high-pressure water mist systems, there are no differential-type sectional control valves. The control valve is electrically activated and must be released by the fire alarm control panel (FACP). The signal to open the valve may come from a pressure sensor that responds to decreasing system pressure when an automatic nozzle is opened by heat. Pneumatic valves designed to open on a differential pressure are available.

Preaction Systems. A preaction system is similar to a dry-pipe system in that it utilizes closed nozzles on a piping system that contains no water. Water is prevented from entering the piping network by means of a valve that can be opened automatically by a control panel. A supplementary detection system is required to signal that there is a fire in the compartment and to open the valve. Water then enters and fills the piping, at which point the system operation is identical to a wet-pipe system. Water is not discharged until the heat is sufficient to actuate a nozzle. Just like a standard preaction sprinkler system, a low air pressure in the piping can be monitored to supervise the integrity of the piping system. A loss of air pressure would reveal a leak in the piping without resulting in a discharge of water.

Wet-Pipe Systems. A wet-pipe system consists of an array of closed nozzles on a piping network that is filled with water. Each nozzle is equipped with a thermal sensing element, like a sprinkler, which opens the nozzle when exposed to fire (hence, an *automatic* nozzle). As nozzles are opened by heat, water discharges immediately. This sprinkler-system-like configuration is suitable for many applications.

Operating Pressure

A second characteristic that differentiates system types is the range of operating pressure. Three categories have been defined by NFPA 750 as (1) low-pressure, (2) intermediate-pressure, and (3) high-pressure systems.

Low-Pressure System. In this water mist system the distribution piping is exposed to pressures of 175 psi (12.1 bar) or less.

Intermediate-Pressure System. In this water mist system the distribution system piping is exposed to pressures greater than 175 psi (12.1 bar) but less than 500 psi (34.5 bar).

High-Pressure System. In this water mist system the distribution system piping is exposed to pressures of 500 psi (34.5 bar) or greater. The working pressure regime of a water mist system is determined by the manufacturer's choice of nozzle. It is possible to create water mist with suitable spray characteristics in all three pressure regimes. With the exception of twin-fluid systems (and Nano-Mist), most commercial water mist systems operate in either the intermediate- or high-pressure range. Even if the nozzle is rated for 175 psi (12 bar) minimum operating pressure, which is the limit of low-pressure water mist, the operating pressure will by definition be higher than the minimum nozzle pressure; hence, it will be an intermediate-pressure system. Most of the advantages and disadvantages of high- versus low-pressure systems have already been discussed. In general, the use of high-pressure nozzles may increase spray velocity,

which may translate to greater nozzle spacings and lower overall flow rates than low-pressure systems.

Although not introduced in NFPA 750, further distinction can be made between constant pressure systems and declining pressure systems. In general the distinction is between a pumped system versus one driven by cylinders of compressed gas. For water mist systems utilizing centrifugal-type pumps, or positive displacement pumps with a single unloader valve on the common header, the nozzle pressures remain approximately constant over the design area throughout the 30-minute discharge. In gas-driven systems, the nozzle pressure declines continuously over the duration of protection. In performing acceptance testing of declining pressure systems, the author has used the minimum pressure available at the end of the discharge in the approval test report as the criterion for minimum operating pressure.

Not all pumped systems are necessarily constant pressure systems, however. For marine water mist sprinkler systems utilizing pumps with a single unloader valve, a constant pressure system is designed on the basis of a minimum operating pressure at the most remote nozzle in a 180 m^2 (2000 ft^2) design area. The minimum operating pressure is the pressure that was used in the approval tests. For systems designed to use assemblies of positive displacement pumps with unloader valves on individual pumps, it is possible to design for at least two pressure regions, one higher than the other (see Figure 16.8.21). During the early stages of a fire, a few automatic nozzles may open. The pump assembly can deliver the required volume of water at a very high pressure. As more automatic nozzles open, the pump assembly can deliver the larger flow but at a lower pressure (determined by the pressure setting on the unloader valves). The system might be designed then for a design area of 100 m^2 (1100 ft^2) at 120 bar (1740 psi) and 180 m^2 (2000 ft^2) at 60 bar (870 psi). A similar concept of having to prove hydraulic capacity for two design conditions has been applied to sprinkler system designs in the past.[90]

Application

Three different types of applications are described in NFPA 750. These are (1) local, (2) total compartment, and (3) zoned applications.

Local Application. This configuration is used to protect a specific hazard or object. An example may be the protection of a piece of equipment in a large compartment. The system would be designed to discharge water mist directly onto the object. Figure 16.8.23 depicts a local application system.

Total Compartment Application. This type of system provides protection to all fire hazards and all areas in a compartment. The open nozzles are positioned in a grid so that water mist discharges approximately uniformly throughout the entire volume. Figure 16.8.24 illustrates a total compartment application system.

Zoned Application. This type of system is configured to discharge mist from portions of a larger system as required to control fire in a specific part of a compartment. It would be considered, for example, in circumstances where the water demand for a total compartment system (i.e., a deluge system), would be beyond the capability of the water supply. Zoning the water mist piping network, however, requires the installation of a detection system capable of pinpointing the exact location of the fire in the compartment or portion of a tunnel and a piping control system capable of opening or closing specific valves in the distribution network. Research focused on achieving accurate fire detection and location for zoning purposes continues.[91]

Figure 16.8.25 illustrates elements of a zoned application system. Clearly, water mist systems for tunnels must be zoned

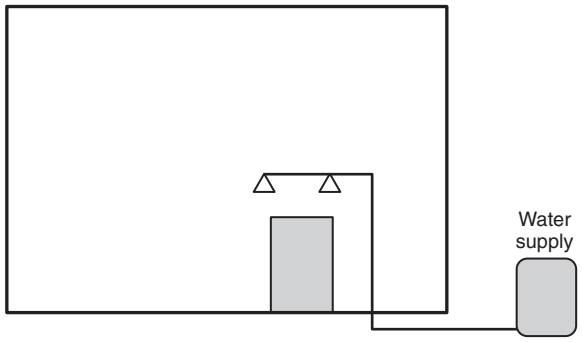

FIGURE 16.8.23 Local Application System

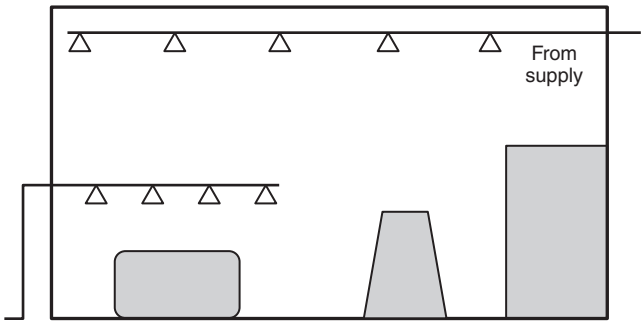

FIGURE 16.8.24 Total Compartment Application with Local Application System

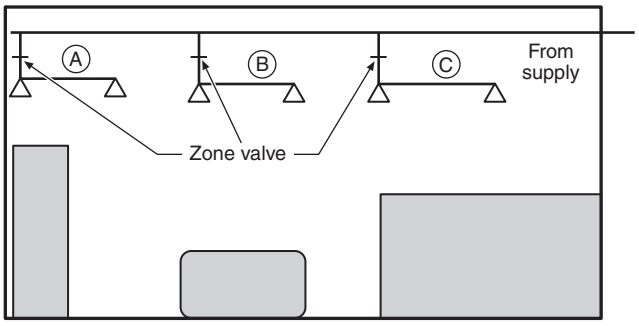

FIGURE 16.8.25 Zoned Application

in order to limit the total waterflow requirement. Typically, the design is based on the flow required for three zones—the zone where the fire is detected, plus one zone upstream and one zone downstream, to accommodate the possibility of a fire occurring at the boundary between two zones.

Nozzle Type

The nozzle type constitutes the fourth parameter for classifying water mist systems. Nozzles have been described as "open" or "closed" in previous text. Open nozzles have also been referred to as "nonautomatic" nozzles because they play no role in whether water is released. That is determined by the supplemental detection system. However, closed nozzles are designed with thermal sensing elements or other features that allow them to open, individually and automatically, in the presence of fire. Thus, NFPA 750 has adopted the terms (1) *nonautomatic,* (2) *automatic,* and (3) *hybrid* to describe the operation principle of types of nozzles. Characteristics of the types of nozzles are described elsewhere in this chapter.

SYSTEM COMPONENTS

As with all fire protection systems, water mist systems require their own unique set of hardware features, components, and materials. Basic components include but are not limited to pipe, fittings, valves, hangers, gas and water containers, nozzles, strainers, pumps, and detection system components.

The quality of system components and the overall reliability of water mist systems can be enhanced by using materials and components that comply with internationally recognized standards or material specifications. This is addressed in NFPA 750 by requirements for most components of systems to be listed for specific duty in water mist systems. The requirement of listing is particularly emphasized in North America. Marine authorities and European users have accepted water mist system technology on the basis of component testing done under the auspices of the International Maritime Organization (IMO) test protocols. The first water mist systems installed in North America contain components that were not listed at the time of installation but were part of systems being marketed internationally. Examples include pumps, motors, controllers, and the tubing clamps used on stainless steel tubing systems. As the acceptance of water mist systems increases, manufacturers continue to complete the North American listing requirements for their components.

It is important to ensure that all components in a water mist system, not just the water mist nozzles, are evaluated for functionality and reliability as part of the listing process. FM Global Approval standard number 5560 contains comprehensive requirements for listing of water mist system components, including positive displacement pump assemblies and controllers. Some additional design considerations for selection of pumps, detection, actuation and supervision of control equipment, and miscellaneous components are offered here.

Pumps

Pumps used to deliver the necessary flow and pressure to system pipe networks will be of the centrifugal type or the positive displacement type. The reliability of centrifugal fire pumps, pump drivers, and controllers are well regulated by NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection.* Centrifugal pumps are suitable for use in low-pressure and possibly intermediate-pressure systems. They are not practical, however, for water pressures in the high-pressure regime (500 psi [34.5 bar]). High-pressure water mist systems utilize positive displacement (PD) pumps.

A number of issues relating to control of positive displacement pumps require close attention. For example, the controller functions necessary for an assembly of positive displacement pumps are not compatible with NFPA 20 requirements for fire pump controllers. Traditional centrifugal fire pump installations did not consider the need to operate many small motors, so each motor has its own controller. For multipump assemblies with many motors, there is one controller for the assembly, not for each motor. This difference invokes a need to modify requirements in NFPA 20 pertaining to locked rotor current and to permit timed shutdown of individual motors. The idea of starting and stopping individual motors in an assembly of motors conflicts with the basic practice of automatic start/manual stop for fire pumps. System features such as the electrical power supply connections, location and sizing of circuit breakers, and supervision are no different than conventional fire pump installations, and NFPA 20 should be followed. Acceptance testing of PD pump assemblies can prove problematic due to the difficulty of achieving accurate pressure setting on unloader valves. Variances of 5 bar (75 psi) or more over nominal settings are common; as a result the measured performance curve for the pump may not match its theoretical value. It is important to evaluate the adequacy of the PD pump or pump assembly on the as-built performance curve.

Table 16.8.9 compares technical features of centrifugal and PD pumps that should be taken into consideration by a designer of water mist systems (from NFPA 750).

Detection, Actuation, Alarm, and Control Equipment

Detection systems for water mist systems must be designed and installed in accordance with *NFPA 72, National Fire Alarm Code®* (CAN/ULC S524-M86 and S529-M87). The releasing device must also comply with these codes when appropriate. All the detection and control equipment used to activate a preaction system or a deluge system must work at the time of the fire. In addition to increasing the reliability of the system, evaluations and performance tests evaluate system controls to ensure that the possibility of inadvertent activation is minimized.

In the same manner that fire pumps require a specific set of features to be supervised, supervision of certain detection and control features is also necessary. System alarm, trouble signals, or both are necessary for critical parts of the electrical control system. These alarms include the following:

- System activation (alarm)
- Power failure (supervisory)
- Valve position (supervisory)
- Detector operation (alarm)
- Detector status (supervisory)

TABLE 16.8.9 Design Considerations for Centrifugal and Positive Displacement Pumps

Feature	*Centrifugal Pump*	*Positive Displacement Pump*
Ability to achieve high pressure	High pressure requires high speed and or multistage design.	High pressure limited only by the power of the driver (brake horsepower or kilowatts) and strength of materials.
Pressure and flow pulsation	Pressure and flow are smooth, varying only with system backpressure or pump speed. Pulsation dampers are unnecessary. Gauges and instruments can be directly mounted on piping or pump skid.	Pressure and flow are sinusoidal, varying with each plunger stroke or gear rotation. Pulsation damper in the suction piping can improve NPSH. Pulsation damper in the discharge piping can reduce vibratory stress to system and relief valve. Gauges and instruments should take their signals via flexible tubing or wiring and should not be mounted on the piping at the pump skid. *Note: Pulsation is not a problem at 1750 rev/min. Use of variable speed drivers in a PD pump system may introduce pulsation problems at slow motor speeds.*
Head curve	Flow from pump depends on backpressure from system. For any given pump speed, there is a maximum pressure that can be achieved. If operated at no-flow shutoff condition and maximum pressure, pump will vibrate and experience accelerated wear but will not fail catastrophically. Churning may heat water to boiling, but small bypass flow sufficient is to prevent boiling.	Flow from PD pump is proportional to pump speed and nearly independent of system backpressure. If flow from the pump is blocked partially or completely, discharge pressure will increase until full flow is forced past the blockage or something breaks. "Multistep pump curve" results when unloader valves are provided on each pump in a multipump assembly.
Relief valve	Not needed if the piping is designed to accommodate the maximum pressure achievable from the pump plus static suction head.	Pressure relief valve is needed. Relief valve must tolerate pressure pulsation produced by the pump.
Net positive suction head (NPSH)	Most centrifugal pumps used in fire service can tolerate a wide range of available NPSH. Ordinary design of suction piping is acceptable.	In general, PD pumps are more sensitive to NPSH than centrifugal pumps. Special care with the design of the suction piping must be taken to provide as much NPSH as possible.
Pump start-up	Conventional pump start-up strategies. Soft-start controllers.	Maximum pressure can be achieved with the first plunger stroke. Use of an unloader valve in the discharge piping is common. Manufacturers recommend motors with high starting torque. Constant torque motors required.
Strainers, sensitivity to dirty water	Silty water is not critical for pump flow passages. Some pumps have water lubricated surfaces that could be adversely affected. Strainer for the protection of water mist nozzles could be on suction or discharge side of the pump.	Silty or murky water is less critical for pump flow passages. Pumps are oil lubricated. Strainers and/or filters for the protection of water mist nozzles are required on the suction side of the pump. Strainers and filters reduce NPSH available. A suction booster pump may be required to meet minimum NPSH for pumps.
Foundation	Ordinary	Compared to centrifugal pumps additional rigidity and mass are helpful because of vibration caused by pulsating flow.
Pump motor link	Typically operate at motor speed. Close-coupled or direct drive via flexible coupling.	May operate at less than motor speed. Belt drive or geared speed reducer is typical. Pulsations and starting torque are considerations in the design of the speed reducer. Possible to have multiple pumps on one motor, with one pump driven directly by the shaft and the other(s) driven by chain drives.

Some systems may use pneumatic lines to activate system valves. These control lines should be protected against mechanical damage as well as fire damage. A means of supervising such pneumatic lines for integrity is necessary.

Water mist systems should also be equipped with a manual means of operation, for those situations in which the fire is discovered by people in the vicinity of the fire, prior to the fire being detected by the detection system. The manual means of activation should be independent of the automatic features, to the extent possible, to allow for the system to operate in the event of a catastrophic control failure. Manual releasing stations should be provided at the main system control valves or at other conspicuous areas within or near the protected hazard.

Miscellaneous Components

The discussion so far has centered on those components that are different than those used in similar types of water-based fire protection systems or special hazard systems.

Water mist systems may use a variety of valves that control everything from the discharge of the water to the discharge of the atomizing medium. Valves should be selected for their particular function and should be capable of sustaining the system pressure to which they will be subjected. All valves should be labeled as to the portion of the system that they control, and they should be supervised in the normal (open or closed) position.

Electrically activated sectional control valves are used on high-pressure systems. These valves can have very high head losses. Manufacturers should provide data on hydraulic performance of such valves to the designer. Electrically activated valves should be supervised. Special methods of supervision may be required where electrical valves operate on AC current. Where possible, valves should be of the indicating type and allow for manual release. Pressure-regulating devices will be found on any part of a system that may subject the valve, pipe, fitting, or nozzle to an operating pressure higher than the working pressure of the device.

Check valves may be necessary in a number of locations on water mist systems. Check valves should be installed in the following locations:

- At the point between the system piping and the system water supply
- On twin-fluid systems, in the pipe network, to prevent atomizing medium from entering the water supply pipe and to prevent the water supply from entering the atomizing medium

Pressure gauges are necessary to monitor key points within the system to verify that proper water pressure or atomizing medium pressure is available. These locations include the following:

- Pressurized side of all water and atomizing media connections
- Pressurized side of all system control valves
- Pressurized storage containers
- Suction side of all pumps

In general, the gauges are used to verify system status as part of a preventive maintenance program. Gauges should be selected such that they can withstand at least two times the working pressure associated with the particular system.

SYSTEM WATER SUPPLY AND ATOMIZING MEDIUM CONSIDERATIONS

Reliability of the water supply and atomizing medium is crucial to the performance of a water mist system. There are various engineering factors that affect reliability. For water, the major issues are whether it is free of silt or debris that could plug nozzles and free of bacteria that could cause algae growth in water storage vessels. For compressed gas media gas-driven systems, the major issue is whether the quantity is sufficient to meet the flow rate and duration required.

Water Supplies

For pumped water supplies there should be an automatic water supply to feed the pump. NFPA dictates that the supply should be at least equivalent to potable water, or natural seawater, with respect to particulates. Screens and filters are required on the supply connection to ensure that particulate matter in the water does not get into the piping and nozzles. Marine systems are equipped with a seawater connection, so that supply can be switched to a seawater source after the fresh-water supply is depleted. Seawater intakes typically draw marine life into the inlet. The IMO dirty water component test is intended to demonstrate that dirty water can be pumped through the screens and filters and not plug the nozzles.

Duration of water supply has been an interesting problem for end users. NFPA 750 requires a minimum supply duration of 30 minutes, except for preengineered systems with stored water supplies, for which there must be capacity to support two complete discharges of 10 minutes each. A problem has arisen in the field: FM Global Research and UL have listed systems for turbine enclosures and machinery spaces. These systems are expected to extinguish fire in less than 5 minutes and provide for 10 minute discharge time. The manufacturer has sold systems to end users with capacity for a 10 minute discharge duration, quoting the fact that the systems are FM approved. The FM Global Research approval documents state that discharge time shall be 10 minutes or the “coast down time of the turbine” (or by implication, the shutdown time of process lines containing hazardous fluids or gases). The systems installed provide only a 10-minute protection time. The installers have ignored the NFPA 750 requirement for either backup discharge or 30 minutes.

The NFPA 750 requirement for a minimum 30 minute discharge time should be observed in all cases. There may be circumstances where the facility is next door to a fire department where a 10-minute total capacity of the system is adequate. In many circumstances, however, 10 minutes is barely enough time for competent persons with necessary resources to react to the reality that a fire exists. To mobilize effective response in that time is unlikely. The fire test protocols for machinery spaces, for example, are based on fires in a compartment with a mockup of a diesel engine and bilge space. There are no overhead pipes, cable trays, or ducts in the test compartment. Real

machinery spaces, in contrast, are filled with pipe, cable trays, and ducts. The clutter in a real machinery space is not simulated in the test compartment. Therefore, the performance of fire extinguishment in "less than 5 minutes" cannot be guaranteed in real spaces.

The time to extinguishment for a given fire size is a function of the fire size and compartment volume (see Figure 16.8.7). New FM Global Research test protocols for large machinery spaces (e.g., 1000 m^3) mandate minimum water supply durations of 60 minutes.

For pumped water supplies on high-pressure systems, it is sometimes necessary to utilize suction booster pumps on the suction supply to the fire pumps. The need arises because of the head losses created by the screens and filters that are required on the infeed to the pumps. Positive displacement pumps are particularly sensitive to low net positive suction head (NPSH) so attention to suction line details is necessary. Control over the additional pump must be worked into the control program to ensure that it operates when required.

In brief, water supplies for water mist systems must provide sufficient quantity (flow rate) at the pressure needed to supply pumps or refill reservoirs in a reasonable time. Minimum duration at design flow should be 30 minutes—shorter durations should only be considered for special cases after a fire protection engineering evaluation. Screens, strainers, and filters are needed to ensure the water is free from particulates that could plug the nozzles.

Water Quality

NFPA 750 mandates that water supplies for water mist systems must be at least equivalent to potable water or natural seawater with respect to particulates and dissolved minerals. Combined with the requirements for strainers and filters on the infeed piping and screens on individual nozzles, these measures were viewed as sufficient safeguards against plugging of nozzles. The requirements for corrosion-resistant pipe were also intended to minimize the possibility of scale in the piping. For systems utilizing a pumped water supply from a continuous source, the screening and filtering measurements are probably sufficient to avoid plugging of nozzles.

Many preengineered water mist systems involve water stored in vessels or pressure cylinders. It is possible that bacteria present in the stored water could result in algae growth in the tank. Filtering out the particulates during infill would not necessarily prevent bacterial activity in the stored water. Diligent maintenance is required to ensure the quality of stored water for water mist systems. Where there is a risk of *Legionella* bacteria in stored water, continuous ultraviolet treatment of the water should be provided. Equipment to achieve this is available.

Mandating the quality of the water supply is not sufficient to prevent plugging of nozzles. Cleaning of pipe and tubing and system flushing following installation are extremely important. High-pressure systems involving welded stainless steel piping have "purge paper" or "rice paper" inside the pipe after a weld is complete. The purge paper is used to provide a backing for argon gas used to minimize oxidation during the welding process. After the weld is complete, the purge paper remains inside the piping. For standard petroleum industry conditions, the purge paper is soluble in hydrocarbons and is usually flushed through the system. For water mist systems the purge paper becomes a jelly, and if it is not completely flushed from the piping it can stick to the inside of the pipe and plug the nozzles over an extended period of time. Extensive flushing of all branches of the piping system is essential to minimize future problems.

Plastic thread sealant tape such as Teflon tape should not be used on piping for water mist systems. Even with the greatest care in following good workmanship practices during installation, bits of Teflon tape appear on nozzle screens and will plug small orifices.

The important requirements with respect to water quality are as follows:

- Draw from a source with quality equivalent to potable water.
- Strain or filter water going into the system, including into storage reservoirs.
- Provide treatment for stored water to minimize possibility of algae or bacterial growth. (Do not use chlorination or bromination of water in systems with stainless steel pipe.)
- If necessary due to evidence of poor quality of stored water, provide screens or strainers on the outlet of stored water containers, sized to pass the design flow without excessive head losses even with partial blockage.
- Monitor water quality at regular intervals.

Atomizing Media

Twin-fluid systems require a supply of atomizing medium in addition to a reliable water supply. Air and nitrogen are the most commonly used compressed gases for water mist systems. The source of compressed gas must have the same level of reliability as the water supply. Two options are the use of dedicated compressed gas cylinders manifolded in banks and the use of plant air supplies in facilities that have the necessary capacity. If used, plant air supplies must be available on a continuous basis, not only while the plant is operating. Also, NFPA 750 limits moisture content to 25 ppm: plant air supplies may not always meet this quality standard. An air compressor that is listed for fire protection service may also be used as an acceptable supply of compressed gas. The unit should be connected to a backup power supply.

Compressed gas supplies must be monitored for high and low pressure and protected against physical or mechanical damage. Some of the supervisory functions expected on fire protection systems are difficult to achieve with gas cylinders. For example, the control valves on standard commercial gas cylinders are not of the indicating type. It is impossible to be certain that the valve has been opened without handling it. Vigilant system maintenance by qualified personnel is very important for the long-term reliability of water mist systems.

SYSTEM MAINTENANCE CONSIDERATIONS

A number of acceptance and commissioning tests must be performed once the installation of a system is completed. NFPA 750 specifies measures involved in the acceptance testing. These

include a review of the design documentation, hydraulic calculations, working drawings, and the as-built installation. System piping is flushed and hydrostatically tested. All mechanical and electrical components are to be examined for correct installation and for functionality. Pumps are flow tested and, where possible, a system discharge test is carried out. Pumps are tested to confirm that they deliver the specified flow rate and pressure and that control features operate reliably. The acceptance tests are intended to identify the problems, which then must be corrected before the system is considered complete. The results of the acceptance tests must be recorded and kept with the system documentation. This basic documentation of all components of the system and acceptance test performance data is the basis on which the success of future maintenance practices rests.

After the acceptance testing, maintaining the reliability of the system depends on carrying out regular maintenance inspections. The owner or the tenant using the system is responsible for ongoing maintenance. NFPA 750 provides a table of recommended maintenance tasks to be carried out weekly, monthly, semiannually, or annually. The table in NFPA 750 was developed from common practices for similar fire protection systems involving pumps, compressed gas cylinders, water storage tanks, and detection and activation systems. Experience with installed water mist systems has increased since the time the table was drafted. A number of concerns specific to water mist systems have been discovered. The following list includes the most important concerns:

1. Water storage vessels must be equipped with a means of checking the level of water inside during a weekly or monthly inspection. Some high-pressure water storage cylinders do not have a means to confirm water levels. Some end users have installed weight scales to monitor the weight of the cylinders. If such cylinders are present in a system, extra measures to confirm water level should be implemented.
2. The quality of water in storage vessels should be checked for algae growth monthly or quarterly for the first year. A means of taking water samples should be provided. The vessels should be drained, flushed, and refilled at least quarterly or more frequently if water quality problems are identified by the monthly check.
3. Water mist systems make use of a variety of valves, some of which are not of the indicating type. It is not always possible to determine whether a critical valve is open or closed from external appearance. Key control valves that must be normally open should be of the indicating type.
4. Some valves on water mist systems are electrically activated. A manual means of operating the valve should be provided.
5. Systems involving the use of banks of compressed gas cylinders connected in parallel use a combination of pneumatic master and slave valves. Operation of the master valve triggers the release of all connected slave valves. Important differences between valves may not be evident to an inexpert maintenance person. Means of checking the readiness and functionality of pneumatic valves should be established. Valves should be marked to indicate whether they are the master or slave status.
6. An annual trip test should be conducted in all cases. If it is not possible to discharge water mist through the system nozzles, the discharge should be conducted through a test connection. The test connection should be designed to have the same K-factor as the actual piping system.
7. Confirmation of the adequacy of compressed gas supplies is best obtained by recording measurements of nozzle pressure throughout the discharge test. The minimum nozzle pressure must be sustained for the specified duration.

Table 16.8.10 is a modified version of the table in NFPA 750 specifying inspection frequencies. More complete discussion of maintenance requirements specific to the different types of water mist systems is provided in the NFPA handbook on inspection and maintenance of fire protection systems.[92]

SUMMARY

This chapter presents an overview of the history of development of water mist fire protection systems since 1990. Water mist fire suppression systems discharge less water, use smaller-diameter piping, and have lower overall weight than conventional water spray or sprinkler systems. Water mist can be used as a replacement for ozone-depleting substances such as halons and can be used in applications where water was not previously considered practical. Water mist fire suppression systems are used in a wide variety of marine-based and land-based applications, including machinery spaces on ships as well as land facilities, turbine enclosures in offshore drilling platforms, marine accommodation areas, electrical equipment rooms, tunnels, hotels, heritage buildings, and art galleries. The last five years have seen an intense effort to develop water mist systems for electrical cable, highway, and rail tunnels.

The objectives and characteristics of water mist systems are described for Class B fires in machinery spaces and turbine enclosures and for Class A fires in accommodation spaces, hotels, and heritage buildings. Use of water mist in electrical equipment rooms and computer rooms is discussed. The mechanisms by which water mist controls or extinguishes fire are described in detail, including flame cooling, evaporation of small droplets, enclosure effects, radiation attenuation, and others. Pressure fluctuations due to rapid cooling of a hot gas layer are described. The concept is established that water sprays must be described in terms of the range of drop sizes contained in the spray, not a single representative diameter. The chapter explains the role of spray momentum in allowing water mist to penetrate a strong fire plume or to penetrate a field of obstructions. The different types of nozzles, including impingement, pressure jet, and twin-fluid types, are described. Nozzles may be of the automatic type (thermally activated like sprinklers) or of the nonautomatic type (open nozzles). New technology involving ultra-fine mist (Nano-Mist) is referenced.

A section on hydraulic calculations for single-fluid and twin-fluid systems is presented. The chapter describes how positive displacement pumps are matched to variable-demand fire protection systems. The role of the unloader valve, which sends unused flow from the pump to a bypass, is explained. Acceptance testing of positive displacement pumps or pump assemblies must allow for variance in unloader valve settings.

TABLE 16.8.10 Recommended Inspection and Testing Frequencies for Water Mist Systems

Item	*Activity*	*Frequency*
Ambient conditions, temperature +4°C to 54°C in water tank/valve area	Check	Daily during extreme weather
Water tank (unsupervised)	Check water level	Weekly
Air receiver (unsupervised)	Check air pressure	Weekly
Dedicated air compressor (unsupervised)	Check air pressure	Weekly
Water tank (supervised)	Check water level	Monthly
Water tank	Check water quality	Monthly
Water tank	Drain, flush, refill	Quarterly first year
System strainer and filters	Inspect	Annually and whenever water has passed through it (after each refill)
Air receiver (supervised)	Check air pressure	Monthly
Dedicated air compressor (supervised)	Check air pressure	Monthly
Air pressure cylinders (unsupervised)	Check air pressure and indicator disk	Monthly
System operating components, including control valves (locked/unsupervised)	Inspect	Monthly
Air pressure cylinders (supervised)	Check air pressure and indicator disk	Quarterly
System operating components, including control valves	Inspect	Quarterly
Waterflow alarm and supervisory devices	Inspect	Quarterly
Initiating devices and detectors	Inspect	Semiannually
Batteries, control panel, interface equipment	Inspect	Semiannually
System strainers and filters	Inspect	Annually
Control equipment, fiber-optic cable connections	Inspect	Annually
Piping, fittings, hangers, nozzles, flexible tubing	Inspect	Annually

The chapter reviews the NFPA 750 classification of water mist systems as wet pipe, dry pipe, or preaction type; total compartment flooding, local application or zoned systems. The respective merits of low-, intermediate-, and high-pressure options are discussed; the concept of constant pressure water mist systems as opposed to declining pressure systems is introduced. Gas-driven systems are generally of the declining pressure type, but a water mist system utilizing assemblies of PD pumps may have a high-pressure mode and a lower-pressure design condition.

The importance of ensuring water quality to avoid potential plugging of small-orifice nozzles is highlighted. Issues relating to the supervision of certain equipment unique to water mist systems are raised. The chapter concludes with an overview of considerations pertaining to inspection testing and maintenance of water mist systems.

Spray System Nozzles and Piping
Water Demand and Supplies
Other Considerations and Maintenance

Key Terms

fixed water spray system, spray nozzle, water mist, water spray system, water supply

The term *water spray* refers to water that is discharged from specially designed nozzles or devices to produce a predetermined pattern, particle size, velocity, and density. The use of these designations cannot be taken as an indication of any specific discharge pattern or spray characteristics of the nozzles. NFPA 750, *Standard on Water Mist Fire Protection Systems,* has been developed to address the use of very fine water droplets from spray nozzles (see Section 16, Chapter 8, "Water Mist Fire Suppression Systems"). The primary distinction between a water spray and a sprinkler system is that of specific coverage versus general area coverage. Water spray systems have typically been provided to protect a specific piece of equipment with surface coverage. Water spray for fire protection has been called by various trade-name designations.

The discharge from water spray nozzles differs, generally, from the discharge from sprinklers. The pattern of the water spray discharged from spray nozzles onto a surface may be elliptical or circular, and the cross section of the projected discharge is conical. The water spray is forcefully directed onto the object or surface being protected. The pattern of spray nozzle discharge must carry water spray over the distance between the nozzle and the target, compensate for wind and draft conditions, and effectively hit the surface to be protected. The required discharge density in gpm/ft^2 (L/min/m^2) and complete coverage of the area to be protected are also essential elements.

Unlike most automatic sprinkler systems, water spray systems are usually of the deluge type. Generally, spray nozzles are not equipped with fusible operating elements. Spray nozzles may be equipped with internal pilot-pressure-controlled valves or with frangible or removable plugs or caps that will be displaced when the water spray deluge system is actuated. Pilot-pressure-controlled valves, plugs, or caps prevent corrosive atmospheres from entering the piping system. They may be used to retain water in the piping system for the purpose of speeding its delivery from the spray nozzles.

NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection,* is the standard applicable to water spray systems and should be consulted on details of system design and installation not covered in NFPA 13, *Standard for the Installation of Sprinkler Systems.*

This chapter covers the uses and applications of water spray systems for fire suppression, control, and extinguishment and describes the components of spray systems and the specialized uses of the systems. Because of the similarities between sprinkler systems and water spray systems, their water supply requirements, some of the equipment used in the systems, and the hydraulic calculations for determining water supplies, the chapters listed below should be consulted. The list includes chapters on releasing devices that can be used with water spray systems as well as protection of conveyor openings: Section 14, Chapter 2, "Automatic Fire Detectors"; "Section 15, Chapter 4, "Water Supplies for Sprinkler Systems"; Section 16, Chapter 3, "Automatic Sprinkler Systems"; Section 16, Chapter 7, "Ultra-High-Speed Water Spray Systems"; Section 16, Chapter 8, "Water Mist Fire Suppression Systems"; and Section 17, Chapter 3, "Characteristics and Hazards of Water and Water Additives for Fire Suppression."

Kerry M. Bell is a principal engineer at Underwriters Laboratories Inc. (UL) specializing in fire sprinkler and pump equipment. A member of NFPA, ASTM International, and SFPE, he is currently a member of NFPA's Residential Sprinkler Systems Committee and Sprinkler System Discharge Criteria and Technical Correlating Committee, chairman of the NFPA Technical Committee on Water Spray Fixed Systems, and vice-chairman of UL's Fire Council.

USES FOR WATER SPRAY PROTECTION

Generally, water spray can be used effectively to extinguish a fire, control a fire, protect exposures, and/or prevent a fire.

Extinguishment

Water spray extinguishes a fire by cooling it, smothering it with the steam produced, emulsifying or diluting some flammable liquids, or by a combination of these factors.

Controlled Burning

With its consequent limitation of fire spread, controlled burning may be applied if the burning combustibles cannot be extinguished by water spray or if extinguishment is not desirable.

Exposure Protection

Exposures are protected by applying water spray directly to the exposed structures or equipment to remove or reduce the heat transferred to them from the exposing fire. Water spray curtains mounted at a distance from the exposed surface are less effective than direct application.

Prevention of Fire

It is sometimes possible to use water spray to dissolve, dilute, disperse, or cool flammable or combustible materials before they are ignited by an exposing ignition source.

SPRAY SYSTEM DESCRIPTION AND APPLICATIONS

Fixed Water Spray Systems

A water spray system is a special fixed pipe system connected to a reliable supply of fire protection water and equipped with water spray nozzles for specific water discharge and distribution over the surface or area to be protected. The piping system is connected to a water supply through a deluge valve that can be actuated both automatically and manually to initiate the flow of water.

Automatic system actuation valves for spray systems can be actuated electrically by the operation of automatic detection equipment, such as heat detectors, relay circuits, and gas detectors, or mechanically by hydraulic or pneumatic systems, depending on the operating mode of the individual valves. Generally, each manufacturer of system actuation valves, most of which can do dual service in deluge systems, provides its own particular combination of system actuation valve, releasing mechanism, detection system, and supervisory service.

Water Spray Applications

Water spray can be used to protect the following types of materials or equipment:

- Ordinary combustible materials, such as paper, wood, and textiles, particularly to extinguish fires in such materials rather than control them
- Electrical equipment installations, such as transformers, oil switches, and rotating electrical machinery
- Flammable gases and liquids, particularly to control fires in these materials and to extinguish types of fires involving combustible liquids
- Flammable liquid and gas tanks, processing equipment, and structures, as protection against exposure fires
- Open cable trays and runs containing electrical cables or tubing

The nature of the equipment to be protected, the physical and chemical properties of the material involved, and the environment of the hazard should be considered when determining the design and effectiveness of the water spray system.

Examples of Systems

Fixed water spray systems are most commonly used to protect equipment from exposure fires in flammable liquid and gas tankage, piping, and equipment; in electrical equipment, such as transformers, oil switches, rotating machinery, and cable trays; in structural supports; and in conveyor systems and the openings in firewalls and floors through which they pass. The type of water spray required for any particular hazard will depend on the nature of the hazard and the purpose for which the protection is provided.

A water spray installation being tested at a group of liquefied petroleum gas tanks is shown in Figure 16.9.1. The spray keeps the tanks cool in case of fire, prevents the liquid contents from boiling away, and protects the tank shells against rupture due to localized high-temperature flame impingement. The spray system shown in Figure 16.9.1 is designed to give complete surface wetting with a specified water density, taking into consideration nozzle types, sizes, and spacing; the influence of wind and drafts; the probability of water rundown; the prevention of the formation of difficult-to-wet deposits of soot or carbon on surfaces; the overlap of water discharge patterns onto the surfaces; and the ability of the water supply to furnish adequate pressure to all of the nozzles. Ordinarily, it is neither

FIGURE 16.9.1 Water Spray Protection for LP-Gas Tanks

desired nor expected that water spray extinguish escaping liquefied petroleum gas. However, the cooling effect of the water on the tanks may reduce and control the rate of burning and reduce the severity of the exposure until the gas supply to the fire is exhausted or can be shut off.

Water spray protection for a group of oil-filled electric transformers is shown under test in Figure 16.9.2. A thick layer of crushed stone and subsurface drainage is provided around the base of the transformer installation to prevent the possibility of burning oil flowing beyond the ground area protected by the spray.

Due to the relatively high flashpoint and boiling point of transformer oil, transformer fires can be extinguished quickly by properly designed water spray systems. However, the metal surfaces of the transformer case and its structural supports must be protected from radiant heat while the burning transformer oil is being extinguished. Care must be taken to locate nozzles, piping, and supports the prescribed distances from electrically charged parts of the transformer installation, and direct application of water spray to electrically charged terminals or insulating bushings should be avoided. Electricity to the transformer should be shut off automatically before water spray is applied.

Water spray systems are also used to provide protection from fire damage for equipment and structures for the petroleum industry. API RP 2030, *Application of Fixed Water Spray Systems for Fire Protection in the Petroleum and Petrochemical Industries,* provides guidance for the petroleum and petrochemical industries in determining where these systems might be used.[1]

SPRAY SYSTEM NOZZLES AND PIPING

General Design Information

The practical location of the piping and nozzles with respect to the surface to which the spray is to be applied or to the zone in which the spray is to be effective is determined largely by the physical arrangement and protection needs of the installation requiring protection. Once the criteria are established, the size of the nozzles to be used, the angle of the nozzle discharge cone, and the water pressure needed can be determined.

The first factor to determine is the water density required to extinguish the fire or to absorb the expected heat from exposure or combustion. When this has been determined, a nozzle may be selected that will provide that density at a velocity adequate to overcome air currents and to carry the spray to the equipment to be protected. Each nozzle must have the proper angle of discharge to cover the area to be protected by the nozzle.

Determining the proper density needed for extinguishment requires considerable engineering judgment and, in the case of flammable or combustible liquids, depends on such characteristics of the fuel as vapor pressure, flashpoint, viscosity, water solubility, and specific gravity. The density varies between 0.2 and 0.5 gpm/ft^2 (8.1 to 20.4 L/min/m^2) of protected surface.

For exposure protection of vessels, a density of 0.25 gpm/ft^2 (10.2 L/min/m^2) should provide sufficient cooling to limit an exposure fire's heat input through the vessel walls to 6000 Btu/hr/ft^2 (18,930 W/m^2). The water density required for exposure protection of structural supports and miscellaneous equipment, such as cable trays and runs, pipe racks, transformers, and belt conveyors, varies from 0.1 to 0.3 gpm/ft^2 (4.1 to 12.2 L/min/m^2) of exposed surface area. NFPA 15 should be consulted for more details on required distribution densities.

When water spray is to be used to protect oil-filled electrical equipment, such as transformers and large switch gear, special care must be taken to provide safe electrical clearances. Special fixed water spray nozzles have been developed to provide adequate spray density and range to accommodate wind, along with a simplified piping arrangement that is spaced safely from energized electrical parts.

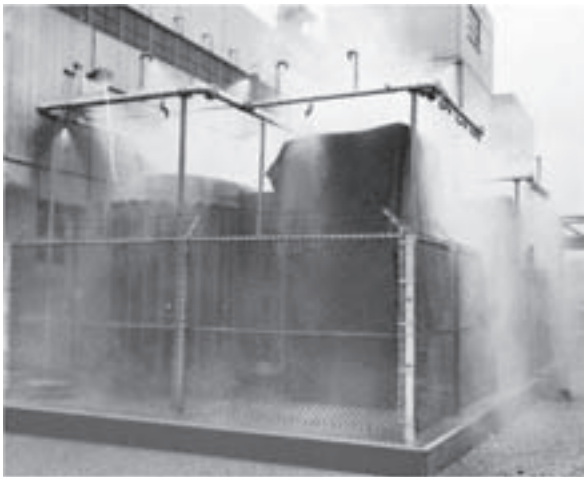

FIGURE 16.9.2 Water Spray System for Oil-Filled Electric Power Transformers

Selection and Use of Spray Nozzles

The selection of spray nozzles should take into consideration such factors as the character of the hazard to be protected, the purpose of the system, and the possibility of severe winds or drafts. In addition to different spray angles, droplet sizes, and velocities, spray nozzles are available in a variety of discharge patterns such as hollow cone, full cone, and flat discharge characteristics.

Nozzles of one type cannot be substituted for nozzles of another type when a water spray system is being repaired or nozzles are being replaced without taking into account the possibility of seriously compromising the effectiveness of the system. In general, the velocity, distribution, and size of water droplets affect the "reach" and coverage of the water spray pattern.

Some spray nozzles produce spray by giving the water streams a rotary motion in spiral passages inside the nozzles. These rotating streams are mixed internally with a center stream to project a solid cone of water spray from the nozzle. These nozzles are known as the internally impinging type (Figure 16.9.3). Another type of water spray nozzle uses the deflector principle of a sprinkler. The water-discharge orifice projects a solid, cylindrical stream of water onto a deflector that alters the stream into a conical distribution of water spray (Figure 16.9.4).

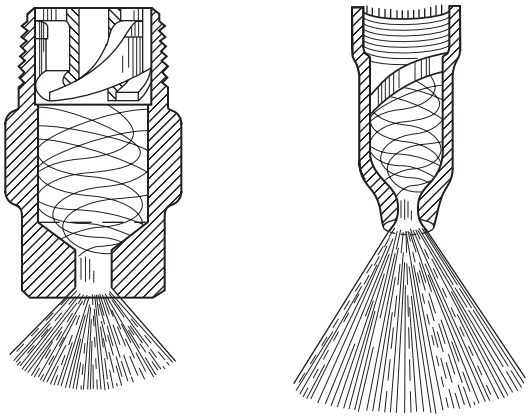

FIGURE 16.9.3 Water Spray Nozzles with Internal Spiral Water Passages

FIGURE 16.9.4 Water Spray Nozzle Using the Deflector Principles of the Standard Automatic Sprinkler

A characteristically different type of water spray nozzle discharges water along the axis of a spiral of diminishing inside diameter. This spiral continuously peels off a thin layer of water from the surface of the cone, and this thin layer of water breaks into spray as it leaves the spiral (Figure 16.9.5). Another unique type of water spray nozzle discharges water in a flat or sheet-type pattern. A flat spray nozzle has a deflector that diverts the discharged water from the axis of the inlet pipe connection (Figure 16.9.6). This discharge characteristic can be useful in developing an overlapping, flat spray between adjacent nozzles. These nozzles are commonly used to protect windows and structures from exposure fires.

Pipe Sizes

Once the type of nozzle has been selected and the location and spacing to give the desired area coverage have been determined, hydraulic calculations are made to establish the appropriate pipe sizes and water supply requirements. Pipe sizes must be calculated hydraulically for each system so that the water at the spray nozzles will have adequate pressure to provide the necessary flow and spray pattern. A procedure for making the hydraulic calculations for a fixed pipe water spray system is given in the Appendix to NFPA 15.

FIGURE 16.9.5 Spiral-Type Water Spray Nozzle

FIGURE 16.9.6 Flat-Spray-Type Water Spray Nozzle (Tyco Issue A) (Courtesy of Tyco Fire and Building Products)

Hydraulic calculations of water spray systems need to take into consideration the velocity head pressure in the calculations where the velocity pressure exceeds 5 percent of the total pressure at any junction point. When velocity pressures are high at a junction, the hydraulic principle in the tie fitting will not allow sufficient water to flow from the side outlet (acting much like a siphon). Ignoring the velocity pressure under these conditions can introduce a significant error, resulting in an actual nozzle pressure that is less than required. The 5 percent value used to determine whether velocity pressure needs to be considered can also be expressed in terms of velocity and total pressure. If $V \leq 2.7\ (P_T)^{1/2}$ then the velocity pressure does not need to be calculated, where V is the velocity (ft/sec) and P_T is the total pressure (psi).

Figure 16.9.7 shows a typical example of where the velocity head pressure needs to be included in the calculation as demonstrated by comparing calculations of the example configuration with (Figure 16.9.8) and without (Figure 16.9.9) veloc-

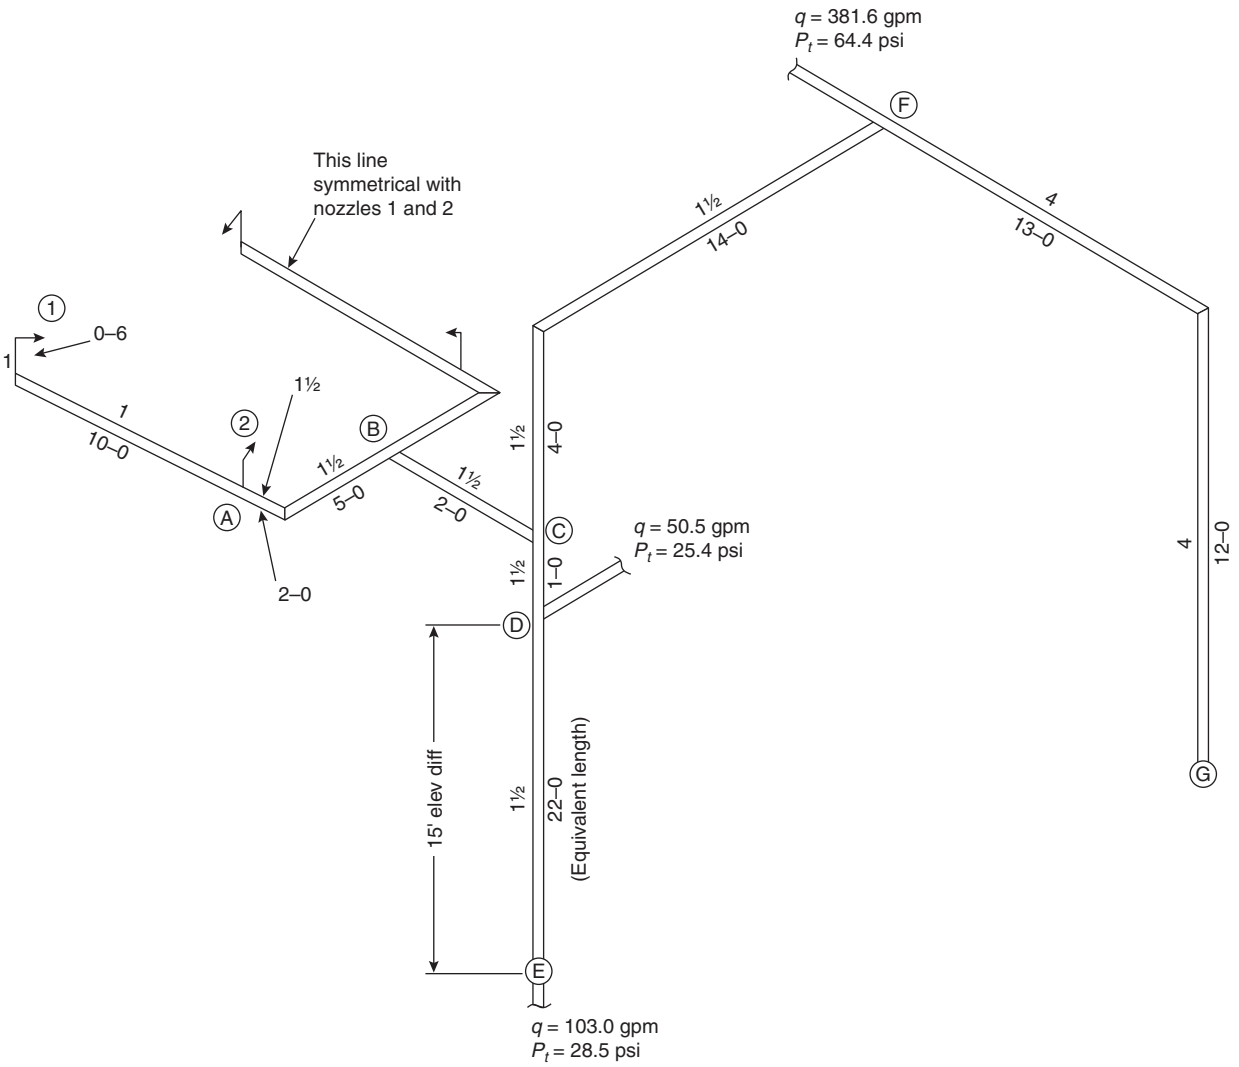

FIGURE 16.9.7 Water Spray System Used for Sample Calculation Shown in Figures 16.9.8 and 16.9.9

ity head pressures used in the calculations. Two methods exist to connect the system to a more balanced configuration, which include (1) increasing the pipe size upstream to reduce the effects of velocity pressure and (2) converting the side outlet tee fitting to a bullhead tee fitting (Figure 16.9.10).

WATER DEMAND AND SUPPLIES

Many factors govern the size of a water spray system, including the nature of the hazard or combustibles involved, the amount and type of equipment to be protected, the adequacy of other protection, and the size of the area that could be involved in a single fire. The size of the system needed may be minimized by taking advantage of possible subdivision by firewalls; by limiting the potential spread of flammable liquids with dikes, curbs, or special drainage; by installing water curtains or heat curtains; or by using a combination of these features.

The water demand will be heavy because water spray systems must perform as deluge-type systems with all nozzles open and because high densities of water are needed. Each hazard should be protected by its own water spray system to limit the cumulative demand on the water supply.

NFPA 15 advises that the size of a single water spray system be limited only by the available water supply so that the designed discharge rate will be calculated at the minimum pressures for which the nozzles are effective. Experience has shown that, in most installations, a single system should not exceed a design discharge rate of 3000 gpm (11,356 L/min). Separate hazard areas should be protected by separate systems.

Water Demand Rate

The water supply must be adequate to supply the operating water spray system(s) with the required gpm (L/min) at effective pressure. Water spray systems adjacent to the hazard initially protected may require additional water. The water supply

For all nozzles shown, K = 5.56; each nozzle covers 100.8 ft^2 at 0.25 gpm/ft^2 = 25.2 gpm minimum (Schedule 40 pipe used in example)

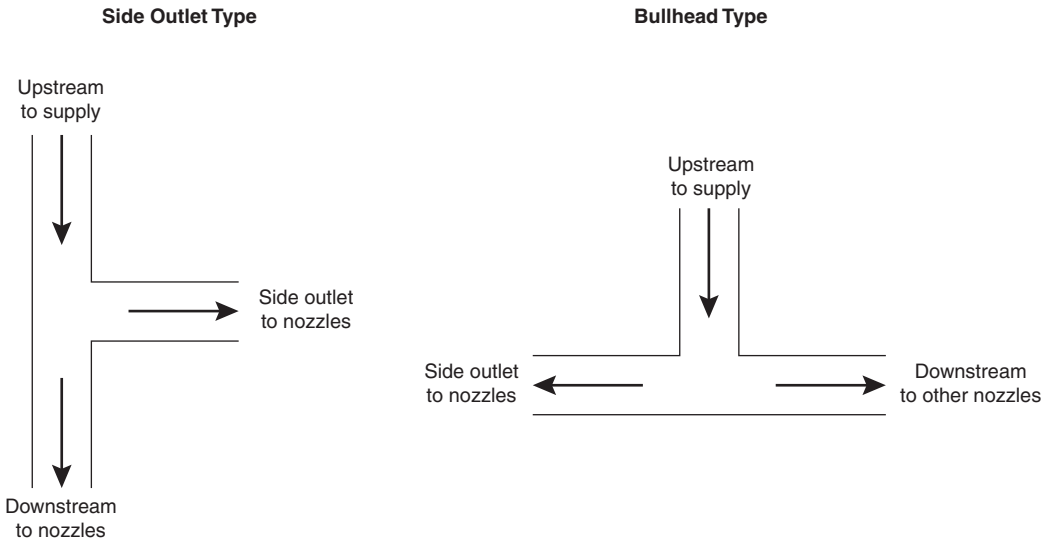

FIGURE 16.9.10 Tee Fittings—Side Outlet and Bullhead Types

should be able to supply hose streams simultaneously. The total required water supply pressure and flow rates should be considered when the system is designed. The duration of the discharge required varies according to the nature of the hazard, the purpose for which the system is designed, and other factors that can be evaluated only for each installation.

Waterflow demand is specified in terms of the density of a uniformly distributed spray measured in gpm/ft^2 (L/min/m^2) of area protected. The discharge rate per unit of area depends on whether the spray system is installed to extinguish a fire, to control a fire, or to protect an exposure, and on the characteristics of the materials involved.

Water Supplies

Fixed spray systems usually are supplied from one or more of the following:

- Connections from a reliable waterworks system of adequate capacity and pressure
- Automatic fire pumps with reliable power and a water supply of adequate capacity and reliability
- An elevated gravity tank of adequate capacity and elevation

The capacity of pressure tanks generally is not adequate to supply water spray systems. However, they may be acceptable as water supplies to small systems whose water and pressure requirements do not exceed the tank's capabilities.

OTHER CONSIDERATIONS AND MAINTENANCE

Strainers

Strainers are required in the supply lines of fixed piping spray systems to keep the nozzles from clogging where the waterways of nozzles are less than ⅜ in. (9.5 mm) or for systems in which the water is likely to contain obstructive material. The baskets of those selected should have a mesh small enough to protect the smallest water passages in the nozzles used. Figure 16.9.11 shows a Grinnell Model A strainer with a basket-type screen of corrosion-resistant metal. This particular strainer is available in 3 in., 4 in., 6 in., 8 in., and 10 in. sizes (1 in. = 25.4 mm). Water spray nozzles with very small water passages may have their own internal strainer, as well as a supply-line strainer to remove larger foreign material.

Drainage

Fixed water spray systems discharge large quantities of water. Special drainage and disposal facilities are important to control the spread of flammable or hazardous liquids to areas adjacent to the fire. Pitched floors, curbs, trenches, dikes, and sumps should be provided to direct the mixture of flammable or hazardous liquids and water runoff. These should be connected to a facility that separates flammable and hazardous liquids from the water. These liquids should be impounded in controlled areas until they can be disposed of safely.

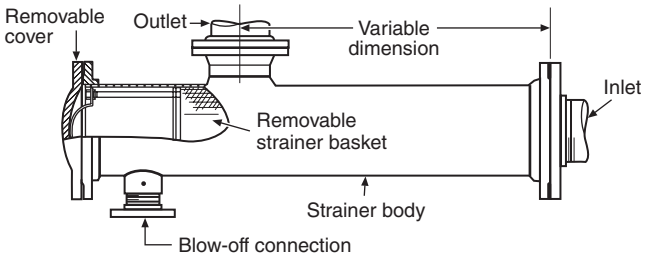

FIGURE 16.9.11 Grinnell Model A Strainer

Maintenance

It is important that fixed water spray systems be inspected and maintained on a regular basis. NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems,* provides specific requirements for periodic inspection, testing, and maintenance of water spray systems. Included in a scheduled inspection program are such items as strainers, piping, control valves, system actuation valves, heat-actuated devices, and spray nozzles, particularly those equipped with strainers. Flow tests are conducted frequently to ensure satisfactory operation. After the tests have been completed, it is necessary to clean all strainers and to check all valves to be sure the system is in normal operating condition.

Nozzles with blow-off caps or plugs are provided to protect the interior of the piping and the nozzles located in areas containing paint vapor, corrosive vapors, dusts, or other foreign matter. Other blow-off caps or plugs are attached to the nozzles to allow them to retain water in the piping system and, thus, reduce the time between the operation of the deluge valve and the discharge of water spray from the nozzles (Figure 16.9.12). Regular inspection and maintenance should confirm that caps and plugs are in place.

Specialized Systems Using Water

Specialized systems using water spray have been developed to fill particular fire control needs in the explosives industry. These systems are referred to as ultra-high-speed water deluge spray systems. (See Section 16, Chapter 7, "Ultra-High-Speed Water Spray Systems," for additional information on these systems.)

SUMMARY

Water spray systems primarily provide fire protection for specific hazards; that is, they are designed to protect specific hazards and equipment with surface coverage. This chapter addresses the applications of water spray systems in terms of fire suppression, control, and extinguishment and describes the components and specialized uses of water spray systems.

Chapter Contents

Standpipe System Design Considerations
Standpipe System Installation Considerations
Commissioning of Standpipe Systems
Fire Department Operations Using Standpipe Systems
Outside Hose Systems

Key Terms

automatic-dry standpipe system, automatic-wet standpipe system, fire department connection, manual-dry standpipe system, manual-wet standpipe system, semiautomatic-dry standpipe system, standpipe system, stationary fire pump, system demand

Standpipe systems are fixed piping systems with associated equipment that transports water from a reliable water supply to designated areas of buildings where hoses can be deployed for fire fighting. Such systems are typically provided in tall and large-area buildings.

Standpipe systems can significantly improve the efficiency of manual fire-fighting operations by eliminating the need for long and cumbersome hose lays from fire apparatus to a fire. Even in buildings that are protected by automatic sprinklers, standpipe systems can play an important role in building fire safety by serving as a backup for, and complement to, sprinklers.

The NFPA standard regulating the design, installation, and testing of standpipe systems is NFPA 14, *Standard for the Installation of Standpipe and Hose Systems* (references to NFPA 14 are based on the 2007 edition). Note that NFPA 14 does not cover where standpipe systems are required. Required installations are set forth in code documents, such as NFPA *101*®, *Life Safety Code*®; NFPA 1, *Uniform Fire Code*™; and model building codes, or they may be established by insurance regulations.

NFPA 13, *Standard for the Installation of Sprinkler Systems,* is a useful reference when considering hydraulically designed systems or combined sprinkler and standpipe systems. Other NFPA standards and recommended practices that may be helpful when dealing with standpipe systems are included in the bibliography at the end of this chapter.

For other information relevant to standpipe systems, see Section 15, Chapter 1, "Fixed Water Storage Facilities for Fire Protection"; Section 15, Chapter 6, "Water Distribution"; and Section 16, Chapter 11, "Care and Maintenance of Water-Based Extinguishing Systems."

STANDPIPE SYSTEM DESIGN CONSIDERATIONS

All standpipe systems share a common purpose of delivering water for manual fire fighting. However, system designs used to accomplish this purpose will vary. Whereas one system may involve a simple pipe network for conveying water from fire department apparatus to hose connections in a building, another may involve a fully automatic water supply and preconnected hoses.

Standpipe system designs are generally dictated by NFPA 14, but local, state, and model building codes and insurance standards may also have an influence. The requirements among these codes and standards vary, so it is essential for system designers to determine which codes and standards have been adopted by the regulating entity.

Because NFPA 14 is often recognized as the design standard for standpipe systems, the following discussion on design considerations focuses on the regulatory requirements in NFPA 14. In addition, model building code requirements and engineering and historical perspectives are also discussed.

The Design Process

The process of designing a standpipe system begins with determining the intended use, that is, whether it is for (1) full-scale fire fighting, (2) first-aid fire fighting, or (3) both. These three uses

David R. Hague, P.E., is a principal fire safety and systems engineer for NFPA. He serves as staff liaison for several water-based standards, including NFPA 14.

correspond with the three classes of standpipe systems—Class I, Class II, and Class III. Most aspects of system design, such as the required water supply, layout, and system components, are affected or dictated by the class of system.

Classes of Systems

Standpipe systems are designated as Class I, Class II, and Class III. Some sources refer to a fourth class of system called a "combined" system; however, combined systems are simply Class I or Class III standpipe systems that also supply water to a sprinkler system. Note that sprinkler systems with hose connections are not necessarily considered to be standpipe systems. Such systems are often regarded simply as sprinkler systems. The design of a combined system is similar to any other Class I or Class III system, except that the water supply and pipe sizes may be larger to accommodate the added sprinkler system demand.

Class I Systems. A Class I system provides 2½ in. (65 mm) hose connections at designated locations in a building for use by the fire department.

A Class I system is typically required in buildings that have more than three stories above or below grade because of the time and difficulty involved in laying hose from fire apparatus directly to remote floors. Class I systems are also sometimes required in malls because these occupancies contain areas that are difficult to access directly with hose from fire apparatus.

Class II Systems. A Class II system provides 1½ in. (40 mm) hose connections at designated locations in a building for first-aid fire fighting. These systems are generally intended for use by trained fire brigades before the fire department arrives, but they are occasionally provided for use by fire departments, as well. With Class II systems, a hose, a nozzle, and a hose rack are typically installed on each hose connection.

Class II systems are often required in large unsprinklered buildings. They may also be required to protect special hazard areas, such as exhibit halls and stages.

With respect to Class II standpipe systems, members of the fire protection community disagree about the desirability of having standpipe systems available for occupant use. Concerns focus on the ability of untrained occupants to safely use a 100-ft (30.5-m) long hose flowing up to 100 gpm (378 L/min) and on the wisdom of encouraging occupants to fight a fire instead of evacuating. These concerns have led to a trend of reducing the requirements for, or eliminating the installation of, standpipe systems with preconnected hoses. Consequently, the use of Class II systems is declining. The 2007 edition of NFPA 14 no longer recognizes "Building Occupant Use" of standpipes but refers to "Trained Industrial Fire Brigades."

Class III Systems. Class III systems combine the features of Class I and Class II systems. They are provided for both full-scale and first-aid fire fighting. These systems are generally intended for use by fire departments and fire brigades. Because of their multiple uses, Class III systems are provided with both Class I and Class II hose connections. This is sometimes accomplished by using 2½ in. (65 mm) hose valves with easily removable 2½- to 1½-in. (65- to 40-mm) adapters that are permanently chained to hose connections. Where Class III systems are required by code, the system may be provided with a 2½ in. (65 mm) hose value, a 2½ in. × 1½ in. (65 mm × 40 mm) reducer, and a cap and chain in lieu of providing hose.

Class III systems are sometimes used when both Class I and Class II systems are required and no useful purpose would be served by installing separate systems. Like Class II systems, the use of Class III systems is declining because of concerns about the safety and effectiveness of untrained occupants fighting fires.

Types of Systems

In addition to being subdivided into classes that delineate the intended use of a system (i.e., fire department use or industrial fire brigade use), standpipe systems are also classified by "type." These types delineate the basic characteristics of systems; that is, whether the piping will be filled with water or not (wet versus dry), and whether the water supply for fire fighting will be automatically available or not (automatic, semiautomatic, or manual).

Beginning with the 1993 edition of NFPA 14, standpipe system types were completely redefined. The result was the creation of five categories, as follows:

1. *Automatic-wet systems* have piping that is filled with water at all times and have an automatically available water supply capable of supplying the water demand necessary for fire fighting.

2. *Automatic-dry systems* have piping that is normally filled with pressurized air. These systems are arranged, through the use of devices such as a dry-pipe valve, to automatically admit water into system piping when a hose valve is opened, and they are connected to an automatically available water supply that is capable of supplying the water demand necessary for fire fighting.

3. *Semiautomatic-dry systems* have piping that is normally filled with air that may or may not be pressurized. These systems are arranged through the use of devices, such as a deluge valve, to admit water into system piping when a remote actuation device located at a hose station, such as a pull station, is operated. They also have a preconnected water supply that is capable of supplying the water demand necessary for fire fighting.

4. *Manual-dry systems* have piping that is normally filled with air, and these systems do not have a preconnected water supply. A fire department connection must be used to manually supply water for fire fighting.

5. *Manual-wet systems* have piping that is normally filled with water for the purpose of keeping the system full of water, thus avoiding "fill time" when the system is used. The water supply for these systems is typically provided by a small connection to domestic water piping, and it is not capable of supplying fire-fighting water demands. A fire department connection must be used to manually supply water for fire fighting.

In summary, wet systems have water-filled piping and dry systems do not. Automatic systems provide a water supply for

fire fighting simply by opening a hose valve. Semiautomatic systems are connected to a water supply for fire fighting but require activation of a device at a hose valve in addition to opening the valve to get water. Manual systems do not have a preconnected water supply for fire fighting, and these systems must be manually supplied by connecting hoses from a fire department pumper truck to a fire department connection.

Design Restrictions Based on System Class and Type

NFPA 14 specifies several design limitations based on the type of system to be used.

Manual standpipe systems are not allowed to be used in high-rise buildings. This is partly to provide an increased level of safety in such buildings and partly in recognition of the fact that a sprinkler system will be required by building codes for high-rise buildings, almost surely necessitating a fire pump. In such applications, the standpipe and sprinkler systems are "combined" using common feed main piping precluding the use of dry systems. Once a pump is called for, it is considered reasonable to require that the pump be capable of supplying the standpipe system demand, given the marginal additional cost.

Manual systems are also prohibited for Class II and Class III systems, because systems with preconnected hose obviously need an available water supply to be of benefit in fighting incipient fires.

Dry systems are not allowed for most Class II or Class III systems because of the risk to untrained users that would be created by delaying the availability of water. Also, dry systems are allowed only in areas subject to freezing, because wet systems are considered more reliable. Dry standpipes have been known to perform unsatisfactorily in the past because open valves or severe leaks went undetected until the system was charged with water. The NFPA 14 committee considered this risk of failure avoidable for most cases by simply requiring system piping to be filled with water unless a risk of freezing is present.

System Layout

Number and Location of Hose Connections. The required number of hose connections is primarily based on a building's design. Codes and standards employ two approaches to determining hose connection locations. The first method, termed the "actual length" method, is used only for 1½ in. (40 mm) hose connections on Class II and Class III systems. This method locates 1½ in. (40 mm) hose connections such that enough are provided to reach all portions of the area served with a 100 ft (30.5 m) hose that has a nozzle with a 20- to 30-ft (6- to 9-m) reach. The 100 ft (30.5 m) length limit is required for ease of handling. Distances should be measured around partitions and obstructions for hose length and along unobstructed straight-line paths for nozzle reach.

Because standpipe systems with preconnected hose are usually intended for extinguishing incipient fires before the fire department arrives, 1½ in. (40 mm) hose stations should be located in central areas, such as corridors, where they are clearly visible and readily accessible. Figure 16.10.1 illustrates the actual length method for locating hose stations. In the actual length method (as illustrated on a partial floor plan), a maximum distance of 130 ft (39.5 m), consisting of 100 ft (30.5 m) of flexible hose-lay distance and 30 ft (9 m) of straight-line nozzle trajectory is the basis for locating the 1½ in. (40 mm) hose stations.

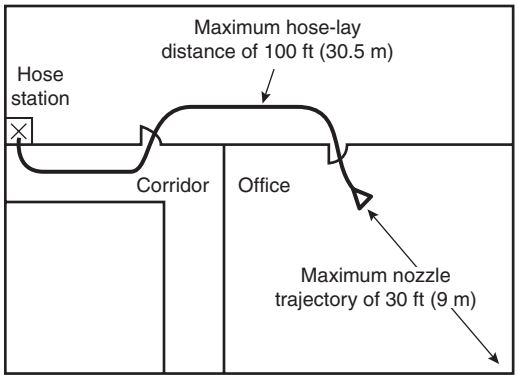

FIGURE 16.10.1 Actual Length Method for Locating Hose Connections

The second method, termed the "exit location method," is used for 2½ in. (65 mm) hose connections on Class I and Class III systems. This method locates connections based on a building's exiting system. Using this method, 2½ in. (65 mm) hose connections are located in exit stairs, at horizontal exits, and in exit passageways, as required by the building code. Because exits must be reasonably distributed within buildings to provide adequate egress, hose connections are considered to be adequately distributed when located at the points of egress from areas served. Figure 16.10.2 illustrates the exit location method for locating hose connections. In the exit location method, maximum travel distance to an exit (door), as established by the applicable building code, is the basis for locating required 2½ in. (65 mm) hose connections. Enclosed exit stairways are also

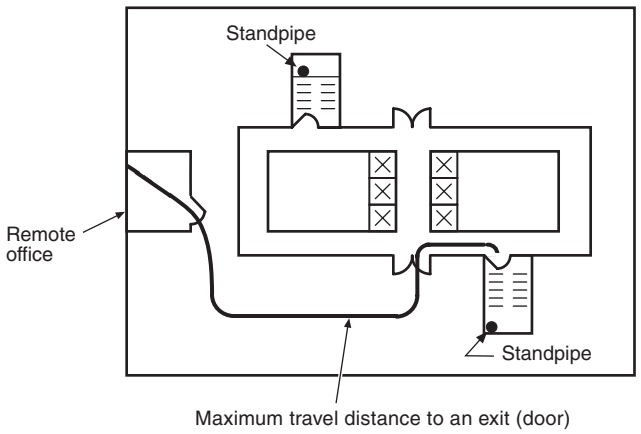

FIGURE 16.10.2 Exit Location Method for Locating Hose Connections

considered to be protected spaces and afford fire fighters an area to stage fire-fighting operations.

In early editions of NFPA 14, Class I hose connections were required to be located using the actual length method. In the 1993 and subsequent editions, the method specified is the exit location method. This switch was made because the actual length method encouraged locating hose connections in open-floor areas to meet distance requirements. Such locations are not advantageous to fire fighters because they may be obstructed by smoke or exposed to fire, preventing their use. NFPA 14 now recognizes that it is preferable to locate 2½ in. (65 mm) hose connections where they will be protected from a fire, such as within protected stair enclosures or on opposite sides of horizontal exits. This location allows fire fighters to connect to a system in relative safety and to have a charged hose available before entering a fire area.

Some have argued that extending hose from the inside of an exit enclosure compromises enclosure integrity and places occupants at risk during evacuation. However, NFPA 14 recognizes that the alternative is an unreasonable expectation of fire fighters to enter an area filled with smoke and heated gases to search for a hose connection, placing them in extreme danger. In addition, time lost while searching for a hose connection would prolong an uncontrolled fire, potentially posing a much greater threat to occupants.

It should be noted that NFPA 14 does permit additional 2½ in. (65 mm) hose connections to be required by local authorities when exit travel distances exceed 150 ft (46 m) in non-sprinklered buildings and 200 ft (61 m) in sprinklered buildings. This special option is provided because exit travel distance for occupants going out effectively equates to the maximum hose-lay distance for fire fighters going in, and deploying more than 200 ft (61 m) of charged hose is recognizably difficult. If additional connections outside of exit enclosures are considered necessary, they should be located only in areas protected by fire-resistive construction so that fire fighters will have a protected environment in which they can connect hoses.

For the purpose of locating standpipe outlets, the roof should be treated as an additional floor. Thus, for buildings with two or more standpipes, the building roof should be provided with two or more outlets. Beginning with the 2007 edition of NFPA 14, roof outlets can be omitted where the roof pitch is greater than 3 in 12. An additional outlet must be provided at the top of the standpipe for testing purposes. This outlet will permit flowing 500 gpm (1893 L/min).

Positioning of Hose Connections at Landings. One other aspect of locating 2½ in. (65 mm) hose connections that is worthy of discussion is the positioning of hose connections within stair enclosures. In earlier editions of NFPA 14, hose connections were required at floor levels within stair enclosures, positioning that actually hampered fire-fighting efforts.

The prior standards failed to recognize that fire departments typically use connections at the floor below the fire floor to leave the doorway to the fire floor uncongested and to give the fire fighters a safer location for connecting hoses. However, connecting hoses an entire story below the fire floor uses up valuable hose length, and connecting at a floor-level landing obstructs the adjacent doorway. The solution now included in NFPA 14 is to place connections at intermediate floor landings. This placement allows hoses to be connected somewhat below the fire floor while minimizing the additional hose length required to do so. It also avoids congestion problems associated with having hose connections located adjacent to exit doors and areas of wheelchair refuge within stairwells. Locating hose connections in this manner also prevents kinking hose, as it bends around doorways.

Interconnection of Piping. One last item to remember when laying out a system is that standpipes must be interconnected as close as possible to the source of supply, or at the top when gravity tanks are used. Interconnection of standpipes ensures that water supplies can service all portions of a system.

Water Supply and Piping Requirements

The class and type of system to be installed will dictate the required water supply. There are three aspects of water supplies that must be taken into account: (1) the minimum flow rate required, (2) the minimum pressure required, and (3) the type of supply to be used. In addition, the maximum pressure available may also be of concern.

Minimum Flow Rate and Minimum Pressure (System Demand). The minimum required flow and minimum required pressure are together referred to as the "system demand." The system demand for a standpipe system is a function of several variables:

1. The required flow rate and pressure at the hydraulically most remote hose connections
2. Required flow rates for additional standpipes
3. The water supply requirements for automatic sprinklers sharing common piping
4. Pressure losses from friction and changes in elevation between the water supply and the hydraulically most remote hose connection

Minimum flow rate and pressure requirements for standpipe systems are determined based on the class of system. According to NFPA 14, Class I and Class III systems are typically required to deliver 500 gpm (1893 L/min) for the first standpipe, plus 250 gpm (946 L/min) for each additional standpipe, up to a maximum of 1250 gpm (4731 L/min). The maximum flow is reduced to 1000 gpm (3785 L/min) for combined systems in recognition of the assistance provided by sprinklers even when sprinklers alone have been unable to control a fire. NFPA 14 also requires the water supply to be capable of providing the minimum flow rate for 30 minutes. This duration is intended to apply to automatic and semiautomatic supplies, and it assumes the fire department runs on a separate water source to supply the system using pumper trucks within 30 minutes. Figure 16.10.3 illustrates these design flow rate requirements for Class I and Class III systems.

With respect to pressure, NFPA 14 requires that a water supply for Class I and Class III systems be able to deliver a residual pressure of 100 psi (690 kPa) at the outlet of the topmost hose

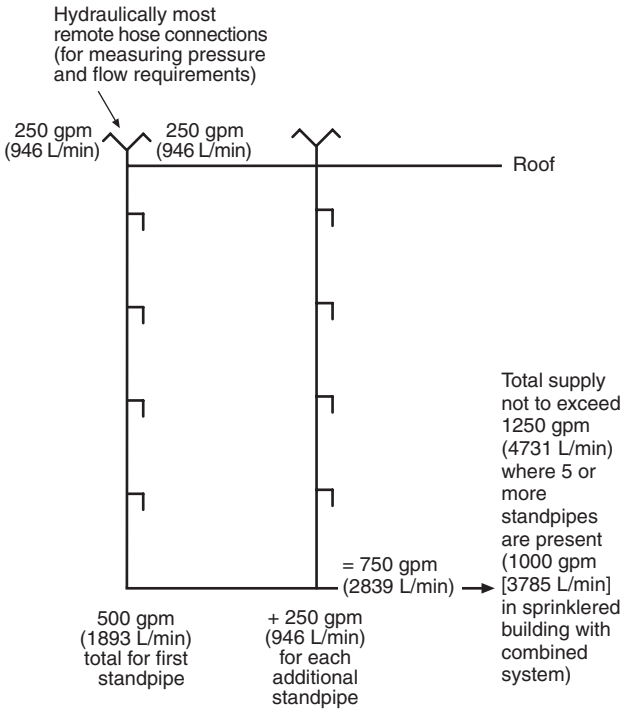

FIGURE 16.10.3 Basic Flow Rate Requirements for Class I and Class III Systems

TABLE 16.10.1 Pressure Limits for Standpipe System Outlets

Outlet Use	*Minimum Residual Pressure*	*Pressure-Regulating Device Required When Pressure Exceeds*[b]
1½ in. (40 mm) hose connection with preconnected hose	65 psi[a] (448 kPa)	100 psi (690 kPa)[c]
1½–2½ in. (40–65 mm) hose connection without preconnected hose	100 psi[a] (690 kPa)	175 psi (1207 kPa)[d]
Sprinkler system connection	per NFPA 13	175 psi (1207 kPa)[d]

[a]Measured at the hydraulically most remote hose connection while flowing at a rate specified by NFPA 14.
[b]Pressures in system piping should never exceed the rating of any system component.
[c]This is a residual pressure limit. Static pressure cannot exceed 175 psi (1207 kPa) before a pressure-regulating device is required.
[d]A setting of 165 psi (1138 kPa) can be used on a combined sprinkler/hose connection on combined systems while achieving acceptable flows and nozzles pressure. Set pressure-regulating device at 165 psi (1138 kPa) because NFPA 13 will require a relief valve set at 175 psi (1207 kPa).

connection on each standpipe. This pressure must be available while flowing 250 gpm (946 L/min) from each of the two topmost hose connections of the hydraulically most remote standpipe, plus 250 gpm (946 L/min) from each additional standpipe, up to the required maximum. Note that NFPA 14 no longer allows a reduction in the minimum pressure requirement.

For Class II systems, NFPA 14 requires that the water supply be capable of delivering 100 gpm (379 L/min) for 30 minutes. It must also be strong enough to maintain a residual pressure of 65 psi (448 kPa) at the outlet of the hydraulically most remote hose connection with 100 gpm (379 L/min) flowing.

In addition to minimum pressure and flow requirements, there are maximum pressure limits for hose connections as well. For a discussion on maximum pressure limits, see the subsection "Maximum Pressure and Zoning in Tall Buildings" later in this chapter.

See Table 16.10.1 for a summary of requirements.

Supplying System Demand for Standpipe Systems. For manual systems (described previously) the system demand must be supplied exclusively through the fire department connection. An automatic water supply is not required on such systems, and even where a manual-wet standpipe is combined with a sprinkler system, the standpipe demand does not have to be available via the preconnected water supply serving sprinklers.

History of Outlet Pressures and Fire-Fighting Nozzles. NFPA 14 was modified in the 1993 edition to increase the minimum outlet pressure for Class I and Class III outlets from 65 psi (448 kPa) to 100 psi (690 kPa) because of questions raised regarding the adequacy of a 65 psi (448 kPa) minimum design pressure on automatic and semiautomatic standpipes. From a performance perspective, the NFPA Committee on Standpipe and Hose Systems (NFPA 14 committee) agreed that the minimum pressure at any hose connection should be adequate to properly operate a fire nozzle while overcoming friction loss in a hose. From a design perspective, the establishment of a minimum design pressure for hose connections has proven difficult because nozzle operating pressures and friction losses in hoses vary, depending on the equipment used by each local fire department.

The concern over nozzle pressure originally became an issue when fog nozzles were introduced for fire fighting in the mid-1900s. Before fog nozzles, fire fighters used solid stream nozzles, which operated well at fairly low inlet pressures. As the use of fog nozzles became common, the fire protection community moved to increase the minimum pressure required at the hydraulically most remote hose connections on standpipe systems to accommodate the greater nozzle pressure required by fog nozzles. The NFPA 14 committee originally recommended a pressure of 65 psi (448 kPa), which was widely implemented. In establishing this pressure, the committee had tried to minimize the pressure required for standpipe system water supplies and assumed that nozzle designers and testing laboratories would establish criteria to ensure that fog nozzles would operate satisfactorily with a 65 psi (448 kPa) pressure at hose connections. Unfortunately, this assumption never materialized, and many later questioned the pre-1993 65 psi (448 kPa) minimum pressure requirement.

In reevaluating the minimum pressure requirement for the 1993 edition, the NFPA 14 committee decided that the minimum pressure required at standpipe hose connections must be chosen conservatively. This is because fog nozzle performance, unlike that of solid stream nozzles, varies significantly with respect to the minimum inlet pressure required to achieve satisfactory streams. Though some fire service fog nozzles operate satisfactorily with as little as 70 psi (483 kPa), others have discharge patterns that quickly deteriorate as the nozzle pressure drops below 100 psi (690 kPa). As a result of this inconsistency, the only pressure that will reasonably ensure satisfactory nozzle performance in all cases is the pressure at which nozzles are tested and rated, 100 psi (690 kPa). This is the residual test pressure for fog nozzles established by NFPA 1964, *Standard for Spray Nozzles.*

To deliver a pressure of 100 psi (690 kPa) at the nozzle, the pressure at the standpipe hose connection must exceed 100 psi (690 kPa) by a value great enough to offset friction loss in the hose connecting the nozzle to the outlet. Ideally, a design should provide an additional 25 psi (172 kPa) for this purpose. This is adequate to compensate for friction loss in (1) 200 ft (61 m) of 2½ in. (65 mm) rubber-lined hose flowing about 250 gpm (946 L/min), (2) 200 ft (61 m) of 2 in. (50 mm) rubber-lined hose flowing about 125 gpm (473 L/min), or (3) 150 ft (46 m) of 1¾ in. (45 mm) rubber-lined hose flowing about 100 gpm (379 L/min).

Based on the foregoing reasoning, the NFPA 14 committee contemplated requiring a 125 psi (862 kPa) minimum pressure at the most remote hose connection but eventually decided on 100 psi (690 kPa). At first glance, this figure appears inadequate for satisfactory streams, and an explanation of the committee's action is warranted. The basis of this figure is an assumption that a fire pump will typically be installed to supply an automatic standpipe and that a pump designed to deliver 100 psi (690 kPa) at the most remote outlet at full system demand will actually deliver 120 psi (827 kPa) or more at lower flows. This takes advantage of excess pressure at the low-flow end of a fire pump curve. (See NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection.*)

The 120-plus psi (827 kPa) initial pressure was considered reasonably adequate to satisfy a 100 psi (690 kPa) nozzle inlet pressure plus friction loss in the connecting hose for the first one or two hose lines deployed, and it was assumed that if fire-fighting operations grew beyond this level, fire apparatus would be available to supply additional pressure to meet fire nozzle demands. Alternatively, smooth-bore nozzles could be deployed. If these assumptions are not valid for a particular installation, consideration should be given to exceeding the minimum pressure specified by NFPA 14 to accommodate fire-fighting needs.

Although the 100 psi (690 kPa) minimum design pressure now specified by NFPA 14 may seem excessive when compared to the 65 psi (448 kPa) pressure specified in the past, it is consistent with established fire-fighting practices. Fire departments for decades have used 100 psi (690 kPa) as the target nozzle pressure when pumping hoses supplying fog nozzles, and fire hoses supplying fog nozzles are routinely pumped by fire apparatus at 150 psi (1034 kPa) or more when such hoses are connected directly to such apparatus.

For hose connections on Class II or Class III systems with preconnected hoses installed, nozzles with operating pressures in the 50 psi (345 kPa) range should be specified. By purchasing low-pressure nozzles, the minimum pressure required at the hydraulically most remote hose connection with preconnected hoses can be limited to 65 psi (448 kPa).

For additional information regarding selection of fire nozzles for use with standpipe systems, see "Fire Department Operations Using Standpipe Systems" later in this chapter.

Type and Number of Water Supplies. Manual standpipe systems may be supplied exclusively by a fire department connection (FDC) with a reliable and adequate water source accessible nearby.

Automatic and semiautomatic standpipe systems require a minimum of one preconnected water supply that is capable of supplying the standpipe system's hydraulic demand for the minimum required duration. Several types of water supplies may be acceptable. These include:

1. Public waterworks systems, supplemented by a booster pump when higher pressures are required
2. Fire pumps connected to a reliable fixed water source
3. Pressure tanks
4. Gravity tanks

In addition to the primary water supply on an automatic or semiautomatic standpipe system, one or more FDCs with a reliable water source accessible nearby are required.

Special Water Supply Requirements. In some cases, special water supply requirements may be applicable. For example, buildings in active seismic areas are often required by local regulations to use in-house tanks and pumps to supply standpipe systems rather than relying on public water supplies, which are susceptible to earthquake-induced failure.

Water Supply for High-Rise Buildings. For high-rise buildings, two remotely located FDCs are required for each zone within the pumping range of fire apparatus in addition to the automatic water supply. Two FDCs reduce the possibility of having falling glass cut all supply hoses and interrupt the secondary water supply during a fire.

Very tall buildings with floors located above the pumping range of fire department apparatus require a permanent secondary water source instead of FDCs because failure of the primary supply would otherwise render a building completely unprotected. If the primary water supply uses a pump, the backup arrangement could consist of a second pump, driver, and controller, or, perhaps, high-level water storage with additional pumping capability. The point at which a system is beyond the capability of fire department apparatus depends on the apparatus's pump and the residual pressure available from the water source. A permanent secondary water source is needed, if the following is "true":

$$AP + RP \leq SD$$

where

AP = Apparatus pressure boost available from a fire department pumper measured at the system demand flow rate

RP = Residual pressure available from the public or private water supply measured at the system demand flow rate

SD = System demand pressure at the system demand flow rate, measured at the pumper truck outlet supplying the hose to the FDC

If the system demand exceeds the sum of the fire apparatus pressure boost and the residual supply pressure (or the rated service pressure of the fire hose that will supply the FDC), fire apparatus will not be able to adequately supply upper portions of the standpipe system, and a secondary water supply is necessary. As a rule of thumb, buildings exceeding 300 ft (91.5 m) in height should be evaluated to determine whether the pumping range of the fire department apparatus has been exceeded.

Water Supply and Fire Pumps for Sprinklered Mid-Rise Buildings. An issue that is often raised in the design of standpipe systems for sprinklered mid-rise buildings is whether the sprinkler demand, the standpipe demand, or both, must be supplied by the automatic water supply serving the sprinkler system. The issue can have a major cost impact on mid-rise buildings, because the sprinkler demand can often be supplied by the public water supply without the use of a pump, whereas the standpipe demand almost always requires a pump.

In the 1993 edition of NFPA 14, an effort was made to provide further guidance on this issue. Although the solution is not clearly stated in the document, the intent is clear.

NFPA 14 allows a Class I standpipe system to be a manual system in buildings that are not high-rise buildings (defined as buildings having the floor level of an occupied floor located 75 ft [23 m] or more above the lowest level of fire department access). By allowing such standpipe systems to be manual systems, NFPA 14 does not require an automatic water supply to meet the standpipe demand. Therefore, where such standpipes also serve sprinklers in a combined system, only the sprinkler system demand must be automatically supplied. The combined system, from a standpipe perspective, is merely a Class I manual-wet standpipe system.

Sizing Pipe. Two methods of sizing standpipe system piping are (1) the pipe schedule method and (2) the hydraulic method.

With the pipe schedule method, pipe sizes are prescribed by a schedule, in NFPA 14, based on the class of system and the height of the standpipe. However, pipe schedule systems are no longer common, because buildings with standpipe systems typically require sprinkler protection as well. Such buildings also make use of combined systems, which must be hydraulically designed.

With the hydraulic design method, pipe sizes are calculated so that a system will deliver the minimum required pressure and flow. Pipe sizes must be large enough to allow each water supply, including fire department apparatus, to deliver the required flow at the hydraulically most remote hose connection.

When performing a hydraulic design, the hydraulic characteristics of each water supply must be known. The procedure for determining the hydraulic characteristics of permanent water supplies such as pumps is fairly straightforward and is described in NFPA 20 and in other chapters of this handbook. The procedure for determining the hydraulic characteristics of fire apparatus supplying a standpipe system is similar. Lacking better information about local fire apparatus, a conservative design would accommodate a 1000 gpm (3785 L/min) fire department pumper performing at the level of design specifications set forth in NFPA 1901, *Standard for Automotive Fire Apparatus*. NFPA 1901 specifies that fire department pumpers must be able to achieve three pressure/flow combinations. These are 100 percent of rated capacity at 150 psi (1034 kPa) net pump pressure, 70 percent of rated capacity at 200 psi (1379 kPa) net pump pressure, and 50 percent of rated capacity at 250 psi (1724 kPa) net pump pressure. Therefore, a 1000 gpm (3785 L/min) pumper can be expected to deliver no less than 1000 gpm (3785 L/min) at 150 psi (1034 kPa), 700 gpm (2650 L/min) at 200 psi (1379 kPa), and 500 gpm (1893 L/min) at 250 psi (1724 kPa). Residual supply pressure on the suction side of a pump from a municipal or other pressurized water supply can also be added.

To perform a hydraulic design, one should determine the minimum required pressure and flow at the hydraulically most remote hose connection and calculate this demand back through system piping to each water supply, accumulating losses for friction and elevation changes and adding flows for additional standpipes and sprinklers at each point where such standpipes or sprinklers connect to the hydraulic design path. When considering fire apparatus as a water supply, flows must be calculated from system piping through the fire department connection and back through connecting hoses to the apparatus. If the pressure available at each supply source exceeds a standpipe system's pressure demand at the designated flow, the design is acceptable. Otherwise, the piping design or the water supply must be adjusted. For more information, see Section 15, Chapter 3, "Hydraulics for Fire Protection."

Maximum Pressure and Zoning in Tall Buildings. In tall buildings, standpipe systems are often divided into subsystems to limit system pressure by controlling the maximum height of a water column. These subsystems are called zones. The goal of zoning is to limit the pressure that can be developed in system piping and at hose connections to reduce the need for high-pressure fittings and pressure-reducing valves.

In the 1993 edition of NFPA 14, the previous height limitation was replaced by a pressure limitation of 350 psi (24.1 bar). Beginning with the 2007 edition, the pressure limitation was eliminated in favor of a performance requirement that limits pressure based solely on the pressure rating of the system components. This revision also introduced the concept of a master pressure-reducing valve (PRV) to control pressures at lower elevations on a standpipe system. Traditionally NFPA 14 required a separate pump for each zone of a standpipe system. The 2007 edition of NFPA 14 permits the use of a single high-pressure pump to serve all areas of a building and employing a master PRV to control pressures for the lower floors. See Figure 16.10.4 for master PRV applications. When a master PRV is used, certain restrictions on its use apply. They are as follows:

- A method to isolate the PRV must be provided to allow maintenance and repair.

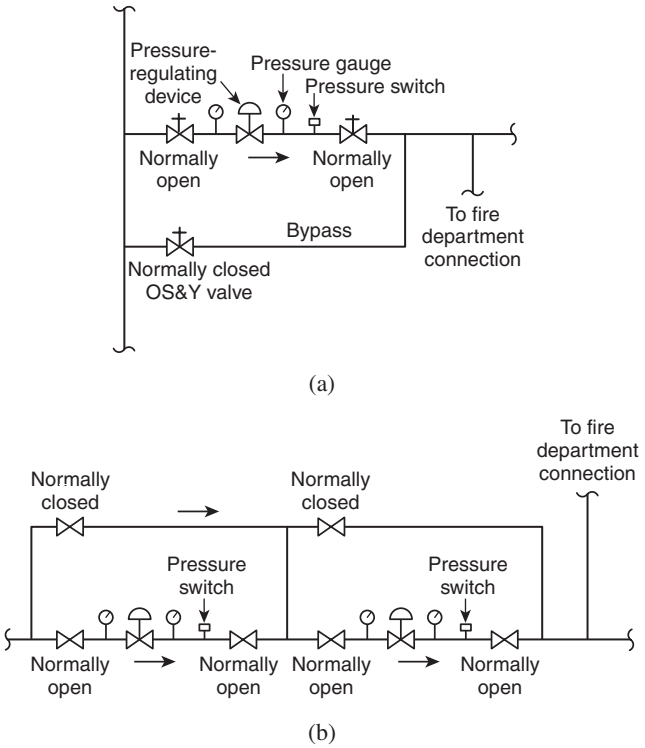

FIGURE 16.10.4 Two Examples of Master PRV Stations

- PRVs must be arranged so that failure of the device does not allow more than 175 psi (12.1 bar) to more than two hose connections.
- An equally sized bypass with a normally closed gate valve must be installed.
- The device must not be located more than 7 ft 6 in. (2.3 m) above the floor.
- Inlet and outlet pressure gauges must be provided.
- FDCs must be connected on the system side of the outlet isolation valve.
- A pressure relief valve must be provided in accordance with the manufacturer's recommendations.
- Remote monitoring for detecting failure of the PRV must be provided.

The maximum pressure in a standpipe system must always be limited based on the pressure ratings of system components. Fittings, valves, and pressure-regulating devices are usually the weakest links among system components with respect to pressure limits. Fittings often have a maximum pressure rating of 175 psi (1207 kPa); however, listed fittings are commonly available with pressure ratings of up to 350 psi (2413 kPa) or more. Listed valves and pressure regulating devices are also available with 350 psi (2413 kPa) or higher ratings. However, zone heights must be further limited if equipment with pressure ratings less than 350 psi (2413 kPa) is used.

Although the maximum zone height corresponding to a particular maximum system pressure can be calculated, zone height limits will be determined by trial and error in most cases. To determine whether a single zone can be used, a designer can lay out a system with one zone and calculate the required pressures and flows from hydraulic demand points back through system piping to the supply to determine the system demand. Assuming that the supply will be a pump, a single zone can be justified if a pump is available that would satisfy the hydraulic demand of the system without exceeding the system component pressure rating at churn, including residual supply pressure. If a pump cannot be found to meet these criteria, adjustments to the design or subdivision into zones can be made or a variable speed pump can be used.

Standpipe system pressures in the 350 psi (2413 kPa) range pose a danger to users and a risk of failure of sprinkler system components on combined systems. Therefore, pressure control devices are required when system pressure could exceed safety limits at hose or sprinkler connections.

The safety limits at hose connections are based on two criteria: (1) hose burst pressure and (2) handling. Hoses for fire department use are required to be tested periodically to 250 psi (1724 kPa) or more, according to NFPA 1962, *Standard for the Inspection, Care, and Use of Fire Hose, Couplings, and Nozzles and the Service Testing of Fire Hose*. NFPA 1962 requires preconnected standpipe hoses to be tested periodically to 150 psi (1034 kPa) or more.

Though a hose may not fail up to these pressures, experience indicates that 175 psi (1207 kPa) is about the maximum pressure on a hose that can be satisfactorily maneuvered by fire fighters and that 100 psi (690 kPa) is the maximum pressure that an untrained user should be expected to handle. Therefore, pressure-regulating devices are required to limit static and residual pressures to 175 psi (1207 kPa) at hose connections without preconnected hoses and to limit residual pressure to 100 psi (690 kPa) at hose connections with preconnected hoses.

The established pressure limit for sprinkler connections is also 175 psi (1207 kPa). This limit is the maximum pressure for which sprinklers are typically listed, and it provides a safety factor to prevent leakage. When higher pressure is expected at a sprinkler connection, both pressure-regulating and pressure relief valves are required. To allow a buffer between the pressure settings for the valves, regulating valves should be set at 165 psi (1138 kPa) and relief valves should be set at 175 psi (1207 kPa).

Table 16.10.1 summarizes the pressure for connections to a standpipe. Figures 16.10.5 and 16.10.6 illustrate sample multiple-zone systems. Note that, on multiple-zone systems, fire pumps may be used in series. In addition, two separate supply risers are always required for high zones supplied by pumps at lower levels so that a water supply can be maintained when one riser is out of service. Separate fire department connections are also required for each zone.

System Components

The selection of standpipe system components is determined largely by the class of system and the system layout. Particular attention should be given to ensuring that components are rated for pressures to which they may be subjected.

Piping and Fittings. Steel pipes assembled with welded joints, screwed fittings, flanged fittings, rubber-gasketed fittings, or a

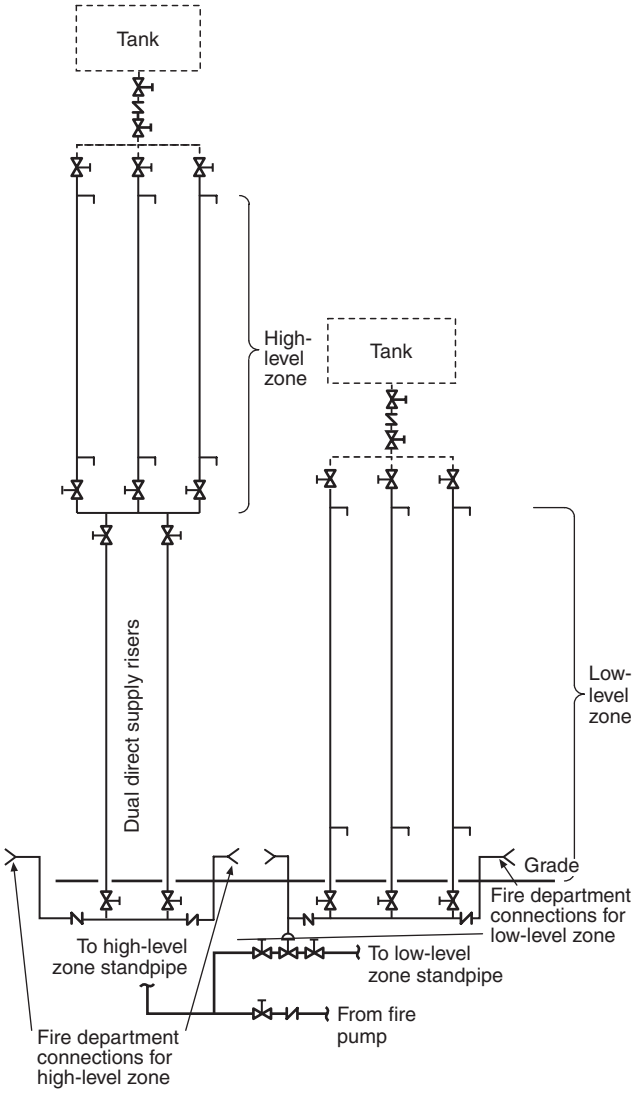

FIGURE 16.10.5 Major Components in a Multizone System with a Low-Level Pump

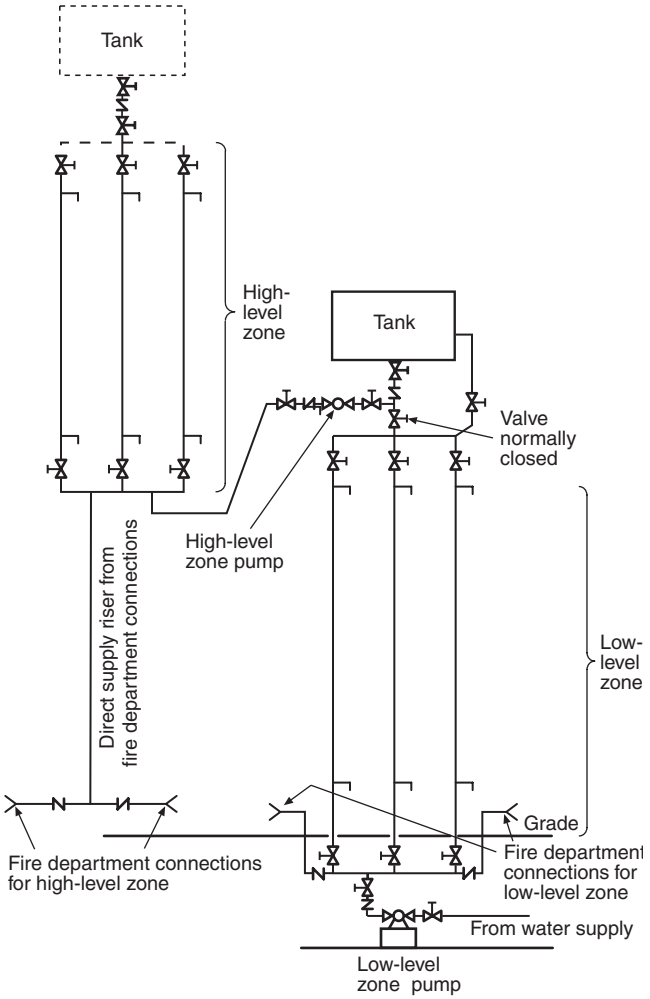

FIGURE 16.10.6 Schematic Diagram of Major Components in a Multizone System with a High-Level Pump

combination of these are the most common configurations of materials used for standpipe system piping and fittings. Piping should be capable of withstanding the maximum pressures that can be developed in a system.

Fittings are required to be rated to withstand either 175 psi (1207 kPa) or maximum system pressures, whichever is greater. When pressures are expected to exceed 175 psi (1207 kPa), extra-heavy fittings or fittings listed for greater pressures should be used for pressures up to 300 psi (2069 kPa), and specially designed fittings should be used for pressures exceeding 300 psi (2069 kPa).

Hose, Hose Racks, Nozzles, and Hose Cabinets. When preconnected hoses are required to be installed on Class II or Class III systems, lined hose must be used. Unlined linen hose has been phased out, because it is subject to rapid deterioration under moist or wet conditions. Usually, the size of choice is 1½-in. (40-mm) hose. However, the use of listed hoses smaller than 1½ in. (40 mm) is permitted by NFPA 14, in light-hazard occupancies when approved by the authority having jurisdiction. The allowance for smaller hose mounted on a reel recognizes that an untrained person might be more capable of using such equipment in the event of a fire. Similar equipment has been used in Europe for many years.

Preconnected hoses on Class II and Class III standpipes are generally limited to 100 ft (30.5 m) in length to minimize the difficulty that untrained users may have advancing a hose and to minimize kinking. Hoses are always required to be kept on compatible racks and should always be positioned in a readily accessible location within convenient reach of a person standing on the floor. Hoses should also be clearly visible and located in a place not likely to be obstructed. Where hoses are kept in cabinets or closets, the doors should have a glass panel or some other means to allow easy identification.

Preconnected hoses are required to be equipped with approved ⅜- or ½-in. (10- or 13-mm) open nozzles or combination spray/solid pattern nozzles. It is preferable to use nozzles that

have operating pressures in the 50 psi (345 kPa) range. This range minimizes the pressure demand on the system and helps to ensure that hoses can be handled by industrial fire brigade members. Because nozzle shutoff valves complicate the operation of a hose, they are considered undesirable unless the users are trained.

For typical hose rack and valve connections, see Figure 16.10.7. A typical hose cabinet is shown in Figure 16.10.8.

Valves. Several different types of valves may be used as components of standpipe systems. These include gate valves, check valves, pressure-regulating valves, and hose valves. Like piping and fittings, valves must be capable of withstanding the maximum pressure that can be developed in a system. The following discussion highlights the most common valves and pressure control devices encountered.

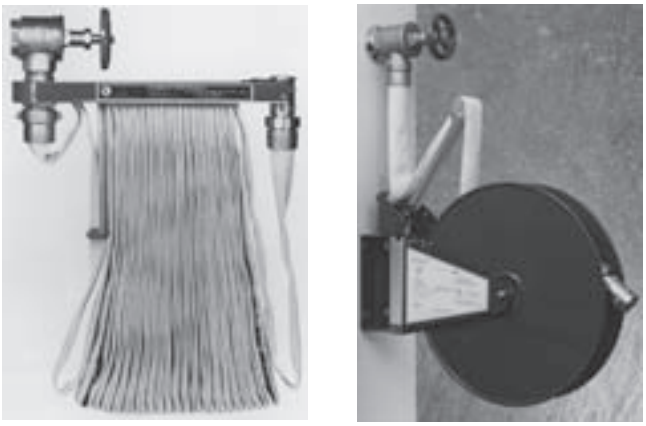

FIGURE 16.10.7 Typical Hose Racks and Valve Connections (Source: Potter-Roemer, Inc.)

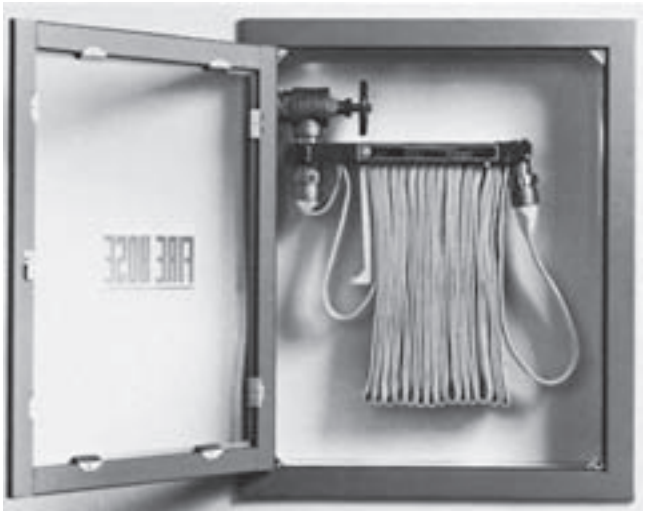

FIGURE 16.10.8 Typical Hose Cabinet

Starting at a permanent water supply, an indicating gate valve is required at each water source to allow isolation of any water source for servicing. Note that a gate valve is not permitted to be installed between a fire department connection and the standpipe system that it serves. This ensures the fire department's ability to pump into a system.

Next, each permanent water source should be protected by a check valve to prevent backflow. Check valves should also be installed between fire department connections and wet standpipe systems that they serve. These valves allow piping that is connected to fire department connections to normally be kept dry, when provided with automatic drain valves at low points. Keeping the FDC dry protects it from freezing and prevents the possibility of having FDC caps "thread-lock" if the internal clapper valves leak water back to the caps.

Moving farther into a system, gate valves should be installed at feed main connections to each standpipe to allow standpipes to be serviced independently without impairing protection to an entire building.

Drain valves also should be provided to allow individual standpipes, as well as an entire system, to be drained for servicing. Finally, each outlet from a standpipe system must terminate at a hose valve or at a sprinkler control valve on combined systems. When excessive pressures are expected at outlets, pressure-regulating devices are required.

Pressure-Regulating Devices. Pressure-regulating devices are used to limit system outlet pressures. Pressure-regulating devices used in standpipe systems can be categorized into three basic types: (1) pressure restricting, (2) pressure reducing, and (3) pressure control. Pressure-restricting devices reduce pressures in flowing conditions only. They do not compensate for changes in input pressure to maintain a constant discharge pressure, and they do not control pressure in static conditions. For these reasons, their use is limited to 1½ in. (40 mm) hose connections for limiting residual pressure to 100 psi (690 kPa) where the static pressure does not exceed 175 psi (1207 kPa). One example of a pressure-restricting device is an orifice plate. An orifice plate is a metal disk with a restricting orifice. Orifice plates may be inserted into connections to standpipe systems to reduce residual pressure on the downstream side. Though relatively inexpensive, orifice plates are generally undesirable because they do not maintain a steady discharge pressure, and because they can damage hoses if the pressure jet from an orifice strikes the inner wall of a hose. If used, orifice plates should always be installed at hose couplings to allow for easy removal.

The preferred devices for regulating excessive pressures are pressure control and pressure-reducing valves. These valves are designed to actively regulate outlet pressures in both static and flowing conditions, and they are required for outlets of systems where static pressure could exceed 175 psi (1207 kPa). Pressure control and pressure-reducing valves are preferred over pressure-restricting devices because hoses and sprinkler systems connected to standpipes are exposed to both static and flowing conditions; and uncontrolled static pressures can cause equipment failure and pose a danger to users.

Pressure control and pressure-reducing valves employ a mechanism that compensates for variations in inlet pressures by

balancing water pressure in an internal chamber or chambers, typically against a spring. Pressure control valves, which are a type of pressure-reducing valve that is pilot operated, are considered by many to be the most reliable method of controlling pressure. Figure 16.10.9 illustrates one example of a pressure control valve. In the example shown, the outlet pressure is a function of the setting on the regulating spring. Often the outlet pressure is not field adjustable, and valves are preset at the factory for use at a specific floor level in a building. In such cases, it is critical to ensure that valves are installed at the intended location.

Standpipe systems with pressure-regulating devices are required to be designed such that each device may be tested, and routine testing must be conducted. To accommodate the need for testing pressure-regulating devices, standpipe systems using such devices must have a dedicated drainage system with connections at every other floor and a central means for measuring flow. Figure 16.10.10 shows one possible design of a floor valve assembly for such an arrangement. The case shown assumes a standpipe pressure in excess of 175 psi (1207 kPa) and a combined sprinkler and standpipe system with a directly connected drainage riser for pressure-regulating device testing. As an option, the drainage riser may simply have a hose connection at every other floor where a short piece of hose can be connected to the two closest pressure-regulating devices for testing.

Where system pressures are extreme, pressure relief valves, which reduce pressure by flowing water into a drain, may be provided as a backup to pressure-regulating valves. Pressure relief valves are commonly available in two types: (1) spring operated and (2) pilot operated. Pilot-operated valves are preferred because they respond more accurately to changes in system pressures; however, these valves may require increased maintenance to prevent excessive accumulation of debris in strainers.

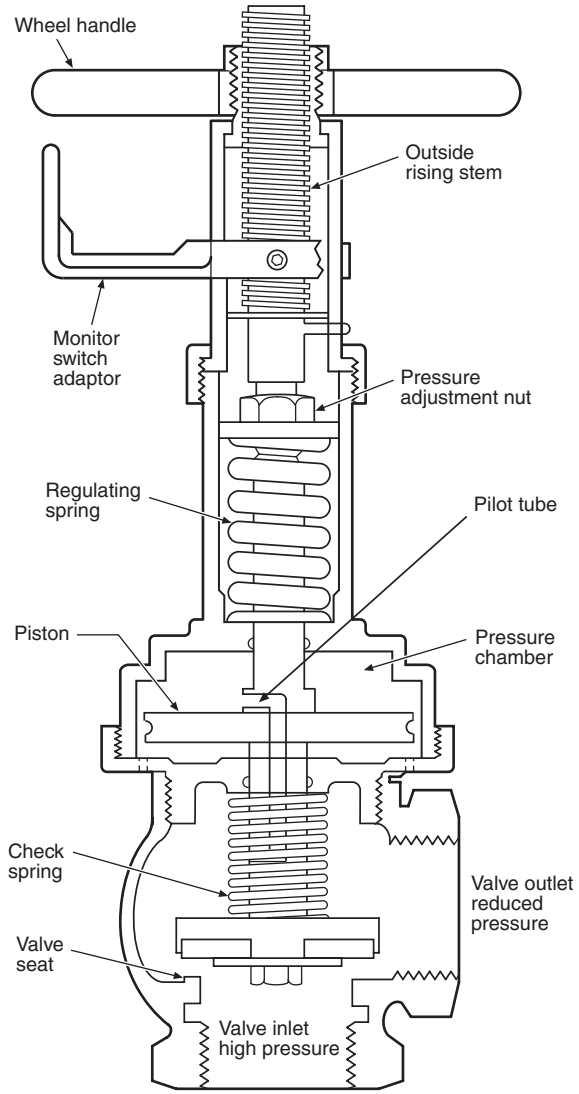

FIGURE 16.10.9 Cutaway of a Typical Pressure Control Valve

Fire Department Connections. (See the additional discussion under "Type and Number of Water Supplies" earlier in this chapter.) Fire department connections (FDCs) are required for all Class I and Class III systems. On manual standpipe systems, FDCs serve as the only water supply. On automatic and semiautomatic standpipe systems, they serve as an auxiliary water supply.

Fire department connections should be located where they are accessible to fire department vehicles and not more than 100 ft (30.5 m) from the nearest fire hydrant. They should not be obstructed by shrubbery, vehicles, or fences that limit visibility or access. For high-rise buildings, two or more connections, located remotely from each other, are required for each zone. This redundancy helps to ensure the fire department's ability to provide an uninterrupted water supply during a major fire. The concern is that falling glass from broken windows can cut supply hoses and prevent personnel from connecting new hoses to the affected FDC, and redundancy improves the chance of gaining access to at least one FDC in such cases.

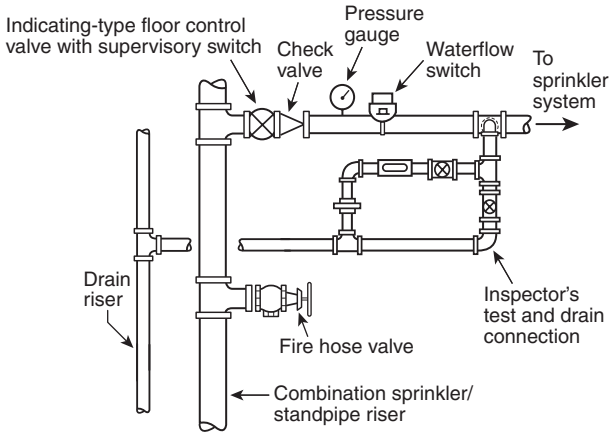

FIGURE 16.10.10 One Possible Arrangement for Valving at a Floor Connection for a Combined System (Not to Scale)

As a rule, most fire department connections are provided with one 2½ in. (65 mm) inlet for each 250 gpm (946 L/min) of design flow rate. Some fire departments require large-diameter inlets that are designed to connect to special high-pressure, large-diameter hoses. Even when large-diameter hoses are used, a second inlet is needed to allow for a backup hose that could be charged if the primary hose ruptures or separates from a coupling.

Another important issue that should not be overlooked is the size of the pipe connecting a fire department connection to system mains. This pipe should be sized to deliver the system demand, as discussed previously under "Sizing Pipe." It is preferable to use 4 in. (100 mm) or larger piping in all cases to avoid obstruction by debris.

Figure 16.10.11 illustrates a typical arrangement for a fire department connection on a wet standpipe system.

System Monitoring and Supervision Devices. To ensure the reliability and performance of standpipe systems, provisions must be made for monitoring system pressure and supervising control valves. Gauges should be provided at each water supply and at the top of each standpipe so that system pressure can be monitored.

Valve supervision can be accomplished by electrical or mechanical means. Supervision is generally required for water supply isolation valves, standpipe isolation valves, and similar valves that are capable of interrupting the water supply to large portions of a system. Supervision is necessary to ensure that the valves remain open at all times.

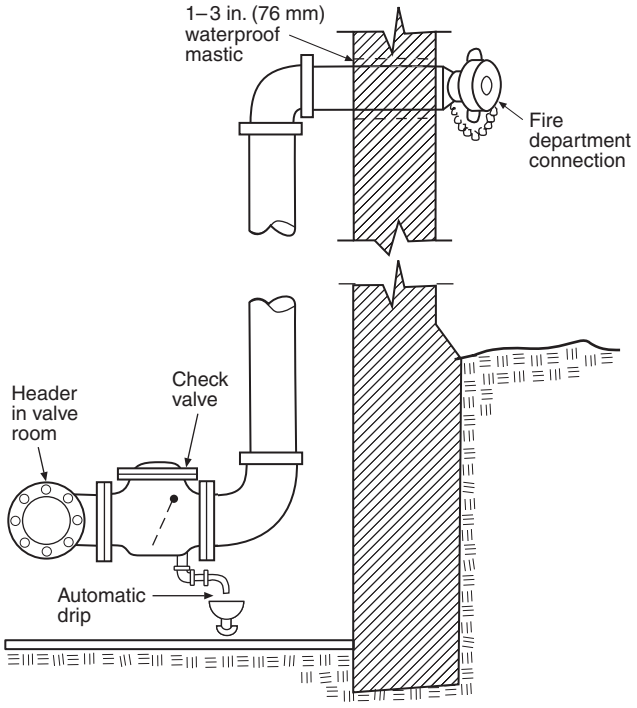

FIGURE 16.10.11 Typical Fire Department Connection for a Standpipe with Water-Filled Piping

Frequently, waterflow alarms are also specified for monitoring a system. This is usually limited to systems having preconnected hoses where immediate notification of waterflow is desired. Also, electronic supervision of hose cabinet doors may be provided where vandalism is a concern.

STANDPIPE SYSTEM INSTALLATION CONSIDERATIONS

Although a proper design establishes the groundwork for a reliable and usable standpipe system, the installation ultimately determines how well a system will perform. A few key considerations are discussed next.

Because most standpipe systems are hydraulically designed, it is essential that the installation conform to design drawings. This is especially true for combined standpipe and sprinkler systems that are based on hydraulically calculated designs. Because the installation of additional pipe or fittings has an adverse effect on hydraulic calculations, as will reductions in pipe sizes, plans should indicate that all such changes should be reported to the designer for approval. Plans should also caution installers of systems with preset pressure-regulating valves to ensure that the valves are installed at the proper floor levels.

To ensure operability and maintainability, it is preferable to label piping and indicate the direction of waterflow. Valve locations must also be clearly identified and accessible. Particular attention should be given to providing access space around hose connections, recognizing that fire fighters will be using large gloves when connecting hoses and operating valves. Twelve inches (0.3 m) of clear space from the valve handles and hose outlets to walls or other obstructions is desirable. Consideration should be given to installing hose valves at a 45 degree angle to prevent kinking the hose.

The key concerns for locating fire department connections are accessibility and visibility. Fire department connections should be clear of shrubbery, parking for vehicles, and other obstructions that could hinder their use. In addition, signs should be provided, preferably reflective, to indicate whether a connection serves standpipes, sprinklers, or both, and to indicate the area served by the connection.

During construction of a building that will have a standpipe system, it is important that the system be made operable before work progresses to a point where deployment of hoses from fire apparatus no longer provides an efficient means of fire fighting. Fire codes usually dictate the point at which standpipes must be made operable during construction.

Noncombustible structures often represent extreme fire hazards during construction because combustible shoring and a variety of ignition sources may be present. To provide protection during construction, the permanent system piping is typically used, along with a temporary fire department connection. At least one hose connection should be provided at each floor level, and all hose connections should be kept capped with an easily removable cap and protected from mechanical injury. Systems should be extended to keep pace with construction progress, and routine inspections should be scheduled to ensure that systems are kept operable.

COMMISSIONING OF STANDPIPE SYSTEMS

Because standpipe systems are essential fire safety systems, they must be routinely tested and inspected to verify that they perform to the original installation requirements and to ensure operational readiness. Testing should be conducted before system acceptance and at intervals adequate to verify reliability. Once accepted, inspection, testing, and maintenance of standpipe systems are regulated by NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems.* See Section 16, Chapter 11, for care and maintenance of water-based extinguishing systems.

Preinspection

Prior to conducting a performance test, the system should be inspected to verify that the installation is complete. This preliminary inspection should include the following:

- Location of control valves
- Method of valve supervision
- Verification of component type
- Valve identification/hydraulic data nameplate installed

Acceptance Tests

On completion of the inspection, the following tests should be conducted:

- Hydrostatic test
- Main drain test
- Pressure-regulating device test
- Alarm test
- Trip test for dry system (including water transit time)
- Trip test for semiautomatic system

The results of these tests are recorded on a form from NFPA 14 titled "Contractor's Material and Test Certificate for Above Ground Piping." The building owner should keep the form on file for the life of the system.

When standpipes are flow tested by flowing water at the roof level, a flow diffuser with a screen is recommended at the point of discharge to control the water stream and intercept any debris that may be ejected. Particular attention should be paid to the adequacy of the drainage route for water to avoid flooding the roof or other areas.

FIRE DEPARTMENT OPERATIONS USING STANDPIPE SYSTEMS

Preplanning

For standpipe systems to be effective, fire fighters must be trained in standpipe operations, and they should preplan to become familiar with systems that they will use. As part of the preplan, fire fighters should identify the locations of fire hydrants, fire department connections, water supply valves, pumps, tanks, and hose connections. The presence of orifice plates in hose connections or pressure-reducing or pressure control valves also should be noted. Fire departments also should develop standard operating procedures that assign personnel and apparatus responsibilities when using standpipe systems.

Equipment

To facilitate the use of standpipe systems, "standpipe packs" should be carried on responding fire apparatus. The packs should contain the equipment necessary to use standpipe system hose connections. Standpipe packs are typically carried on carts or in bags and contain between 100 and 200 ft (30.5 and 61 m) of hose, a nozzle, and miscellaneous tools and wrenches. A gated wye may also be carried to allow a second hose to be connected to a single hose connection. The length of hose carried should be based on local practices regarding which hose connections are expected to be used (at the fire floor or the landing below) and local building code requirements for locating hose connections. Probably the most versatile hose arrangement is one that includes 1¾- or 2-in. (45- or 50-mm) hose and a high-volume nozzle capable of flowing 200 gpm (757 L/min) or more. Such an arrangement can provide a flow capability comparable to a 2½ in. (65 mm) hose with a standard selectable flow fog nozzle when adequate pressure is available, but it is significantly easier to handle.

A fog nozzle that produces an effective pattern at operating pressures less than 100 psi (690 kPa) should be used to take maximum advantage of the pressure available. Use of piston-type automatic nozzles is not advised for standpipe systems because such nozzles may require high pressures to produce satisfactory steams. Some automatic nozzles require pressures in excess of 90 psi (621 kPa) to produce a reasonable fog pattern, and delivering this amount of pressure to the nozzle may prove difficult in some cases, particularly on older standpipe systems designed to provide only 65 psi (448 kPa) and to limit pressures to a maximum of 100 psi (690 kPa). Although low-pressure automatic nozzles designed to operate with inlet pressure in the 70 psi (483 kPa) range are available, the most reliable fog nozzle for use with standpipe systems is a selectable flow nozzle without an automatic piston.

In addition to standpipe packs, fire apparatus should also carry coiled or packed sections of 2½ in. (65 mm) hose for cases where large volumes of water are needed and the pressure available from a standpipe is limited. Such cases may occur in very tall buildings that have floor levels beyond the range of fire apparatus or where pressure regulating valves on a standpipe system have been improperly adjusted.

Operations

It is reasonable to expect the first fire-fighting crew on the scene of an incident in a building with a standpipe system to take a standpipe pack into the building when investigating the call. Meanwhile, an engine should connect to a fire department connection to supply the system. More than one supply hose should be connected to a system if a fire is discovered to prevent the water supply from being interrupted if a supply hose breaks. It is also preferable for additional apparatus to connect to a second

FDC, during major fires when more than one FDC is present. This connection reduces the risk of interruption of the water supply if glass breakage on upper floors makes conditions at some parts of a building's perimeter unsafe, perhaps cutting supply hoses.

When fire fighters determine that hoses are needed, they should select a hose connection located in a protected stairway enclosure, as opposed to a connection located in a corridor or open area (when such connections are present) because it is desirable to have a charged hose before entering a floor if smoke or flame is detected. In multiple-story buildings, a hose connection located at the intermediate landing below or one floor below a fire floor is often preferred over a connection at a fire floor because it provides additional space to spread a hose before charging it, and minimizes congestion at the fire floor entrance. It should be noted that using a hose connection on a lower level will create a need for additional hose to reach all areas on a fire floor, and by providing a gated wye preconnected in a standpipe hose line, fire fighters can add hose without having to shut off and disconnect an attack line. Fire fighters should also be aware that, depending on desired flows, they may have to remove pressure-restricting devices or adjust pressure-regulating valves if they are field adjustable.

The pressure to which a standpipe system should be charged varies from one fire department to another based on local preferences. Some departments use recommendations previously published in NFPA 13E, *Recommended Practice for Fire Department Operations in Properties Protected by Sprinkler and Standpipe Systems,* which suggested that the pressure at the FDC should be initiated at 100 psi (690 kPa) when smoothbore nozzles will be used at elevations of 100 ft (30.5 m) or less, and at 150 psi (1034 kPa) when fog nozzles will be used at elevations of 100 ft (30.5 m) or less. For elevations above 100 ft (30.5 m), 5 psi (34.5 kPa) should be added for each floor level above 100 ft (30.5 m). Other departments simply pump 150 psi (1034 kPa) plus 5 psi (34.5 kPa) for each floor level above grade. The latter method is more commonly used and should deliver adequate pressure for fog nozzles in most cases.

OUTSIDE HOSE SYSTEMS

Outside hose systems are not standpipe systems. Rather, they are appendages to a water supply. However, outside hose systems and standpipe systems have similar purposes. They both provide an efficient means for manually applying water to fires. Though not mandated by model building or fire codes, outside hose systems may be requested by insurance authorities or by owners as an additional safety measure to minimize potential fire losses. For a discussion of outside hose systems, see Section 15, Chapter 4, "Water Supplies for Sprinkler Systems."

SUMMARY

Standpipe systems deliver water for manual fire fighting. This chapter provided an overview of standpipe system design and installation considerations. The chapter also included a discussion of the testing and inspection of standpipe systems and fire department operations using standpipe systems. The chapter concluded with a brief description of the design and equipment considerations of outside hose systems.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on standpipe and hose systems discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 1, *Uniform Fire Code™*
NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 13E, *Recommended Practice for Fire Department Operations in Properties Protected by Sprinkler and Standpipe Systems*
NFPA 14, *Standard for the Installation of Standpipe and Hose Systems*
NFPA 20, *Standard for the Installation of Stationary Pumps for Fire Protection*
NFPA 22, *Standard for Water Tanks for Private Fire Protection*
NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems*
NFPA 72®, National Fire Alarm Code®
NFPA *101®, Life Safety Code®*
NFPA 1901, *Standard for Automotive Fire Apparatus*
NFPA 1961, *Standard on Fire Hose*
NFPA 1962, *Standard for the Inspection, Care, and Use of Fire Hose, Couplings, and Nozzles and the Service Testing of Fire Hose*
NFPA 1963, *Standard for Fire Hose Connections*
NFPA 1964, *Standard for Spray Nozzles*

Chapter 11

Care and Maintenance of Water-Based Extinguishing Systems

David R. Hague

Chapter Contents

System Maintenance Basics
Types of Sprinkler System Inspections
General Maintenance of Sprinklers and Sprinkler Piping
Care and Maintenance of Specific Components
Obstructions in Piping
Other Sources of Obstruction
Extent of Cleaning Required
Cleaning Methods
Sprinkler Leakage
Reducing Water Damage
Water Spray Systems
Water Supplies
System Impairment

Key Terms

automatic sprinkler system, central station, fire pump, microbiologically influenced corrosion (MIC), standpipe, unintended discharge, water-based fire protection, waterflow alarm, waterflow detector, water spray fixed system, water supply (private), water supply (public), zebra mussel

Sprinkler systems are exceptionally reliable, such that the chance of dying in a fire is reduced by one-half to three-fourths when sprinklers are present. Statistics also indicate that property damage is reduced by one-half to two-thirds when sprinklers are present. This, of course, is only true for systems that have been designed, installed, and maintained properly. Maintenance procedures are critical, such as those required by NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems.*

This chapter covers the care and maintenance of sprinkler and water spray systems. It discusses the agencies involved in inspecting and testing these systems and the techniques they use. The chapter also covers sources of obstruction in sprinkler system pipes and methods for flushing and cleaning them, as well as sprinkler leakage and water damage.

For related topics, see Section 15, Chapter 1, "Fixed Water Storage Supplies for Fire Protection"; Section 15, Chapter 2, "Water Supply Requirements for Public Supply Systems"; Section 15, Chapter 5, "Microbiologically Influenced Corrosion in Fire Sprinkler Systems"; Section 16, Chapter 4, "Hanging and Bracing of Water-Based Systems"; Section 16, Chapter 8, "Water Mist Fire Suppression Systems"; and Section 16, Chapter 9, "Water Spray Protection."

SYSTEM MAINTENANCE BASICS

Importance of System Maintenance

Care and maintenance includes more than the inspection and testing of system components. For effective protection, an evaluation of the factors that affect system performance should be made. These factors include such items as the following:

- Occupancy changes
- Process or material changes
- Building modifications such as relocated partitions or ceilings or the addition of mezzanines
- Modifications to the heating system exposing systems to potential freezing

To maintain the proper level of protection for a water-based extinguishing system, there are four areas of concern:

1. Adherence to a regular inspection schedule as determined by the needs of the system
2. Execution of any special investigations or tests that can assess the performance of the devices and equipment
3. Exercise of due diligence in the repair of devices and equipment
4. Assurance that all personnel involved in maintenance are properly trained to correctly execute the procedures for inspection, testing, and maintenance of equipment

David R. Hague, P.E., is a principal fire safety and systems engineer at NFPA.

Responsibility for Inspection, Testing, and Maintenance

Ultimately, the building owner is responsible for inspection, testing, and maintenance of fire protection systems. In the case of an absentee owner or where the complexity of the system is such that the building owner lacks the appropriate training and experience, that responsibility can be transferred to another qualified person or firm.

TYPES OF SPRINKLER SYSTEM INSPECTIONS

In addition to the indispensable inspection procedures followed by the property owner, other inspection services are available.

Insurance Company

In insured properties, extinguishing systems may be given special attention by the insurance carrier. Routine testing of sprinkler systems and devices at regular intervals is a service extended by some insurance companies. This service can benefit both the insurance carrier and the property owner. By these routine tests, the equipment can be shown to be in good operating condition or in need of repair or replacement. The purpose of these tests is also to verify reliability of the system to establish an insurance rate for the protected property.

Fire Department

Inspections are made of extinguishing system equipment by many fire departments at varying intervals. This type of inspection is principally done to make sure that valves are fully open for preplanning purposes and may not include the level of detail prescribed by NFPA 25. Inspections are customarily made by the fire department in the district where the property is located.

Sprinkler Contractor

Inspection and maintenance services are offered by sprinkler manufacturers, sprinkler contractors, and inspection service companies. This service provides periodic examinations and reports and is valuable to the property owner not only for a regular checkup of the sprinkler system and components but also for the valuable instruction that can be given to employees in the process. The inspection contract should include all components and systems needed for the proper protection of the property.

Central Station Supervision

Central station supervision of sprinkler alarm and control devices provided under contract is a valuable aid to any maintenance program. Reporting each incident involving waterflow or valve closure or other supervised events keeps a constant check on the condition of the equipment and encourages care on the part of the plant fire organization as well as the building owner.

All of the foregoing inspection procedures should follow the prescribed guidelines in NFPA 25 and *NFPA 72®, National Fire Alarm Code®*. For prescribed frequencies and sample report forms, see NFPA 25.

GENERAL MAINTENANCE OF SPRINKLERS AND SPRINKLER PIPING

Frequently, sprinklers are installed in areas that will subject them to harsh environments, causing loading (contamination), corrosion, exposure to high temperatures, and mechanical damage.

Frequency and Timing of Testing and Inspection

Testing Criteria. If sprinklers have generally performed satisfactorily through their service life, NFPA 25 requires testing of representative samples of installed sprinklers periodically to verify continued performance. The testing criteria for sprinklers are as follows:

- Sprinklers installed for 50 years must be tested, and tests must be repeated every 10 years thereafter.
- Sprinklers manufactured prior to 1920 must be replaced.
- Fast-response sprinklers must be tested after 20 years, with tests repeated every 10 years thereafter.
- High-temperature sprinklers (temperature ratings of 325°F [163°C] or greater) must be tested every 5 years.
- Dry-type sprinklers must be tested every 10 years.

The test sample should comprise 1 percent of the total number of sprinklers installed in the facility and should never be less than four sprinklers. Any sprinkler that shows signs of contamination (loading), corrosion, or paint (other than the paint applied by the manufacturer) should be replaced because the testing laboratory will not evaluate such sprinklers. See Figure 16.11.1 for an example of a loaded sprinkler. The test results will provide an indication of the service conditions that all sprinklers represented by the test sample are exposed to. Any sprinkler that fails the test requires that all sprinklers represented by the test sample be replaced. When removing or installing sprinklers, the manufacturer's instructions should be followed to minimize damage to the sprinkler.

Inspection procedures may be affected by their frequency as well as seasonal changes. The following are examples of inspections governed by seasonal effects.

Spring Inspection. When the danger of freezing temperatures (32°F [0°C]) has passed, spring inspections may be performed. Pertinent operations are as follows:

1. Open cold weather valves (it should be noted that these are prohibited for use on new systems).
2. Inspect, test, and reset dry-pipe valves.
3. Test water motor gongs.
4. Conduct waterflow tests.
5. Test fire pump.

Fall Inspection. At the approach of freezing weather, the system inspector(s) must perform the following functions:

FIGURE 16.11.1 Loaded Sprinkler

1. Close cold-weather valves and drain pipes exposed to freezing temperatures (drain valves on the exposed piping are left slightly open), and test the specific gravity of the solution in an antifreeze sprinkler system.
2. Check dry-pipe valves to make sure that the systems are holding air properly and that the pressure switches and water motor alarms are in order, check drains at the low points of the dry piping to ensure that they are properly clear of water, and check heating provisions for the dry-pipe valve enclosures.
3. Examine gravity tanks to verify that they are protected against freezing, and check that the employed heating system is in operating condition.
4. Check the condition of fire pump reservoirs and suction intakes from other water sources.
5. Carefully inspect buildings to make sure that cold air will not enter or unduly expose sprinkler piping to freezing.

Accumulation of Foreign Materials on Sprinklers

In many classes of properties, conditions exist that cause an accumulation of foreign material on automatic sprinklers. This accumulation is commonly known as loading. The operation of the sprinkler may be delayed or prevented by the loading effect.

Deposits on sprinklers tend to retard their operation as a result of the insulating effect of the loading material. If the deposit is hard, it may physically delay or prevent the sprinkler from operating. The best practice is to replace loaded sprinklers with new sprinklers rather than to attempt to clean the sprinkler. Attempts at cleaning, particularly in instances where deposits are hard, are likely to damage the sprinkler, thus rendering it inoperative or possibly causing leakage.

Deposits of light dust on sprinklers, such as may be found in woodworking plants and grain elevators, are less serious than hard deposits. Dust may be expected to partially delay the operation of sprinklers but ordinarily will not prevent the eventual discharge of water. Dust deposits can be blown or brushed off. Blowing by compressed air should not be undertaken where it can create a dust explosion or ignition hazard. When using a brush, make sure that it is soft to avoid possible injury to sprinkler parts. If these two methods prove unsatisfactory, then a damp, soft cloth may be used to clean the sprinkler. Water-solution cleaning liquids of caustic or acid type are likely to be destructive to sprinklers and should not be used for cleaning. Hot solutions of any kind should not be used.

Sprinklers are sometimes protected when ceilings or sprinkler piping are being painted by temporarily placing small, lightweight paper bags, plastic bags, or aluminum foil over them and securing them with rubber bands. Any such covering is likely to delay the operation of the sprinklers and should be removed immediately after the painting is completed. Should paint cover one of the sprinklers, the sprinkler should be replaced. There is no known method of adequately removing paint under the water cap or on the fusible link. Sprinklers that have been painted by anyone other than the manufacturer must be replaced with new sprinklers.

Sprinklers in spray booths present a special problem. To help minimize this problem, one acceptable solution is to conduct the spray process in a downward manner to avoid contaminating the sprinkler. Cleaning will be necessary; therefore, sprinklers must be installed in an easily accessible location. To facilitate the washing or wiping off of deposits, a light coating of a mild, soft soap should be used. Unless cleaning is done very carefully, deposits are likely to accumulate to such an extent as to interfere seriously with sprinkler operation. The use of paper, polyethylene, or cellophane bags to protect sprinklers in spray booths is fairly common and is permitted by NFPA 25 when the thickness of such bags does not exceed 0.0003 in. (0.008 mm).

Corrosion of Automatic Sprinklers

Corrosive conditions can make automatic sprinklers inoperative or delay the speed of operation. They can also seriously impede the waterways of spray nozzles, affecting the spray patterns of sprinklers. Corrosive vapors may seriously affect not only the heat-actuated element and the water-retaining mechanism of an automatic sprinkler but also may be severe enough to weaken or destroy other portions of the sprinkler. In most instances, such corrosive action is slow and chronic. Thus, the process must be monitored vigilantly. Illustrations of some typical corroded sprinklers are shown in Figure 16.11.2.

Some types of sprinklers are less susceptible than others to corrosive conditions. Nonferrous metal is used for some sprinkler parts, but special protective coatings are still necessary for sprinklers that are exposed to extreme corrosive conditions. Approved corrosion-resistant or special coated sprinklers

FIGURE 16.11.2 Examples of Corroded Automatic Sprinklers

are needed in locations where chemicals, excessive moisture, or corrosive vapors exist.

Protection of Pipe against External Corrosion

Under some conditions, corrosive vapors may cause rapid deterioration of steel pipe and hangers. Proper protection can prevent the frequent replacement of these components. Cast-iron fittings are generally not affected by corrosive vapors.

In severe corrosive conditions where protective methods are not wholly satisfactory, copper or special alloy, noncorrosive pipe will yield the best results. Galvanized steel may offer the most economical method of obtaining a reasonably long life for the piping system. Galvanized piping systems have met with success in chemical plants, saltworks, or similar properties where severe corrosion exists. Stainless steel and copper piping have also been used in some cases.

Corrosion of existing equipment becomes a maintenance problem. The options available are replacement of the components or corrective measures, such as an application of a recognized protective coating.

Advance Preparations Before Shutoff

When maintenance or testing requires systems to be shut off, the work should be planned for a time when the least amount of hazard exists and when there is the least disruption. Both considerations lead to impairment during idle periods rather than during normal business operations. Therefore, work that requires system shutoff should be performed during weekends or other idle periods. A fire watch may be required to aid in the detection of any fire that might develop while the systems are shut down.

Sectional valves, rather than main valves, should be used to reduce to a minimum the number of systems removed from service and to take advantage of multiple water supplies. All personnel, materials, and tools should be on hand before the system is impaired.

If underground mains are involved, a tapping machine should be used when possible to avoid shutting off the water. If mains are to be opened, wood or other plugs or caps and clamps to close the ends of pipes should be available and ready to install. Emergency measures should be taken to maintain the maximum possible water supply. One possibility is to make a temporary hose connection from a hydrant that is still in service to the system riser(s) (Figure 16.11.3). Other options include the use of a domestic or industrial supply to the riser(s) (Figure 16.11.4). These connections are usually made to the nominal 2 in. (50 mm) drain with the drain valve and hydrant valve left open. Adapters for connecting 2½ in. (65 mm) hose to sprinkler systems should be kept on hand.

FIGURE 16.11.3 Temporary Hose Connection from Hydrant

A formal procedure should be established and followed for closing valves, notifying the fire department and insurance companies, and making waterflow tests after the work is completed. Such impairment procedures will help to ensure that systems are out of service for a minimal period of time and that complete system protection is restored.

Emergency Measures for Maintaining Protection During Repairs or Alterations

The seriousness of having extinguishing systems shut off when a fire starts has been well documented. There is a danger if the water supply is shut off for extensions or alterations to piping, repairs due to accidental damage to sprinklers and spray nozzles, replacement of sprinklers after a fire, or maintenance or replace-

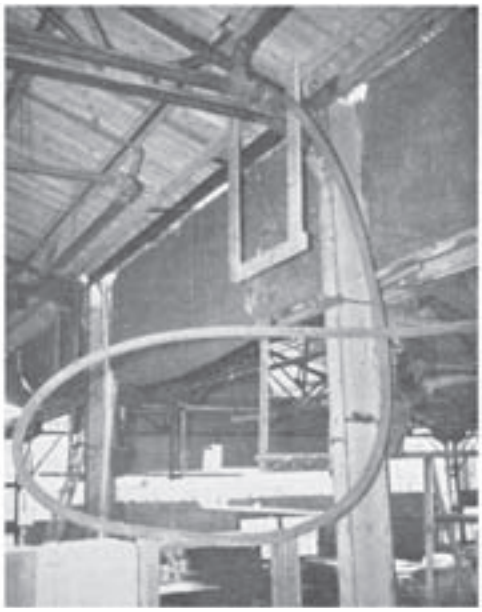

FIGURE 16.11.4 Temporary Hose Connection with Hose Connected to Sprinkler System Flushing Connection

ment of sprinklers and other system devices. When protection is interrupted, every effort must be made to limit the extent and duration of the interruption. A cardinal rule is to notify the fire department whenever an impairment exists so they will not place false reliance on the systems. Insurance companies also may request that building owners advise them when there is an interruption in protection, so that alternate means of protection can be arranged if necessary.

CARE AND MAINTENANCE OF SPECIFIC COMPONENTS

The following components are treated in relation to routine inspection, test, and maintenance programs. They are, however, independent of the organization performing the inspection and maintenance functions. These are in-house responsibilities and should be left in the care of trained and competent individuals.

Public and Private Water Supply Equipment

The inspection and testing of public water supplies and of private water-supply equipment, such as tanks and fire pumps, is covered elsewhere in Section 16. See NFPA 25 for a summary of valve and fire department connection inspection, testing, and maintenance.

Control Valves and Meters

Inspection and supervision of valves in fire protection systems is necessary because closed valves are the leading cause of unsatisfactory performance. The following paragraphs summarize some of the more salient points of valve inspection and supervision.

Service Valves. Service valves at private fire system connections to public systems are usually under the control of the water department and are seldom operated. Their condition is usually indicated adequately by waterflow tests made from the private protection system, as covered later in this chapter.

Meters. Meters in public water system connections are also generally under the control of the water department but are sometimes located in pits on the protected property.

Check Valves. Check valves in public water connections, where needed to prevent backflow into the public systems, are usually a part of the protection system for which the property owner is responsible. Tightness of check valves should be determined periodically by proper tests, depending on water supplies.

Check valves and any corresponding control valves should be properly arranged and located in accordance with the appropriate NFPA standards for sprinkler systems, water spray protection, or standpipe and hose systems.

Control Valves. All control valves should be readily accessible and unobstructed so they can be operated promptly and examined to see that they are open and in good operative condition, turn easily, and do not leak.

Pits for gate valves and check valves should be kept reasonably dry and clean, so that valves can be tested, examined, and maintained in good condition. Manhole covers should be kept clear of snow and ice. See Section 15, Chapter 2, "Water Supply Requirements for Public Supply Systems," for an example of a well-arranged check valve pit with access for inspection.

Each control valve should be numbered or otherwise identified at the valve and cataloged, giving location, use, or portions of the system controlled, on a plant fire inspection form or value chart. A plan showing valve locations should be posted at a central point known to plant and public fire officials.

Each valve should have a sign showing what it controls, with the legend "Must Be Open at All Times," or other proper wording. Underground valve sites should be shown by location and by distance markings on nearby buildings and on accurate plans of the property.

All control valves should be sealed or locked open, unless there is a central station supervisory service. Wrenches should be kept at post indicator valves or at locations where they are readily accessible.

For larger facilities or plants, there should be someone on premises at all times who knows the use and location of all the control and drain valves. This includes the person on watch or any others who may be on duty at night.

Sprinklers and Sprinkler Piping

In the inspection of the sprinkler system, the following eight categories should be considered.

Absence of Sprinklers. Observe whether there is any room or building from which sprinklers have been omitted. The following should be used as a basic checklist:

- Basement
- Lofts
- Show windows
- Concealed spaces
- Towers
- Under stairwells
- Under skylights
- Inside elevator shafts
- Vertical shafts
- Small enclosures, such as those for drying and heating
- Closets, unless open on top

Observe whether there are sprinklers under the following:

- Air ducts over 4 ft (1.3 m) in width
- Shelves
- Benches and tables
- Overhead storage racks
- Platforms or similar obstructions

Proper Clearance for Sprinklers. There are a few areas to review for clearance of sprinklers:

- Sprinklers cannot be obstructed by high-piled stock, walls, or partitions that might prevent free and proper water distribution.

- There must be a clear space of 18 in. (457 mm) below the deflectors of the sprinklers. This value is 36 in. (914 mm) for large-drop and ESFR sprinklers.
- Installation guidelines of special sprinklers have not been violated. This may include installation under certain construction types.
- Refer to NFPA 13, *Standard for the Installation of Sprinkler Systems,* for spacing recommendations for various occupancy classes, types of sprinklers, and construction factors.

Proper Position of Deflectors. The distance of deflectors from the ceiling or the bottom of beams or joists should conform to NFPA 13.

Proper Pitch of Dry-Pipe Systems. Note whether all pipes in a dry-pipe system have the proper pitch. This feature is of special importance, because water remaining in pockets or low points is likely to freeze and disable the system.

Proper Support of Piping. Are any hangers loose or pipes not properly supported? Observe whether sprinkler piping is used for any purpose unrelated to its function, such as hanging clothing. Sprinkler piping and hangers should never be used for such purposes.

Proper Sprinkler Installation. There are five areas to check for the proper installation of sprinklers:

- Sprinklers must be installed in the positions for which they are intended, in compliance with the rules for special application, whether they be pendent, upright, or sidewall types.
- Note the type and design of the sprinklers, the year of their manufacture, and the date of their installation.
- Are all sprinklers of the proper temperature rating? Ordinary-degree sprinklers should be substituted for high-degree sprinklers when the latter are unnecessary. Wherever the temperature around the sprinkler exceeds 100°F (37.8°C), substitute those sprinklers with intermediate-degree sprinklers.
- Are any sprinklers loaded or corroded? If so, remove immediately and replace with sprinklers of equal performance characteristics. In areas where corrosion is common, use sprinklers with the proper coating to decrease the likelihood of future corrosion.
- Sprinklers with coatings of paint, whitewashing, bronzing, or excessive deposits should be replaced immediately with new sprinklers.

A supply of extra sprinklers should be kept in a spare sprinkler cabinet so that any sprinklers that have operated or been damaged in any way can be replaced promptly. These sprinklers should correspond in type, style, and in temperature ratings to the sprinklers in the property. The cabinet should be situated in a cool, easily accessible location. The number of sprinklers stocked for replacement purposes is governed by the size and number of systems. Other considerations include the location of the protected property relative to the source of supply for replacement sprinklers and the number of sprinklers likely to be opened in the event of a fire.

The stock of spare sprinklers, under normal conditions, should be as follows:

System Size	*Number of Spares*
Up to 300 sprinklers	6 sprinklers
From 300 to 1000 sprinklers	12 sprinklers
More than 1000 sprinklers	24 sprinklers

For systems aboard vessels or in isolated locations, a greater number of sprinklers should be carried to permit restoring equipment to service promptly after a fire.

A sprinkler wrench should be kept in the sprinkler cabinet to be used for the removal and installation of sprinklers. This wrench should always be used for installing new sprinklers in order to minimize the chance of damaging the sprinkler.

System Waterflow Tests

NFPA 13 requires a water supply test of pipe and pressure gauges to be provided at locations that will permit flowing tests to be made to determine whether water supplies and connections are in order. A 2 in. (50 mm) drain at the sprinkler riser may suffice as a water supply test pipe. The valve of the water supply test pipe must be installed so that the valve may be opened wide for a sufficient time to ensure a proper test, without causing water damage. A similar main drain valve in a water spray system can serve the same purpose.

There should be provision for checking the system's gauge and its pressure recordings with an inspector's test gauge.

The pressure on the sprinkler system side of the alarm or check valves may be higher than that of the water supply, because any momentary high pressure on the supply will be transmitted to the system and retained by the check valves. This excess pressure is relieved when a waterflow test on the system side of such valves is made.

The drop in pressure below the normal static pressure with the 2 in. (50 mm) main drain pipe wide open should be noted, and general flow conditions evaluated. For instance, if the normal pressure is 50 psi (345 kPa), and if previous tests have shown a pressure drop to 45 psi (310 kPa) when the main drain valve is opened, it will be apparent that, if during a subsequent inspection the pressure drops to 35 psi (241 kPa) or lower, there is some obstruction to the flow, which should be investigated. Such a pressure drop could indicate a defect that should be located and remedied.

At each inspection, an individual flow test should be made for each water supply and each connection from a supply. This can be accomplished by closing all water supplies temporarily, except the one under test. Too much emphasis cannot be placed on the value of flow tests to determine whether there is any obstruction to full flow. It is mandatory that all water supplies be returned to service immediately after testing.

If there is a waterflow supervisory service, tests should not be made without first notifying the fire department, central station, or other alarm receiving facilities.

There should be a 1 in. (25 mm) test pipe having a test orifice of a size to simulate the flow of a single sprinkler at the remote point of each sprinkler system. This should be operated at least twice each year to make sure that there is free flow at good pressure and to test the waterflow alarm. In dry-pipe systems, this test pipe can also be used to trip the dry-pipe valve and determine water delivery time.

Dry-Pipe Sprinkler Systems

The best practice is to keep dry-pipe systems in the dry condition throughout the year. When water flows into sprinkler piping, rust scaling and other foreign materials tend to be carried into the smaller pipes. Accumulation and obstruction can occur due to the waterflow. Annual tripping of the dry-pipe valve to make the system wet may accelerate this condition.

When systems are wet, with the dry-pipe valve tripped, the waterflow alarm feature of the dry valve would have to be taken out of service.

Any old, obsolete, unapproved dry-pipe, or mechanically damaged valves should be replaced with the proper approved listed device. Instruction charts are provided for the maintenance of dry-pipe valves by the sprinkler manufacturing company and should be posted at or near the valves. All dry-pipe valves should be numbered and listed on inspection report forms.

The air pressure on each dry-pipe system should be checked at least once a week. A daily check is recommended for the first week after a dry-pipe valve is reset. If pressure is lost rapidly, requiring frequent replenishment of the air pressure, the piping system should be repaired and made tight. Air pressure higher than that called for by the valve manufacturer's instructions should be avoided as this may damage the gasketing on the valve or severely delay the operation of the valves.

Make sure that the priming water is maintained at the proper level above the dry-pipe valve.

Freezing of a dry-pipe valve may cause it to be inoperative. It is extremely important to make sure that adequate provisions are made for heating the valve enclosure or the room in which it is located, and that the heating equipment is safe and in proper working order.

Dry-pipe system piping should be thoroughly drained at all drum drips or low-point drains before freezing weather and kept clear of water during the winter. The freezing of a small amount of water in the piping may cause rupture of the piping or sprinklers and valve malfunction. Make sure that all low-point drains of the system are kept free of water and that the automatic drip or drain is clear and free to operate.

Dry-pipe valves should be examined externally at frequent intervals to detect evidence of deterioration. Thoroughly clean and reset each dry-pipe valve yearly during the warm weather. On such occasions, the valve body should be thoroughly washed out with warm water. Make sure that all small ports and piping leading to the alarm connections are free from obstructions.

Operating tests of dry-pipe valves and their quick-opening devices should be conducted annually. Such tests may be combined with the annual cleaning and resetting. Operating tests should also be conducted when any repairs, such as renewal of rubber gaskets, or the adjustment of gauges, alarm devices, connecting piping, and quick-opening devices, are performed.

When dry-pipe valves are tripped for testing purposes, the procedure should be such that only the minimum flow of water needed to trip the valve is admitted into the sprinkler riser. This can usually be done by opening the control valve only two to six turns and by closing it immediately after the dry-pipe valve trips.

Operating tests and servicing of dry-pipe valves, including quick-opening devices, should be conducted only by fully qualified personnel.

No grease or other sealing material should be used on seats of dry-pipe valves in an effort to stop leaks. Force should not be used to make dry-pipe valves tight.

Dry-pipe valves should carry a tag or card showing the date on which the valve was last tripped and the name of the organization making the test. Such tags are usually available from the installing company or the insurance company.

Quick-Opening Devices

The operation of quick-opening devices usually can be tested either with or without operating the dry-pipe valve. The manufacturer's instructions for testing and resetting the valve must be followed. If the device does not operate properly during a test, it can, if necessary, be removed and the sprinkler system kept in operation. The device can also be sent to the manufacturer for repair, adjustment, or replacement.

Pressure Gauges

Water and air pressure gauges should be tested for accuracy whenever the system valve is repaired or reset but not less frequently than every five years. Comparison with a calibrated gauge is considered sufficient for this test, or the gauge should be replaced if a calibrated gauge is not available.

Waterflow Alarm Devices

Vane-type waterflow alarm devices should be tested semiannually and pressure switches tested quarterly. Consideration should be given to the proper disposal of test water, particularly where freezing conditions exist. Water motor gongs in particular should never be tested in freezing weather.

Deluge and Preaction Systems

Complete charts are furnished by the installing contractor showing in detail the proper method of operating and testing thermostatically controlled systems. Only qualified persons, fully instructed with respect to the details and operation of such systems, should be employed in their repair and adjustment. It is highly advisable for the owner to arrange with the installing contractor to provide periodic inspection, testing, and maintenance of the equipment.

The automatic valves controlling the flow of water into these systems operate through the effect of fire temperatures on actuating devices. Ordinarily, when it is necessary to repair the actuating system of a preaction system, as distinguished from

the piping system itself, the piping system can be temporarily converted to a wet system, and automatic sprinkler protection is, thus, maintained on a preaction system, provided there is no danger of freezing.

Sprinkler System Supervisory Systems

Central station, proprietary, remote station, fire alarm, and supervisory services for sprinkler systems interpret sprinkler system waterflow signals as fire alarms and immediately initiate occupant notification and fire department response. Signals of other types, such as valve supervision and pressure or temperature supervision, do not serve as fire alarms but initiate appropriate courses of action as prearranged between the supervisory service and the property owner. It is extremely important that these services be notified and any special arrangements made in advance of any inspection or tests of equipment that will cause a signal to be transmitted.

Fire Department Connections

Inspect each fire department connection regularly to make sure caps are in place, threads are in good condition, the ball drip or drain is in order, and the check valve is not leaking. A hydrostatic test should be conducted periodically on old fire department connection piping to ensure that it will withstand the required pressure.

Open Sprinkler Equipment

Outside or open sprinkler equipment should be tested once each year during warm weather. These tests should be coordinated with the authority having jurisdiction and, if desired, the fire department.

Before making operational tests, care should be exercised to make sure that all windows and doors through which water might enter are tightly closed. Proper precautions must be taken to prevent damage from obstruction or accumulation of water to sidewalks, streets, pedestrian ways, or adjoining buildings.

Determine by test whether the sprinklers and system piping are in good condition and free from obstruction. Any piping or sprinklers found clogged should be removed, cleaned, and replaced at once.

OBSTRUCTIONS IN PIPING

Obstructions in system piping or yard mains reduce or cut off the flow of water from all or part of the system, compromising the expected performance of the protection. Obstructed piping is a well-recognized cause of unsatisfactory sprinkler performance. One source of obstruction is foreign material in the water supply. Another is foreign material originating from the interior of the pipe itself. Figure 16.11.5 graphically illustrates an example of obstructions removed from the sprinkler system water supply piping.

Foreign material, such as sand, gravel, stones, and pieces of wood, may enter the underground mains as a result of the carelessness of workers when laying or repairing the mains.

FIGURE 16.11.5 Work Gloves and Pipe Scale Recovered from Sprinkler System Water Supply Pipe

Sand, silt, or wood chips may also enter the mains through inadequately protected fire pump suction inlets. Sometimes when gravity tanks are cleaned, foreign material enters the discharge pipes unless preventive care measures are taken.

Keeping foreign material out of piping for water-spray systems is particularly critical. If the waterways in discharge nozzles are less than ⅜ in. (9 mm) in size or if it is suspected that the water is likely to contain obstructive material, then a strainer is required in the pipeline supplying the system. Small nozzles are prone to clogging if waterborne debris reaches them. Thus, it is imperative that strainers are maintained in good condition. Strainers used in fire protection systems should be approved and listed by a recognized testing laboratory for fire protection service. Strainers must be flushed through the flushing connection periodically, or in cases in which there is a substantial amount of obstructing material, the strainer basket must be removed and cleaned.

Scale and corrosion can form inside system piping. Dry sprinkler systems in particular are subject to the formation of scale because the condensation of moisture in the air supply reacts with the inner surface of the steel pipe. In many cases, dry systems are installed with galvanized pipe to prevent scaling. Untreated water from natural sources such as wells may contain salts that accelerate corrosion. Scale and corrosion can also affect wet-pipe systems.

Obstructing material can be distributed throughout a system when systems operate, during tests, or when systems are filled. The material may obstruct one or more fittings or a number of sprinklers, usually at the end of the branch line. The effective

pipe diameter can also be reduced by pipe tuberculation when the water contains dissolved calcium and magnesium salts.

If the water is badly discolored during waterflow tests, or if gravel or stones are discharged with the water, foreign material is probably present in the piping. Finding foreign material in a fire pump suggests that there may be similar material downstream in the system piping. Finding foreign material when resetting dry-pipe valves or examining check valves indicates a possible serious impairment of the entire fire protection system.

Obstruction to the flow of water from sprinklers usually comprises concentrations of the lighter materials, such as silt, sand, and small pebbles, piling up in the ends of the cross mains and in the nearby branch lines, with the heaviest solids collecting near the system risers (Figure 16.11.6). There are some cases where the foreign material deposits extend so far back into the system from the ends of the cross mains that complete cleaning of the entire system is necessary. More often, however, a preliminary investigation will disclose that, although foreign material may cause complete obstruction of waterflow from sprinklers on branch lines connected to the ends of cross mains, there may be no obstruction at any point on branch lines farther back in the system.

OTHER SOURCES OF OBSTRUCTION

Microbiologically Influenced Corrosion (MIC)

Although generally considered to be a source of corrosion and pitting of pipe, microorganisms can colonize inside of piping systems to the extent that the effective diameter of the pipe is substantially reduced (Figures 16.11.7 and 16.11.8). This can have the same effect as other types of obstructing material by reducing the amount of waterflow through the system and plugging sprinklers.

MIC is caused basically by two types of microbes—aerobic, those requiring the presence of oxygen, and anaerobic, those not requiring the presence of oxygen. MIC can be recognized by the presence of orange or black tubercules and/or mud-like slime in steel pipe. MIC also affects copper systems and can be recognized by green or blue discoloration.

The most effective method to determine the presence of MIC is laboratory analysis of a water sample. Once the presence of MIC is confirmed, several treatment strategies can be employed, such as altering the residual chlorine, pH (acidity), temperature, and oxygen concentration of the water. It is important to note that altering the oxygen concentration of the water only affects aerobic microbes. The most common method of treatment is a permanently attached chlorine injection system, which automatically introduces chlorine into the sprinkler system any time waterflow occurs. Excessive flushing and flow testing of systems should be avoided to reduce the introduction of new microbes and renewed oxygen supplies to the piping system. (Section 15, Chapter 5, "Microbiologically Influenced Corrosion in Fire Sprinkler Systems," provides additional information on MIC.)

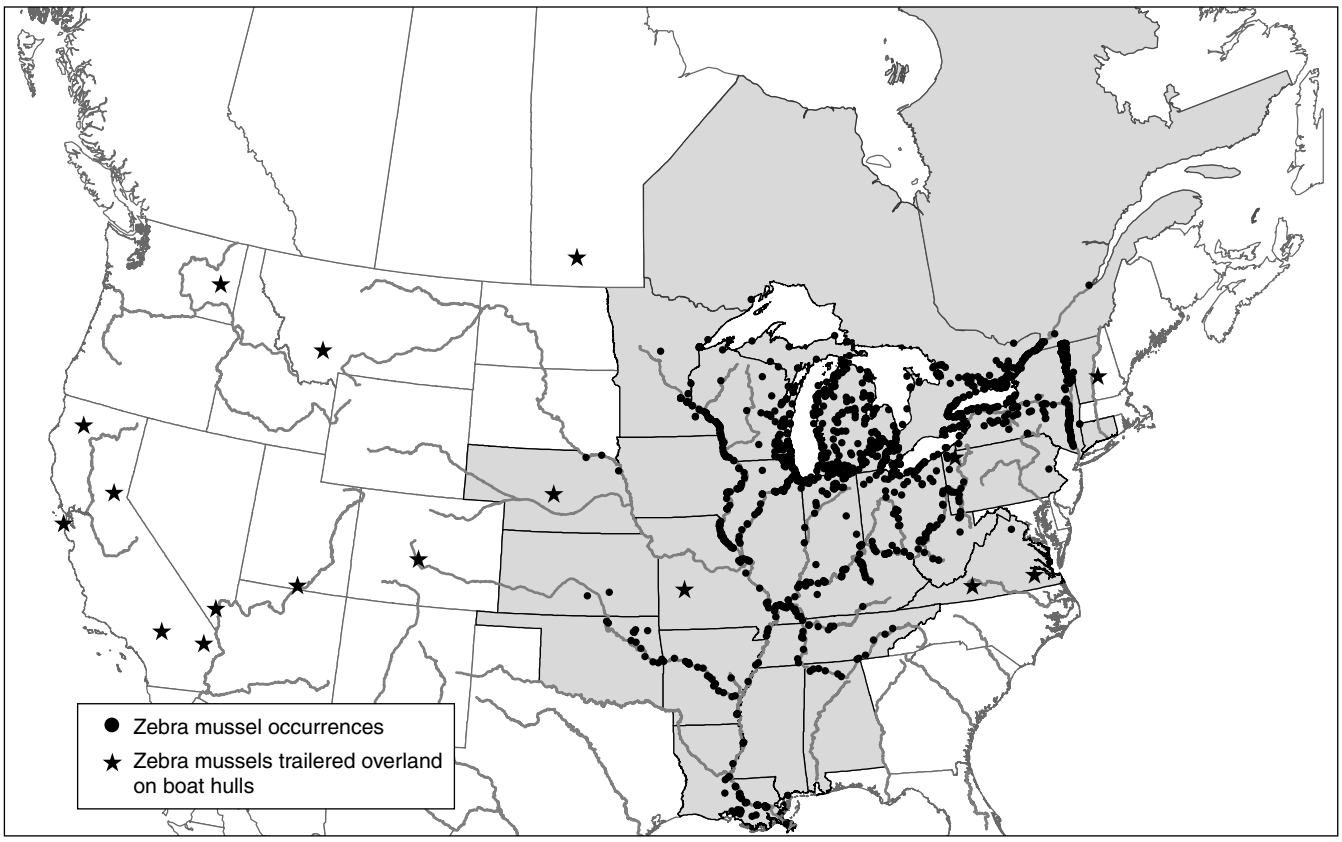

FIGURE 16.11.9 Zebra Mussel Sightings Distribution (*Dreissena polymorpha*) (Source: U.S. Geological Survey, Gainesville, Florida, June 13, 2005, http://www.unl.edu/nac/atlas/Map_Html/Ecosystem_Health/National/Current_zm_map/Current_zm_map.htm)

Zebra Mussels

Largely concentrated around the Great Lakes and Mississippi River areas (Figure 16.11.9), zebra mussels enter a sprinkler system through the water supply, particularly those systems that take their water from a natural body of water such as a lake or river. The mussels enter the pipe as larvae or young adults and colonize inside the piping, feeding from nutrients and oxygen in the water (Figures 16.11.10 and 16.11.11). As they continue to grow, they begin to obstruct waterflow to the system. The presence of zebra mussels is evidenced through the discharge of shells or live mussels during flow tests. An adult zebra mussel measures about ⅝ in. (16 mm) across the shell. Its name is derived from the distinct stripes on the shell resembling that of a zebra.

Treatment strategies for zebra mussels are similar to that for MIC, in other words, chlorination of water entering the system. Treatment with potassium in the range of 100 mg/L has shown promise; however, there are no commercially available systems at present.

Conditions Indicating Possible Obstructions in Piping

Evidence of possible obstruction in piping is given by any one of the following:

1. Plugging of test connections or discharge of dirty or colored water
2. Discharge of foreign material during routine water tests
3. Foreign material in dry-pipe valves, check valves, or fire pumps

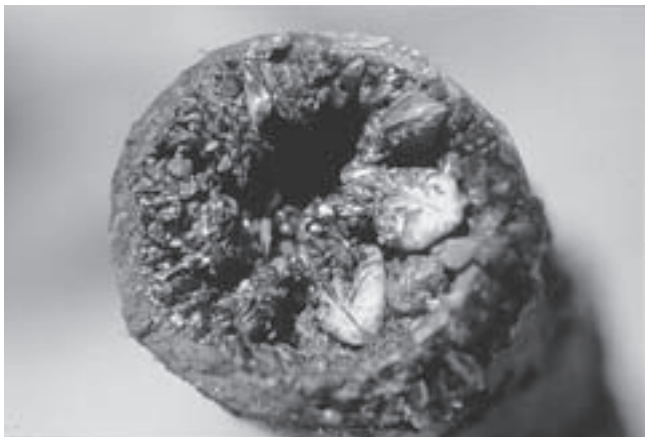

FIGURE 16.11.10 One Inch Pipe Completely Obstructed by Zebra Mussels

FIGURE 16.11.11 Two Inch Pipe Sample with Zebra Mussel Infestation

4. Obstructing material found in piping that is dismantled for building alterations
5. Defects found in fire pump suction screens when the water supply source is from open bodies of water
6. Repairs made to public water mains in vicinity
7. Underground piping not flushed before connection to systems
8. Plugged sprinklers or spray nozzles at time of fire
9. Old equipment, especially in dry-pipe systems

Investigation of Severity and Extent of Obstruction

An investigation of conditions must be made when evidence of foreign materials in systems is found or when obstructions are suspected. Where needed, cleaning or flushing procedures subsequently must be carried out to remove obstructing materials. Inspection and flushing methods outlined in this chapter are treated more completely in NFPA 25.

Flushing Feed Mains

Existing yard piping suspected of containing obstructing material should be thoroughly flushed through hydrants at dead ends of the system, blow-off valves, or groups of riser drains, by opening simultaneously as many outlets as possible and allowing the water to run until clean. If the water is supplied from more than one direction or through a looped system, divisional valves should be closed to produce a high-velocity flow through each single line.

It is usually desirable to learn the nature and extent of foreign material that may be in the piping. This can best be done by fastening burlap bags to the flowing outlets and examining the effluent remaining in the bag.

The connections to system risers should next be flushed through drain valves. If the foreign material is too large to pass through a main drain valve, some ingenuity must be used to procure a larger opening. Fire department connections can be used by removing the check valve. Flanged check valves or check valve covers or flanged fittings can be removed and a Siamese fitting can be substituted to facilitate such flushing.

Flushing System Piping

In choosing the critical points for examination, consideration should be given to the arrangement of the piping and the probable pattern of the flow of water when a system is rapidly filled (as in a dry-pipe system), or when a large flow of water from the system occurs due to operation of many sprinklers on a wet-pipe system.

After selection of the area in which the heaviest deposit of foreign material ordinarily would be expected, the investigation should take into consideration how much of the system's equipment in that area might be made ineffective by the obstructing material at the time of a fire. It is important that the preliminary investigation sufficiently indicates the extent of cleaning that may be required.

Flow Tests

Flow tests at critical points in a sprinkler system provide a positive means of determining the presence of foreign material in the system that may cause obstruction of flow from any of the sprinklers and also of indicating how much of the system is affected. To achieve this, valved hose connections are installed at the ends of two, three, or four branch lines on one side of and at the end of the affected cross main in the selected area. Flows are then taken simultaneously from these points and examined.

If obstruction occurs at any of the branch lines tested, additional tests may be necessary at points upstream on the system toward the system riser. Tests may next be extended to other floors to help make a judgment on the extent of cleaning operations that may be necessary for removing all foreign material that might cause obstructions.

Foreign deposits in sprinkler systems tend to be accumulated toward the ends of the cross mains and in the ends of branch lines. Of course, there will be exceptions to this general rule. For example, where highly corrosive material has been introduced into the system, severe corrosion and scaling of the interior surfaces of the piping will be evident uniformly throughout the system.

Visual Examination

The visual inspection of a system is a critical starting point of any flushing program. This first step will not tell the entire story of the condition of the piping; however, it can aid the trained person in an accurate determination of the piping condition. The visual examination encompasses the inspection of the interior and exterior of the piping, as well as the condition of and tuberculation in said piping.

The initial inspection should start by removing the end sprinklers at the upper- and lowermost portion of the system. Take extra care when removing any pendent sprinklers to check for sediment clogging the orifice.

The removal of the flushing connection is a simple method to determine the condition of the cross main.

Should these steps reveal the presence of obstructing material, and an internal inspection becomes necessary, the following should be used as a guideline:

1. Approximately 10 percent of the system should be examined when an internal inspection is recommended.
2. Remove
   a. Three to four endlines
   b. Riser nipples
   c. Elbows and tee feed for the cross main
3. Examine any areas where the water velocity decreases rapidly when draining the system piping.

If the internal inspection reveals substantial tuberculation and piping deterioration, a determination must be made by cost-efficiency analysis. The options available are flushing, whether it be by the hydropneumatic method or just with water, or the partial to total replacement of the affected area of the system.

The expense of flushing can be high when labor costs and materials are considered. Even though the system is flushed and back on line, the piping may have a shorter life expectancy than a new system.

EXTENT OF CLEANING REQUIRED

When preliminary tests show evidence of obstruction in sprinkler system piping, the next step is to undertake a cleaning program to remove the obstructing material. There are three levels of cleaning: (1) complete cleaning, (2) limited cleaning, and (3) flushing extremities only.

Generally, when obstruction occurs only in the branch lines at extremities of the system, only these areas of the system require flushing. If obstruction occurs at several test points, but indications are that free flows are available on the other lines back toward the riser, a limited cleaning procedure may be followed. If the obstruction is more extensive, then a complete cleaning procedure should be undertaken.

Before any cleaning efforts begin, written specifications or a flushing procedure covering the entire operation should be understood by all concerned. After completion of work, the sprinkler contractor or other party performing the cleaning operations should furnish a written report to those concerned indicating that all work has been completed in accordance with the approved procedure, that the specified examinations and tests have been made, and that the system has been left in normal condition.

Complete Cleaning

There are some cases where the foreign material is of such nature and extends so far back into the system from the ends of the cross mains that complete cleaning of the entire system will be necessary. In such cases, it is of prime importance that a plan of the piping system be prepared and be marked numerically to show the proper sequence of the cleaning operations, the size and length of hose to be used, the points where the hose is attached, and the number of flows to be made at each point.

Limited Cleaning

Where points of impairment can be identified as occurring within restricted areas rather than throughout the system, the limited cleaning procedure can be used. If these points exist in any appreciable amount but only in the ends of cross mains and in the branch lines connected at or near those points, not all branch lines need to be cleaned. The cleaning procedure may be limited to the branch lines at or near these points and to the cross mains on each floor.

Limited cleaning operations serve to minimize the time during which the sprinkler system is impaired. They lessen the interruption to normal activities within the premises where the cleaning operations are underway. Limited cleaning lowers the cost of the work as compared to more extensive cleaning. Because only a fraction of the total number of branch lines are being cleaned directly under the limited procedure, periodic flow tests should be made as the cleaning progresses in order to determine the effectiveness of the work.

Cleaning System Extremities Only

This method should be used only in cases in which obstruction of dry-pipe sprinkler system piping has been found to occur solely at the system extremities, and it relates to every floor protected, regardless of the number of floors. Extreme care should be exercised before this method is employed. Adequate examinations and flow tests are made to make certain that only the sprinklers located at the extremities of the system are subject to plugging. It should not be used where the deposits extend back into the cross main beyond the second branch line from the end of the cross main.

CLEANING METHODS

Generally, there are two methods used for cleaning sprinkler systems: (1) water flushing and (2) hydropneumatic. Convenience is a key factor that may make the hydropneumatic system preferable to the water flushing method. With the former, there is no open discharge of water outside the building, there is less interruption of plant operations, frequent filling and draining of the sprinkler system are unnecessary, there is considerably less pipe work, and a complete operation is performed at a single flush point.

Both methods are appropriate for complete cleaning and limited cleaning procedures. Good practice is to flush the underground piping and then to clean all private sources of water supply that might cause silting in the underground main. Both of these methods are thoroughly discussed in NFPA 25.

If it is anticipated that a sprinkler system may need periodic testing for obstruction or repeated flushing, a branch line tester may be installed permanently at the end of each branch line or between the last sprinkler and the end fitting on each branch line. The tester has a normally closed and capped outlet connection for hose. Turning a wrench fitting opens a passage to the outlet which has a 1 in. (25 mm) hose coupling thread. It is not necessary to remove the sprinkler when this type of device is used.

SPRINKLER LEAKAGE

The term *unintended discharge* is ordinarily used to describe leaks due to system component failure or damage, excluding fire conditions. Leaks, although infrequent, can occur in practically any portion of the system that has been damaged.

Unintended discharge from a properly designed, manufactured, and installed system should be very low because a sprinkler has undergone pressure testing during the commissioning process. Sprinkler pipe, fittings, and other components, including the sprinklers themselves, are rated for pressures far greater than are met with in practice. The supports are also designed to carry five times the weight of the pipe and water with a safety factor of 250 lb (113 kg). In some systems, the pipe supports are also intended to deal with the stress encountered during a seismic event. (See Section 16, Chapter 4, "Hanging and Bracing of Water-Based Systems.")

Automatic sprinkler systems protecting hazards vulnerable to water damage, such as computer equipment, works of art, valuable books, or important records, require an extra degree of attention due to the unusually severe consequences of any unintended discharge, which could occur, for example, if reasonable precautions are not taken against freezing, overheating, and mechanical damage. The use of single- or double-interlock preaction systems should be considered for these applications.

Mechanical Damage

Automatic sprinklers are designed to withstand at least 500 psi (3448 kPa) pressure without injury or leakage. If properly installed, there is little danger of the sprinkler breaking apart, unless it is physically damaged in some way. All of the listed sprinklers are very durable and will withstand considerable abuse. The frames can be bent somewhat, without opening the sprinkler.

When sprinklers are located in areas where they may suffer mechanical damage, they can be protected by commercially available metal guards (Figure 16.11.12).

The use of lift trucks or tractors in handling materials indoors must be carefully planned and supervised to avoid damaging sprinklers and sprinkler piping. Precautions should be taken where fast-response sprinklers are installed to reduce the chances of mechanical and environmental damage.

FIGURE 16.11.12 Metal Guard Protection Against Mechanical Injury

Freezing

The freezing of water in pipes is a common cause of trouble and the remedy in most cases is self-evident. Water expands slightly when it freezes, causing sprinklers to fail. When the ice melts, water is discharged. In other cases, the pipe or fittings may burst, causing more serious damage and more costly repairs. In some types of sprinklers, a moderate amount of freezing may not break the sprinkler open, but may cause it to leak at the seat after the ice has melted.

Some of the conditions that cause systems to freeze include the following:

1. Insufficient heat for severe weather conditions in certain portions, such as concealed spaces under roofs or blind attics, large open doorways for trucks or railway cars, entryways, or space under buildings
2. Windows left open during severely cold weather
3. Insufficient heat due to a shortage of heating fuel or power failure
4. Branch lines of dry-pipe systems not correctly pitched to drain
5. Feed mains or piping in unheated areas properly protected to prevent freezing
6. Freezing of tank risers due to lack of heat or lack of adequate protection; or obstructed circulating pipes of heating systems
7. Freezing of water in underground mains not buried deep enough

Overheating

"Overheating" is another potential cause of accidental discharge from sprinklers and is the term used when an automatic sprinkler operates as a result of abnormally high temperatures, without the presence of fire. This condition is usually caused by hot manufacturing processes, artificial heating, or lack of ventilation. It may result from a sudden increase in temperature that operates the thermal response element of the sprinkler, or from longer exposure to temperatures sufficiently high to cause gradual weakening of the element. In solder-type sprinklers, the latter condition, sometimes termed "cold flow" or "cold soldering," is indicated by partial separation of the soldered members.

In practice, there are a number of conditions that cause unsafe temperatures, such as the following:

1. Climatic conditions exceeding 100°F (41.3°C).
2. Ordinary temperature sprinklers located in close proximity to steam mains, unit heaters, or heating ducts. Temperatures higher than anticipated may occur after installation of sprinklers. Changes in heating methods, installation of unit heaters, or changes in manufacturing processes or equipment after sprinklers are installed can occur.
3. Changes in temperatures due to an occupancy change or processes that cause higher temperatures than contemplated.

These changes may be general or in isolated portions of a building.

4. In some cases, a fire that opens a number of sprinklers may weaken other sprinklers in that vicinity. This may not be apparent. Change all sprinklers in an area of fire influence and not just those that have opened.
5. Low-mass fusible linkage of quick-response sprinklers will enhance the negative influence as mentioned earlier. The installation and maintenance of this device requires great care.

NFPA 13 and NFPA 25 provide some information on sprinkler temperature ratings near unit heaters. Unit heaters should never be used without a careful study of conditions, and, in most cases, sprinklers near unit heaters must be replaced with a higher temperature rating in order to avoid unintended operation.

When conditions occur that require sprinklers higher than ordinary-degree rating, the maximum temperature at the sprinkler level must be determined and sprinklers of the correct temperature rating installed to avoid accidental discharge.

REDUCING WATER DAMAGE

It is evident that, if unintended waterflow occurs when there is no one in the building and no proper means of alarm notification to outsiders exists, the waterflow may continue for a considerable amount of time. This can result in serious damage to property, even with a small amount of water from just one leaking or flowing sprinkler.

Although security guard service is of value, it may not be adequate unless there is a sprinkler alarm device, which will notify the guard if water is flowing. Every sprinkler system should have a waterflow alarm device and properly located water motor gong to notify the proper personnel in case of fire or discharge of water due to inadvertent system discharge.

Large losses from sprinkler leakage or flow can result from lack of, or failure of, isolated sprinkler devices or the lack of waterflow alarms. Losses can also be attributed to the failure to promptly notify authorized person(s) who can investigate immediately and shut off the water if there is no fire. In some cases, water may run for many hours undetected.

Sprinkler supervisory service is of great value in the prompt discovery of system operation from a fire event. In addition, it is also useful to detect leakage from the system and in securing appropriate action to minimize the water loss.

WATER SPRAY SYSTEMS

Water spray systems are similar to sprinkler systems in that they contain a water supply, control valves, piping, hangers, and discharge devices. As such, these systems also require the same inspection, testing, and maintenance as sprinkler systems. However, water spray systems can have, in addition to these items, a detection system that is hydraulic, pneumatic, or electronic, other devices such as pipeline strainers (not normally found on sprinkler systems), and directional water spray nozzles. Each of these systems or devices requires special attention in order to maintain the operational status of the water spray system.

Strainers are usually present due to the small size of the orifice of the spray nozzles. They must be periodically flushed and/or cleaned to ensure that the perforations in the strainer basket are free of obstructing material. A small flushing connection, usually 2 to 2½ in. (50 to 65 mm) in diameter, is provided for this purpose. The strainer basket can be removed and cleaned when flushing is not sufficient for proper cleaning.

Water spray systems should be subject to a discharge test annually to verify automatic operation (if provided) of the systems and components and to verify proper orientation of spray nozzles (Figure 16.11.13). The nozzles used on these systems are directional type and are intended to directly impinge on the protected surface.

Some nozzles may be equipped with a protective cover, commonly referred to as a blow-off cap. It is important to ensure that the caps are in place before the test and that they are reinstalled following the discharge test. The cap prevents obstructing material, such as dirt or dust, from entering the system through the orifice of the nozzle (Figure 16.11.14).

FIGURE 16.11.13 Directional Spray Nozzle Testing (Source: NFPA 25 Handbook, 2002, Exhibit 10.3)

FIGURE 16.11.14 Nozzle with Blow-Off Cap (Source: NFPA 25 Handbook, 2002, Exhibit 10.6)

Pneumatic or hydraulic detection systems (pilot systems) also require some attention. Usually, a sprinkler with a fusible link is used as a thermal detector. These pilot sprinklers must be subject to the same inspection, testing, and maintenance as sprinklers installed in a common wet-pipe sprinkler system. They should be inspected to ensure that they are free of corrosion or contaminant loading.

Pneumatic systems rely on a source of compressed air. This can take the form of an air compressor, nitrogen cylinder, or plant air. In any case, the air supply should be inspected to determine its condition and operation, and any damaged or corroded parts should be replaced immediately.

Foam-Water Sprinkler and Foam-Water Spray Systems

In addition to the requirements for sprinkler and water spray systems, foam-water sprinkler and foam-water spray systems require special attention. These systems are equipped with a foam-proportioning system. The common types of proportioning systems are standard pressure, bladder tank, line, standard balanced pressure, and in-line balanced pressure type. Regardless of the proportioning system type, each component should be inspected quarterly for signs of corrosion or damage and to ensure that it is in good operating condition. In addition to inspection, at least every 10 years, the foam concentrate storage tank should be pressure tested to its working pressure. All components that are in contact with foam concentrate must be flushed and cleaned annually.

Foam-water sprinkler and foam-water spray systems are subject to an annual discharge test. During this test, a foam sample is taken and the proper concentration of foam is measured by refractometric or other methods to verify concentration of the foam-water solution. The results should be within 10 percent of the acceptance test results but not less than 10 percent below the minimum design standard. Foams are usually designed and listed for concentrations of 1, 3, and 6 percent. Following the discharge test, the foam concentrate tank must be refilled to capacity with adequate space remaining for expansion.

Standpipe Systems

Standpipe systems consist of pipe, fittings, valves, and sometimes hose intended to supply water for manual fire fighting in all areas of a building. A standpipe system eliminates the need to stretch long lengths of hose vertically and horizontally through a building to deliver water to a fire. There are three classes of standpipe systems—Class I provides a 2½ in. (65 mm) hose valve specifically for fire department use, Class II provides a 1½ in. (40 mm) hose valve, complete with hose and nozzles for building occupant use, and Class III is a combination of Classes I and II and may or may not include hose and nozzles. Standpipe systems may be automatic, providing a permanent water supply that is capable of supplying the required pressure and flow, or manual, relying on a fire department pumper to supply pressure and flow. Standpipe systems may also be wet or dry in cases in which the system may be subject to freezing temperatures.

Inspection of standpipe systems should begin at the water supply and continue throughout the entire system on a quarterly basis. This inspection, as for that of a sprinkler system, should reveal signs of damage, leaks, corrosion, or any condition that may impair system operation. Where building occupant hose is present, the hose should be removed from the rack or reel annually and inspected for evidence of vandalism. The hose should be free of obstruction and not damaged by mildew or abrasion of any kind. The hose should be reracked or rereeled in such a way that folds do not occur in the same position on the hose. Standpipe hose should be removed from the system for hydrostatic testing at five years and every three years thereafter.

Hose valves should be inspected quarterly to ensure that the handwheel is not missing or broken, the threads are not damaged, the valve is not leaking, and the cap is in place. In cases in which high pressures are present, the valve should be of the pressure-regulating type. Pressure-regulating hose valves are generally of two types—pressure reducing, which controls both static (nonflowing) and residual (flowing) conditions, and pressure restricting, which controls residual conditions only. Pressure-regulating devices should be flow tested every five years to verify that the pressure-reduction setting is correct. Valves that are not set properly should be reset; valves that are not adjustable should be replaced.

During commissioning, all standpipe systems must be hydrostatically tested at 200 psi (1379 kPa) for 2 hours, or 50 psi (345 kPa) in excess of the maximum anticipated static pressure, whichever is greater. Unless modifications to the piping system are made, no further hydrostatic testing is necessary. In the case of a manual dry-standpipe system, however, a hydrostatic test at five-year intervals is necessary to verify the piping system integrity. As defined in NFPA 14, *Standard for the Installation of Standpipe and Hose Systems,* a manual dry-standpipe system has no permanently attached water supply; the fire department is expected to supply waterflow and pressure through the fire department connection. Therefore, these systems must be hydrostatically tested periodically to confirm that they do not leak.

Standpipe systems of all types should be flow tested every five years at the most remote connection to reverify that the system can supply the required flow and pressure. Care should be exercised due to the potential high pressures involved and the proper disposal of test water should be considered.

WATER SUPPLIES

Private Fire Service Mains and Appurtenances

Since inspection of private fire service mains is not practical, flow tests should be conducted at least every five years. Flow test results should be compared to previous tests to reveal any sign of deterioration of the flow and pressure in the system. Should any deterioration be discovered, a complete investigation to determine the cause should be conducted.

Hydrants should be flushed annually by allowing full flow for at least one minute. Dry barrel hydrants should drain thoroughly in less than one hour. During this procedure, hydrants should be inspected for accessibility and operation, and hydrants should be lubricated.

Fire Pumps

A fire pump (when present) is a significant component of the system water supply. Therefore, it is imperative that fire pump equipment operates when needed. The lack of an inspection, testing, and maintenance program for a fire pump can result in costly repairs and system impairment.

Fire pumps should be inspected and tested on a weekly basis. The test is accomplished without flowing water. To begin the test, a pressure drop should be simulated by opening a valve on the fire pump sensing line. The pressure drop will cause the pressure switch in the pressure maintenance pump controller to start that pump. As system pressure continues to drop, the fire pump will start.

An electric pump should be run for a period of 10 minutes. During this time, several observations can be made. Of utmost importance, the casing relief valve should open, allowing a small discharge of water. This will cause an introduction of cool water into the fire pump casing, preventing overheating of the fire pump. The pump packing glands should be adjusted to provide a slight discharge of water. During the operation of the pump, other observations should be made such as unusual noise or vibrations and evidence of overheating. Suction and discharge pressures should be recorded and an inspection/operation test report filed (Figure 16.11.15).

A diesel pump should run for a period of 30 minutes. During operation, the following observations should be made and recorded: engine oil pressure, speed, water and oil temperature, and a check of the heat exchanger for cooling waterflow. Observations should be recorded and an inspection/operation report filed.

A diesel pump is operated for 30 minutes to allow the engine and cooling system to reach operating temperature. Another reason for the 30 minute operation time is to slowly consume fuel, since diesel fuel can become contaminated over time. By operating the engine weekly, diesel fuel will need to be replaced, thus avoiding problems with stale diesel fuel (Figure 16.11.16).

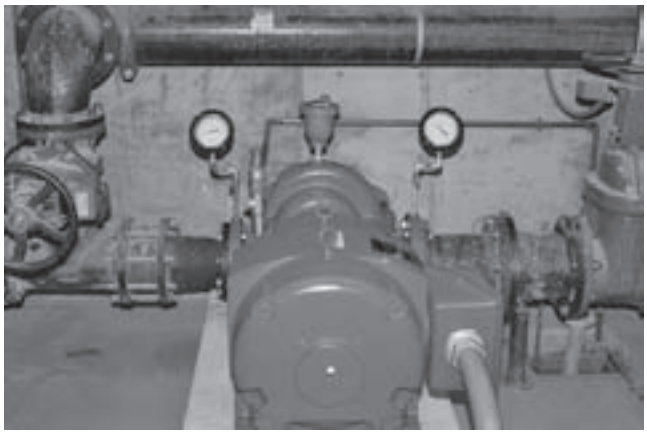

FIGURE 16.11.15 Electrically Driven Fire Pump

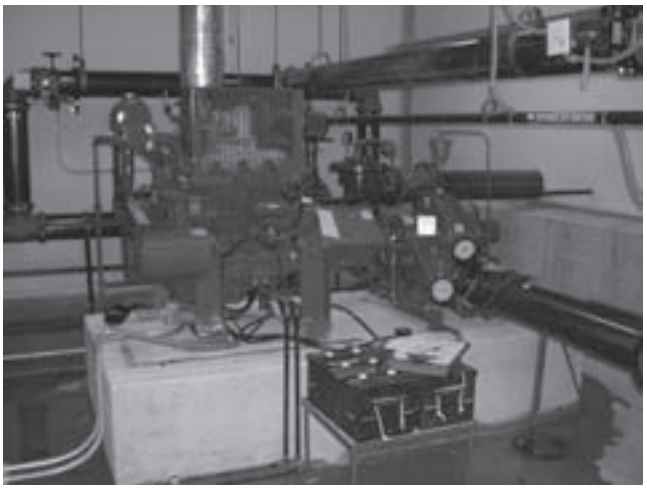

FIGURE 16.11.16 Diesel-Driven Fire Pump (Source: Mechanical Designs, Ltd.)

Fire pumps should be flow tested annually to verify that the pump is functioning properly. This test, identical to the initial commissioning test, is intended to discharge water through the pump at minimum, rated, and peak flows. The preferred test method is to discharge water through the fire pump test header and measure flow by means of a Pitot tube. The use of a flowmeter via a bypass is acceptable; however, once every three years, a test through the test header is necessary.

The results of the annual pump test should be recorded and compared to previous results. It is not the intent to reverify the fire pump curve each year; however, deterioration of performance should be recorded. The intent of the test is to verify that the pump is capable of supplying the maximum system demand.

Water Storage Tanks

Water can be stored in tanks for fire protection purposes, where no other source is available. The types of tanks used are described in Section 15, Chapter 1, "Fixed Water Storage Supplies for Fire Protection." Regardless of the type of tank in use, water tanks require inspection to ensure that they are in good condition.

All tanks should be inspected monthly to verify the correct water level and condition of the water. When installed in areas subject to freezing, tanks should be equipped with a heating system to maintain a minimum water temperature of 42°F (5.6°C). The heating system must be kept in operating condition to avoid the formation of ice that can cause an obstruction to the discharge pipe or cause tank walls to buckle. High and low water temperature alarms may be installed and should be kept in operating condition.

Steel tanks should be inspected for corrosion, including painting systems and cathodic protection where provided. Interior inspections should be done every five years by either a certified diver or by draining the tank completely and following confined space entry procedures.

SYSTEM IMPAIRMENT

When repair or modifications are necessary, a fire protection system may need to be taken out of service. To minimize this downtime, the building owner should appoint an impairment coordinator. The impairment coordinator should be familiar with the operation of the system, the tools and equipment necessary to make repairs, the operations affected by the repairs, and be thoroughly knowledgeable of the organizations that must be notified whenever a system is taken out of service. The impairment coordinator is responsible for supervising the impairment activity from system shutdown to restoration of service.

During any equipment shutdown, a lockout and/or tagout procedure should be in place. A tag should be posted on any valve that is closed (Figure 16.11.17). The tag should indicate that the system has been removed from service, the date, and person responsible for the procedure. Any electrical equipment, such as a fire pump, should be locked in the off position to avoid accidental start-up while the equipment is being serviced. Each tag or lock should be documented in the procedure and retrieved during restoration to service.

If systems must be taken out of service for extended periods of time, that is, four hours or more in a 24 hour period, additional safety procedures should be arranged. Consideration should be given to complete evacuation of the building, establishment of a temporary water supply, a fire watch, or an approved fire prevention program. In such cases, the building owner and the authority having jurisdiction should be consulted prior to system impairment.

Emergency impairments, such as replacement of sprinklers following a fire, leaks, or other service interruptions, should be supervised by the impairment coordinator following the same procedures for a preplanned impairment.

Restoration to service should include a complete inspection of the system to verify the following:

- Repairs are completed.
- All valves are returned to their normal operating position.
- Valve tags are retrieved and documented.
- The authority having jurisdiction, insurance and alarm companies, and all other interested parties are notified.

Closeout of the lockout/tagout program should be documented and filed.

SUMMARY

Of the leading causes of sprinkler system failures, 55 percent of those reported can be directly attributed to improper or lack of maintenance. NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems,* establishes a maintenance program that will improve sprinkler system performance. The standard devotes an entire chapter to valves, as water control valves account for 35.4 percent of unsatisfactory performance and defective dry-pipe valves account for 1.7 percent. Obstruction to water distribution accounts for 8.2 percent. A frozen system is responsible for 1.7 percent of unsatisfactory performance and, in general, 8.4 percent of sprinkler system failure is related to inadequate maintenance. (See *U.S. Experience with Sprinklers: Who Has Them? How Well Do They Work?* by Rohr.) By following the requirements of NFPA 25 and this chapter, the already excellent performance of fire protection systems can be improved.

SECTION 17

Fire Suppression Systems and Portable Fire Extinguishers

Mark T. Conroy

17.1 Carbon Dioxide and Application Systems
17.2 Chemical Extinguishing Agents and Application Systems
17.3 Characteristics and Hazards of Water and Water Additives for Fire Suppression
17.4 Foam Extinguishing Agents and Systems
17.5 Fire Extinguisher Use and Maintenance
17.6 Halon and Halon Replacement Agents and Systems
17.7 Application of Gaseous Agents to Special Hazards Fire Protection
17.8 Explosion Prevention and Protection

Fire suppression systems and portable fire extinguishers are the subjects of Section 17 of the *Fire Protection Handbook*®. For this edition, two earlier chapters on halogenated agents and systems and direct halon replacement agents and systems have been combined to form one chapter entitled "Halon and Halon Replacement Agents and Systems." A new chapter on the application of gaseous agents for special hazards is also included.

Chapter 1, "Carbon Dioxide and Application Systems," presents the properties and extinguishing characteristics and limitations of carbon dioxide and its methods of application, as well as components, design considerations, and testing and maintenance of carbon dioxide systems.

Chapter 2, "Chemical Extinguishing Agents and Application Systems," contains information on the properties of both dry and wet chemicals that contribute to their use as extinguishing agents. The limitations; methods of application; system design; and the inspection, testing, and maintenance associated with these systems are addressed.

Water is the most widely used and most readily available extinguishing agent. Chapter 3, "Characteristics and Hazards of Water and Water Additives for Fire Suppression," discusses the properties of water as an extinguishing agent, including its advantages and limitations.

Foam is generated by proportioning foam concentrate with water; the resulting foam solution is used in fixed and portable fire extinguishing systems. Chapter 4, "Foam Extinguishing Agents and Systems," describes those agents and systems, along with their uses and limitations. Specialized foam fire-fighting vehicles are described.

Chapter 5, "Fire Extinguisher Use and Maintenance," provides basic information on matching extinguishers to hazards, types of extinguishers, and health and safety considerations.

Chapter 6, "Halon and Halon Replacement Agents and Systems," describes extinguishing mechanisms, flame suppression effectiveness, toxicity and environmental factors, thermophysical properties, and similar fundamental information.

Chapter 7, "Application of Gaseous Agents to Special Hazards Fire Protection," examines the key characteristics of special hazards that are particularly relevant to the use of gaseous fire extinguishing agents. This chapter also provides information aimed at evaluating a given fire hazard and selecting an appropriate gaseous extinguishing agent system to protect it.

The section concludes with Chapter 8, "Explosion Prevention and Protection." The contents of this chapter include a description of events leading to an explosion, explosion hazard analysis, explosion protection, deflagration prevention and suppression, and enclosure integrity and strength.

Mark T. Conroy is a senior fire protection engineer for Brooks Equipment Company of Charlotte, North Carolina.

Chapter 1

Carbon Dioxide and Application Systems

Thomas J. Wysocki

Carbon dioxide (CO_2) has been used in fire extinguishing systems for nearly 100 years. The first systems were installed between 1910 and 1915 in Europe. CO_2 has no doubt safely extinguished more fires than any other gaseous fire-extinguishing agent. In the process, carbon dioxide systems have saved lives, maintained livelihoods, and prevented property damage. The benefits of carbon dioxide systems, properly applied, are enormous.

To gain the benefits of carbon dioxide extinguishing systems while minimizing risk to people, serious attention must be given to personnel safety in the design, installation, and maintenance of carbon dioxide systems. Training of personnel is essential.

This chapter will discuss the properties of carbon dioxide and its proper use in fixed fire-extinguishing systems; its limitations as a fire-extinguishing agent; life safety considerations; methods of application; system components; design considerations; and requirements for testing, maintenance, and training. NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems,* provides guidance to those responsible for the purchase, design, installation, testing, inspection, operation, and maintenance of carbon dioxide systems.

Other chapters in the handbook that reference carbon dioxide systems include Section 9, Chapter 8, "Protection of Records"; Section 16, Chapter 7, "Ultra-High-Speed Water Spray Systems"; and Section 21, Chapter 10, "Marine Vessels."

Carbon Dioxide System Design Considerations
Testing and Maintaining Carbon Dioxide Systems

Key Terms

carbon dioxide, carbon dioxide hand hose line, electrical control panel, gas standpipe system, inerting, local application discharge nozzle, lockout, odorizer, total flooding system

USAGE

Carbon dioxide has been used for nearly a century to extinguish flammable liquid fires, gas fires, fires involving electrically energized equipment, and, to a lesser extent, fires in ordinary combustibles, such as paper, cloth, and other cellulosic materials. Carbon dioxide will suppress fire effectively in most combustible material. Exceptions are a few active metals and metal hydrides and materials, such as cellulose nitrate, that contain available oxygen. Furthermore, practical limitations of carbon dioxide are related to the physiological effects of carbon dioxide and to restrictions imposed by the hazard itself.

PROPERTIES OF CARBON DIOXIDE

Carbon dioxide has a number of properties that make it a desirable fire-extinguishing agent. It is noncombustible, it does not react with most substances, and it provides its own pressure for discharge from the storage container. Since carbon dioxide is a gas, it can penetrate and spread to all parts of a fire area. As a gas or as a finely divided solid called "snow" or "dry ice," it will not conduct electricity and, therefore, can be used on energized electrical equipment. It leaves no residue, thus eliminating cleanup of the agent itself.

Thomas J. Wysocki is a consultant with Guardian Services, Inc., in Frankfort, Illinois. He is active on several NFPA technical committees, including those covering carbon dioxide, halon fire-extinguishing systems, and clean agent halon alternative systems.

Thermodynamic Properties

At room temperature and pressure, carbon dioxide is a gas. It is easily liquefied by compressing and cooling, and, with further compressing and cooling, it can be converted to a solid. The effect of temperature changes on compressed carbon dioxide in a closed container is shown in Figure 17.1.1. Above the critical temperature of 87.8°F (31°C), irrespective of pressure, it is entirely gas. Between 87.8°F (31°C) and the temperature of the triple point, which is –69.9°F (–57°C), in a closed container, it is part liquid and part gas. Below the triple point, it is either a solid or a gas, depending on the pressure and temperature.

On the part of the curve between –69.9°F (–57°C) and the critical temperature of 87.8°F (31°C), carbon dioxide in a closed container may be a gas or a liquid. The pressure is related to the temperature, as long as both vapor (gaseous) and liquid states are present. As the temperature and pressure increase, the density of the vapor phase increases while the density of the liquid phase decreases. At 87.8°F (31°C), the density of the vapor becomes equal to the density of the liquid, and the clear demarcation between the two phases disappears. Above the critical temperature, high-pressure carbon dioxide exists only in a gaseous form.

When the temperature is reduced to –69.9°F (–57°C) at 75 psia (517 kPa), carbon dioxide may be present in vapor, liquid, and solid forms in equilibrium with each other. Hence, the term "triple point" to describe this condition. Below the triple point, only vapor and solid phases can exist. Thus, when liquid carbon dioxide is discharged to atmospheric pressure, a portion instantly flashes to vapor while the remainder is cooled by evaporation and converted to finely divided snow, or dry ice, at a temperature near –110°F (–79°C). The proportion of carbon dioxide converted to dry ice depends on the temperature of the stored liquid. Approximately 46 percent of the liquid stored at 0°F (–18°C) will be converted to dry ice, compared to approximately 25 percent for liquid stored at 70°F (21°C).

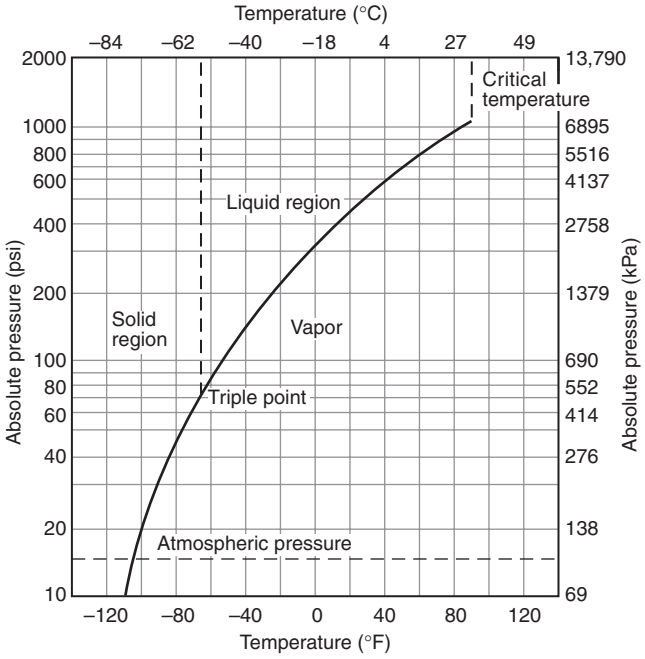

FIGURE 17.1.1 Effect of Pressure and Temperature Change on the Physical State of Carbon Dioxide

Storage

Liquid carbon dioxide may be stored in high-pressure cylinders with storage temperature varying with ambient temperature or in low-pressure refrigerated containers designed to maintain a storage temperature near 0°F (–18°C). Freezing (solidifying) in storage is not a problem. However, any substantial reduction in storage temperature—and corresponding storage pressure—could reduce the discharge flow rate below acceptable design limits. High-pressure systems normally are designed to operate properly with storage temperatures ranging from 32 to 120°F (0 to 49°C). Low-pressure systems, which normally operate at 0°F (–18°C), would not be affected unless the ambient temperature surrounding the storage container dropped to –10°F (–23°C) or lower for a prolonged time. Extreme climatic environments may require special design considerations to ensure proper operation. For low storage temperatures, high-pressure cylinders may require special "winterization" treatment, while low-pressure storage units may require heaters with circulation pumps.

Discharge Properties

A typical discharge of liquid carbon dioxide has a white, cloudy appearance due to finely divided dry ice particles carried along with the flash vapor. Because of the low temperature, some water vapor from the atmosphere will condense, creating additional fog that will persist for a time after the dry ice particles have settled out or sublimed.

Static Electricity

The dry ice particles produced during a discharge of carbon dioxide can carry a charge of static electricity. Static charge can also build up on ungrounded discharge nozzles. To prevent shock hazard to personnel or unwanted static discharge in a potentially explosive atmosphere, all discharge nozzles must be grounded. This is particularly important in the case of nozzles and playpipes used in hand hose line systems.

Vapor Density

Carbon dioxide gas has a density of one and one-half times the density of air at the same temperature. The cold discharge has a much greater density, which accounts for its ability to replace air above burning surfaces and maintain a smothering atmosphere when used in local application systems. When carbon dioxide is used for total flooding, the resulting mixture of carbon dioxide and air will be more dense than the ambient atmosphere.

Physiological Effects

Carbon dioxide is normally present in the atmosphere at a concentration of approximately 0.038 percent. It is present in humans and animals as a normal by-product of cellular respiration.

In the human body, carbon dioxide acts as a regulator of breathing, thus ensuring an adequate supply of oxygen to the system. Up to a point, an increase in carbon dioxide in the blood causes an increase in breathing rate. The maximum increase in respiration occurs when breathing 6 to 7 percent carbon dioxide in air. Higher concentrations of carbon dioxide slow down breathing. Finally, with 17 to 30 percent carbon dioxide in air, a narcotic effect takes over and stops breathing almost immediately—even with a sufficient supply of oxygen in the air. Death can result in a matter of minutes if prompt remedial action is not taken. Reduced oxygen supplies will cause a very much lower concentration of carbon dioxide to suppress breathing and cause death from asphyxiation. The exact concentration of carbon dioxide in air that will cause a decrease in respiration varies from person to person and is not constant even in the same person from time to time.

Six to 7 percent carbon dioxide is considered the threshold level at which harmful effects become noticeable in human beings. At concentrations above 9 percent, most people lose consciousness within a short time. Since the minimum concentrations of carbon dioxide in air used to extinguish fire far exceed 6 percent, adequate safety precautions must be designed into every carbon dioxide fire-extinguishing system.

The dry ice that is produced during a discharge can produce "burns," due to the extreme low temperature. Personnel should be warned not to handle any residual snow after a discharge.

EXTINGUISHING PROPERTIES OF CARBON DIOXIDE

The primary mechanism by which carbon dioxide extinguishes fire is oxygen reduction (smothering). The cooling effect of carbon dioxide is relatively small but does make some contribution to fire extinguishment, particularly when carbon dioxide is applied directly to the burning material.

Extinguishment by Smothering

In any fire, heat is generated by rapid oxidation of a combustible material. Some of this heat raises the unburned fuel to its ignition temperature, whereas a large part of the heat is lost by radiation and convection, especially in the case of surface burning materials. If the atmosphere that supplies oxygen to the fire is diluted with carbon dioxide vapor, the rate of heat generation is reduced until it is below the rate of heat loss. When the fuel is cooled below its ignition temperature, the fire dies out and is extinguished completely.

The minimum concentration of carbon dioxide needed to extinguish surface burning materials, such as liquid fuels, can be determined accurately, since the rate of heat loss by radiation and convection is reasonably constant. Table 17.1.1 lists the minimum concentrations of carbon dioxide for some common liquid and gaseous fuels as determined by the U.S. Bureau of Mines.[1] Minimum CO_2 concentrations for flammable liquid and gas hazards are based on inerting the air/fuel mixture. The theoretical minimum carbon dioxide concentration is the actual concentration of carbon dioxide required to extinguish and prevent fire in a given fuel. The minimum design concentration is

TABLE 17.1.1 Minimum Carbon Dioxide Concentrations for Extinguishment

Material	*Theoretical Minimum CO_2 Concentration (%)*	*Minimum Design CO_2 Concentration (%)*
Acetylene	55	66
Acetone	27*	34

Quench, lubricating oils	28	34

Note: The theoretical minimum extinguishing concentrations in-air for the above materials were obtained from a compilation of Bureau of Mines Limits of Flammability of Gases and Vapors (*Bulletins* 503 and 627). Those marked with * were calculated from accepted residual oxygen values.

20 percent more than the theoretical minimum carbon dioxide concentration but is never less than 34 percent (per NFPA 12). It is difficult to obtain similar data for solid materials because the rate of heat loss by radiation and convection can vary widely, depending on shielding effects caused by the physical arrangement of the burning material. Design concentrations for hazards containing solid fuels have been determined from testing and experience. NFPA 12 gives design concentrations for a number of such hazards.

Extinguishment by Cooling

Although the temperatures involved in a carbon dioxide discharge may approach –110°F (–79°C), the cooling capacity of the carbon dioxide is quite small compared to an equal weight of water. The latent heat of 1 lb (0.4536 kg) of liquid carbon dioxide is about 120 Btu (126 kJ) from low-pressure storage and 64 Btu (67.5 kJ) from storage at 70°F (21°C). The cooling effect is most apparent when the agent is discharged directly on the burning material by "local application." A massive application quickly covering the entire surface area smothers the fire and helps cool the fuel.

LIMITATIONS OF CARBON DIOXIDE AS AN EXTINGUISHING AGENT

The use of carbon dioxide on general Class A fires is limited by its relatively low cooling capacity, compared to that of water, and by enclosures incapable of retaining an extinguishing atmosphere. True surface burning fires are extinguished easily because natural cooling takes place quickly. On the other hand, if the fire penetrates below the surface of the fuel and the mass of fuel provides a layer of thermal insulation that slows down the rate of heat loss (generally referred to as "deep-seated burning"), a higher concentration of carbon dioxide and a much longer holding time are needed for complete extinguishment. Some deep-seated fires may not be extinguished by carbon dioxide even after a long holding time. In such cases, carbon dioxide can be used to suppress open flaming and slow the propagation of the fire. This holding action should be maintained long enough to permit response by a properly equipped and trained fire brigade.

Carbon dioxide is not an effective extinguishing agent for fires involving chemicals that contain their own oxygen supply, such as cellulose nitrate. Fires involving reactive metals, such as sodium, potassium, magnesium, titanium, zirconium, and the metal hydrides, cannot be extinguished by carbon dioxide because the metals and hydrides decompose carbon dioxide.

METHODS OF APPLICATION

Two basic methods are used to apply carbon dioxide in extinguishing fires. One method is to discharge a sufficient amount of the agent into an enclosure to create an extinguishing atmosphere throughout the enclosed area. This is called "total flooding." The second method is to discharge the agent directly onto the burning material without relying on an enclosure to retain the carbon dioxide. This is called "local application." Other methods include hand hose lines, standpipe systems and mobile supply, extended discharge, and special applications.

Total Flooding

In total flooding systems, carbon dioxide is applied through nozzles designed and located to develop a uniform concentration of CO_2 in all parts of an enclosure (Figure 17.1.2). Calculation of the quantity of carbon dioxide required to achieve an extinguishing atmosphere is based on the volume of the room and the concentration of carbon dioxide required for the combustible materials in it.

The integrity of the enclosure is a very important part of total flooding, particularly if deep-seated fire potential exists in the hazard. If the room is tight, especially on the sides and bottom, the CO_2 extinguishing atmosphere can be retained for a long time to ensure complete control of the fire. If there are openings on the sides and bottom, however, the heavier mixture of carbon dioxide and air may leak out of the room rapidly. If the extinguishing atmosphere is lost too rapidly, glowing embers may remain and cause reignition when air reaches the fire zone. Therefore, it is important to close all openings to minimize leakage or to compensate for the openings by an extended discharge. Because of the relative weight of carbon dioxide, an opening in the ceiling helps to relieve internal air pressure during the discharge, with very little effect on leakage rate after the discharge.

Local Application

In local application systems, carbon dioxide is discharged directly on the burning surfaces through nozzles designed for this

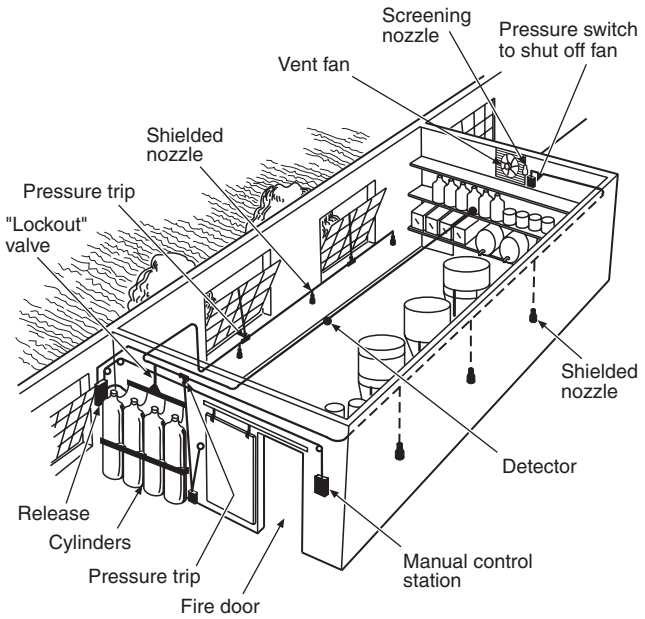

FIGURE 17.1.2 High-Pressure Carbon Dioxide System for Total Flooding

purpose. The intent is to cover all combustible areas with nozzles located so they will extinguish all flames as quickly as possible. Any adjacent area to which fuel or fire may spread also must be covered, because any residual fire could cause reignition after the carbon dioxide discharge ends (Figure 17.1.3).

Local application discharge nozzles usually are designed for relatively low velocity to avoid splashing and air entrainment. Automatic detection is a necessity to provide fast response and minimize heat buildup. Although not essential, an enclosure would help retain carbon dioxide in the fire area. Local application of carbon dioxide can also be used for fast fire knockdown in an enclosure where final total flooding can provide extinguishment.

Hand Hose Lines

Carbon dioxide systems can consist of hand hose lines permanently connected by means of fixed piping to a fixed supply of carbon dioxide. Such systems frequently are provided for manual protection of small localized hazards. Although not a substitute for a system with fixed nozzles, a hose line may be used to supplement a fixed system where the hazard is accessible for manual fire fighting, as well as to supplement portable equipment. There must be a sufficient carbon dioxide supply to permit the use of the hand hose line nozzle for at least 1 minute. Nozzles should be connected to a good electrical ground to permit static electrical charges produced by the carbon dioxide discharge to drain off. A wire-braided hose properly coupled to the discharge piping can provide a path to ground. Figure 17.1.4 shows a hand hose line system that offers flexibility for attacking fires.

FIGURE 17.1.3 Discharge of a Local Application Carbon Dioxide Extinguishing System (Source: Ansul Incorporated)

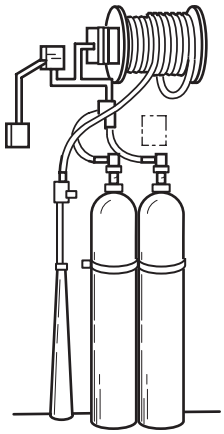

FIGURE 17.1.4 Carbon Dioxide Hand Hose Extinguishing System with Hose Mounted on a Reel

Standpipe Systems and Mobile Supply

Total flooding, local application, and hand hose line systems without a permanently connected carbon dioxide supply are known as gas standpipe systems. They are supplied by containers of carbon dioxide mounted on mobile units that can be moved and quickly coupled to a standpipe in case of fire.

Gas standpipe systems can be used as a supplement to complete fixed fire protection systems or as the only protection of hazards under certain circumstances. Mobile supplies may be equipped with hand hose lines for the protection of scattered hazards. If the possible fire damage that might occur while the mobile supply is moved to the scene and deployed is unacceptable, a fixed automatic system should be used.

Extended Discharge

An extended discharge of carbon dioxide is used when an enclosure is not tight enough to retain an extinguishing concentration as long as is needed. The extended discharge normally is at a reduced rate, following a high initial rate used to develop the extinguishing concentration in a reasonably short time. The reduced rate of discharge should be a function of the leakage rate, which can be calculated on the basis of leakage area, or of the flow rate through ventilating ducts that cannot be shut down.

Extended discharge is particularly applicable to enclosed rotating electrical equipment, such as generators, where it is difficult to prevent leakage until rotation stops. Extended discharge can be applied to ordinary total flooding systems, as well as to local application systems where a small hot spot may require prolonged cooling.

Special Applications

Carbon dioxide systems are sometimes used for inerting or purging to prevent fire or explosion. Carbon dioxide vapor is typically used in these applications. NFPA 69*, Standard on Explosion Prevention Systems,* gives guidance on these applications. Fire suppression in coal storage silos also can use carbon

dioxide vapor. Low-pressure storage with an in-line vaporizer can conveniently supply the large quantities of carbon dioxide vapor typically required for these applications.

LIFE SAFETY CONSIDERATIONS

To gain the benefits of carbon dioxide extinguishing systems while minimizing risk to people, serious attention must be given to personnel safety. Personnel safety must be considered in the design, installation, maintenance, and use of carbon dioxide systems. NFPA 12 discusses personnel safety at length.

General Safety Considerations

The minimum design concentration for total flooding systems is 34 percent. This is well above the acceptable exposure threshold for personnel. Breathing such a concentration of CO_2 will cause almost immediate unconciousness followed by death in a matter of minutes if appropriate emergency rescue action is not begun immediately. All total flooding systems will produce lethal concentrations of carbon dioxide in the protected space. For such systems, predischarge evacuation is always required.

Local application systems produce high concentrations of carbon dioxide in the immediate vicinity of the fire hazard. Each local application system must be evaluated to determine if evacuation of personnel is necessary prior to the start of the discharge.

If the local application hazard is located in a large open space, the initial discharge of carbon dioxide generally presents little risk to personnel. Indeed if personnel are in the immediate vicinity of the fire, they are likely at risk from exposure to the fire itself. On the other hand, if the local application hazard occupies a large portion of the space, dangerous concentrations of carbon dioxide can build up quickly throughout the space, particularly at lower elevations within the space. Again the risk of exposure to uncontrolled fire must be weighed against the risk that the carbon dioxide discharge will endanger personnel before they can leave the area.

In all cases, both local application and total flood, migration of CO_2 from a discharge to adjacent low-lying spaces can produce dangerous concentrations of carbon dioxide, and if personnel are present in such spaces, such migration of CO_2 can present a danger to life. Suitable warning devices must be incorporated into the system.

Safety Guidance

NFPA 12 prohibits the use of total flooding carbon dioxide systems in normally occupied spaces with certain specific exceptions. NFPA 12 contains guidance as to the circumstances where the use of carbon dioxide total flooding systems in a normally occupied space could be permitted. Where a gaseous extinguishing agent is desired for a normally occupied space, the "clean agents" covered in NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems,* are generally recommended.

Arrangements to ensure evacuation before discharge must be made for all spaces protected by total flooding systems, including those that are not normally occupied but in which personnel might be present for maintenance or other purposes. If evacuation cannot be assured, the system should be locked out while personnel are within the space. Local application systems must be evaluated on a case-by-case basis, giving consideration to potential for hazardous concentrations within the enclosure containing the fire risk as well as potential for migration of CO_2 to adjacent low-lying areas.

Lockouts

NFPA 12 requires system "lockouts" to be provided for all systems except those where the dimensional characteristics of the space will prevent personnel from entering the space. The system must be locked out to prevent accidental or deliberate discharge when persons unfamiliar with the system and its operation are present in the protected space. Lockouts are also needed when personnel egress from a space is hampered (e.g., when persons are climbing ladders, working on scaffolds, or entering confined spaces).

NFPA 12 defines a system lockout as "a manually operated valve in the discharge pipe between the nozzles and the (carbon dioxide) supply which can be locked in the closed position to prevent flow of carbon dioxide to the protected area." Such a lockout will prevent both automatic and manual discharge. The emergency manual release required by NFPA 12 should *not* override the lockout. The lockout should be supervised to give an indication to those responsible for the system when the system is locked out. An adequate fire watch should be established to deal with any fire that might occur during a system lockout.

Alarms

NFPA 12 gives detailed guidance on the requirements for alarms that must be installed as part of a carbon dioxide system. In general, audible and visual predischarge alarms are required for all systems except hand hose lines. Personnel who will enter an area that could be made hazardous by discharged carbon dioxide must be trained as to the correct response to these alarms. For total flooding systems, every precaution must be taken to ensure that personnel in a protected area are evacuated before the area is flooded with carbon dioxide. This is the primary purpose of a predischarge alarm, which must provide a suitable time delay before the carbon dioxide discharge.

NFPA 12 requires that all total flood systems protecting enclosures which personnel could possibly enter be equipped with pneumatic predischarge time delays and pneumatic predischarge alarms. Both the time delays and alarms are typically powered by carbon dioxide from the system storage; neither the pneumatic time delay nor the pneumatic alarms depend on electrical power. Such pneumatic time delays and alarms are likewise required for local application systems, if the discharge will expose personnel to hazardous concentrations of carbon dioxide. The NFPA 12 standard gives details as well as specific exceptions for the pneumatic time delay and alarm requirement.

For systems that will produce a hazardous concentration of carbon dioxide throughout an enclosure, warning signs and discharge alarms must likewise be located outside each entryway to the enclosure. The purpose of these devices is to warn persons

against entering the space containing a dangerous concentration of carbon dioxide.

Consideration should be given to any possibility that substantial volumes of carbon dioxide vapor could leak or flow into adjacent low-level areas, such as cellars, pits, or narrow hallways (i.e., spaces not included in the protected area). If this potential exists, alarms and warning signs should be extended to include these areas. Arrangements for safely ventilating all carbon dioxide–flooded spaces following a discharge must be made.

Odorizers, such as oil of wintergreen, are sometimes added to the carbon dioxide discharge to provide an olfactory indication of the presence of carbon dioxide. Odorizers are particularly useful to indicate that carbon dioxide has leaked from the protected area to adjoining areas.

Other Safety Features/Considerations

Manual controls for the system must be located to avoid confusion, and they must be clearly labeled with safe operating procedures. Avoid grouping manual controls for more than one hazard in order to avoid confusion. Self-contained breathing apparatus (SCBA) should be provided. This apparatus should be used by trained personnel to effect rescue of anyone who might be trapped in a carbon dioxide discharge.

Periodic maintenance is required to ensure proper function of these systems. Those doing maintenance must be thoroughly trained in the functions of the system. Whenever maintenance involves work on system controls, discharge valves, or other devices that could possibly initiate carbon dioxide discharge, personnel must be evacuated from areas where a discharge from the system could produce a dangerous concentration of carbon dioxide.

COMPONENTS OF CARBON DIOXIDE SYSTEMS

Components of a carbon dioxide system include the carbon dioxide supply, the piping system, the discharge nozzles, alarms, and control devices.

Carbon Dioxide Storage

The carbon dioxide supply may be stored in high- or low-pressure containers. Because of the differences in pressure, system design is influenced by the storage method.

High-Pressure Storage. High-pressure containers, usually cylinders, are designed to store liquid carbon dioxide at atmospheric temperature. Since the maximum pressure in the cylinder or other container is affected by the ambient temperature, it is important that the container be designed to withstand the maximum expected pressure. Figure 17.1.5 shows the change in gauge pressure with temperature.

Storage cylinders are designed, tested, and filled to applicable national codes and standards. In the United States the U.S. Department of Transportation (DOT) specifications apply. The maximum filling density permitted is equal to 68 percent of

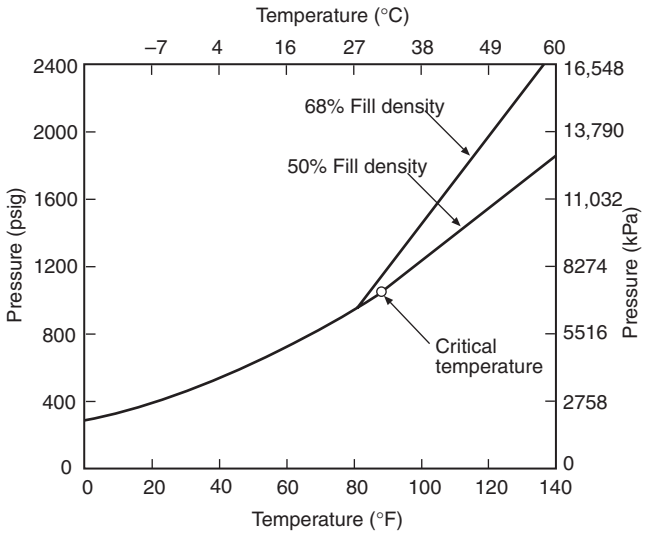

FIGURE 17.1.5 Variation in Pressure of Carbon Dioxide with Change in Temperature, Showing the Effect of Filling Density in High-Pressure Storage

the weight of water that the container can hold at 60°F (16°C). Standard cylinder capacities are 5, 10, 15, 20, 25, 35, 50, 75, 100, and 120 lb (2.3, 4.5, 6.8, 9.1, 11.3, 15.9, 22.7, 34, 45.4, and 54.4 kg) of carbon dioxide. Fire-extinguishing cylinders are fitted with an internal dip tube so that liquid will be discharged from the bottom when the cylinder is upright and the valve is opened.

Abnormally low storage temperatures adversely affect the rate of discharge. For this reason, NFPA 12 does not permit storage temperatures below 0°F (–18°C) for total flooding systems or below 32°F (0°C) for local application systems. Lower storage temperatures may be permitted only if the design includes special features to compensate for the reduced pressure. Techniques for "winterizing" cylinders are also available. Proper use of winterizing techniques can permit use of high-pressure storage at temperatures as low as –60°F (–51°C).

Low-Pressure Storage. Low-pressure storage containers are pressure vessels with a design working pressure of at least 325 psi (2240 kPa). These containers are maintained at a temperature of approximately 0°F (–18°C) by use of insulation and mechanical refrigeration. At this temperature, the pressure is approximately 300 psi (2069 kPa). A compressor, controlled by a pressure switch in the tank, circulates refrigerant through coils near the tank top. Tank pressure is controlled by condensation of carbon dioxide vapor by the coils. In the event of refrigeration failure, pressure-relief valves bleed off some of the vapor to keep the pressure within safe limits. This permits some of the liquid to evaporate, creating a self-refrigerating effect that reduces the pressure in the tank. Figure 17.1.6 shows a typical low-pressure container. Heaters with recirculating pumps are required if ambient temperatures will cool the tank contents below approximately –10°F (–23°C) (250 psi [1724 kPa] pressure level).

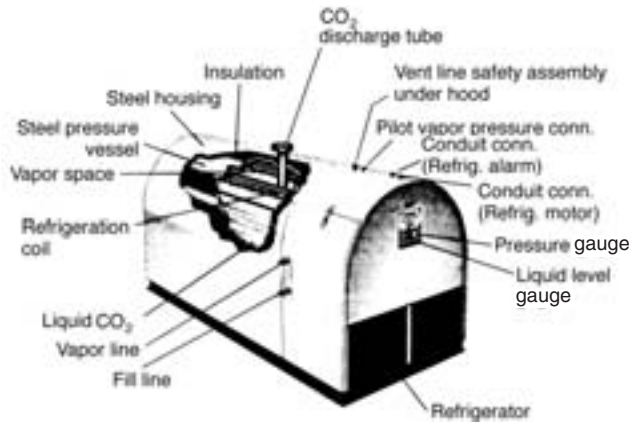

FIGURE 17.1.6 Low-Pressure Storage Unit—Carbon Dioxide Maintained at 0°F (–18°C) by Refrigeration; Pressure Is 300 psi (2069 kPa)

With low-pressure storage, it is common practice to protect multiple hazards from one central storage unit. The quantity of carbon dioxide discharged on a particular hazard is controlled by opening and closing the discharge valves in a preset timed sequence. Central low-pressure CO_2 storage units may have capacities ranging from less than 1 ton to 100 tons or more (1 ton is approximately 907 kg). For large hazards, the distance between hazard and storage may be several hundred feet (100 ft is approximately 30.5 m).

Piping System

Piping systems, normally empty, convey carbon dioxide from the storage container to open nozzles where there is a fire. Since the proper rate of flow is a critical requirement for fire extinguishment, it is important that the piping be designed and installed accurately. Minimum pressure in the pipeline must be kept well above the triple point pressure of 75 psia (5.2 bars). If the pressure of the flowing carbon dioxide falls below the triple point pressure, dry ice will form in the pipe and block orifices in the discharge nozzles, thus stopping the flow of carbon dioxide. NFPA 12 limits design nozzle pressures to a minimum of 300 psia (20.7 bars) for high-pressure storage and a minimum of 150 psia (10.3 bars) for low-pressure storage.

Carbon dioxide drawn from the bottom of the storage container enters the piping as a liquid. Friction causes loss in pressure. As pressure drops, the liquid boils, resulting in a mixture of liquid and vapor in the piping. The vapor increases in volume as the mixture passes through the piping, with a further drop in pressure. Thus, the flow is two-phase, a mixture of liquid and gas, a fact that pressure drop calculations must take into account.

NFPA 12 covers the calculation of carbon dioxide flow in some detail and provides pertinent equations and data tables. Although charts and tables are available for manual calculation of system piping, the use of available computer programs speeds and simplifies the design of piping systems.

The piping must be adequately supported to prevent movement during the discharge, and provision must be made for its contraction and expansion. Because liquid carbon dioxide is a refrigerant, it will substantially reduce the pipe temperature during discharge. Low-pressure liquid, in particular, starts at 0°F (–18°C) and may reach temperatures as low as –50°F (–46°C) in the piping before the discharge ends.

Valves and Operating Devices

Valves for controlling the discharge of carbon dioxide must withstand the maximum operating pressure, be absolutely bubbletight when closed, and be capable of both manual and automatic operation. Valves and allied devices, such as timers and pressure switches, must be listed or approved for use in carbon dioxide systems.

Discharge Nozzles

Many nozzle types are available for fire extinguishment applications. Nozzles used in total flooding simply may be orifices producing high-velocity jet streams, or they may be partially shielded to achieve reduced velocity or a specific discharge pattern. High-velocity types provide substantial mixing to ensure uniform concentration of carbon dioxide throughout an enclosure. Low-velocity types have a tendency to create high concentrations in the lower levels, which may be desirable under certain conditions.

Nozzle types used in local application systems normally are designed for relatively low discharge velocity. This helps to avoid splashing of liquid fuels and minimizes turbulence and air entrainment. All such nozzles must be tested for fire-extinguishing characteristics and listed or approved by a testing laboratory on the basis of test performance.

Figure 17.1.7 shows a typical performance curve for a nozzle designed for overhead mounting. The rate of discharge

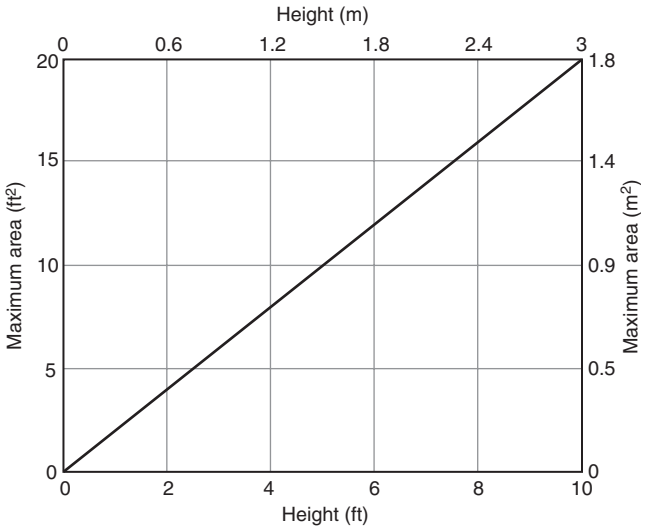

FIGURE 17.1.7 Listing or Approval Curve of a Typical Carbon Dioxide Nozzle Showing Maximum Area Versus Height or Distance from Liquid Surface

used is based on the height of the nozzle above the hazard or the fuel surface and is given in listing cards or approvals. (Testing is based on the maximum rate that will not splash liquid fuels.) The maximum fire area that the nozzle will extinguish also is based on the height above the hazard surface, using the design flow rate.

Performance information enables the system designer to select and properly locate the number of nozzles necessary to cover the entire fire area of the hazard. It also establishes the design flow rate that must be used on the hazard. The effective design flow rate must continue for a minimum of 30 seconds.

Figures 17.1.8 and 17.1.9 show typical performance curves for nozzles designed for mounting on the sides of open tanks containing flammable liquids. In such cases, the design flow rates are based on the area of coverage for the tankside nozzles or on the width of the hazard for linear nozzles mounted to extend the full length of one side. In each case, the design flow rate must be in the shaded area of the curves.

System Controls

Most carbon dioxide systems incorporate three methods of actuation: automatic, normal manual operation, and emergency manual operation.

Automatic Actuation. Automatic actuation is an operation that does not require any human action. Generally, fire detectors that sense abnormal heat, smoke, or flame initiate automatic actuation. The detector, on sensing a fire condition, initiates a signal at an electrical control panel.

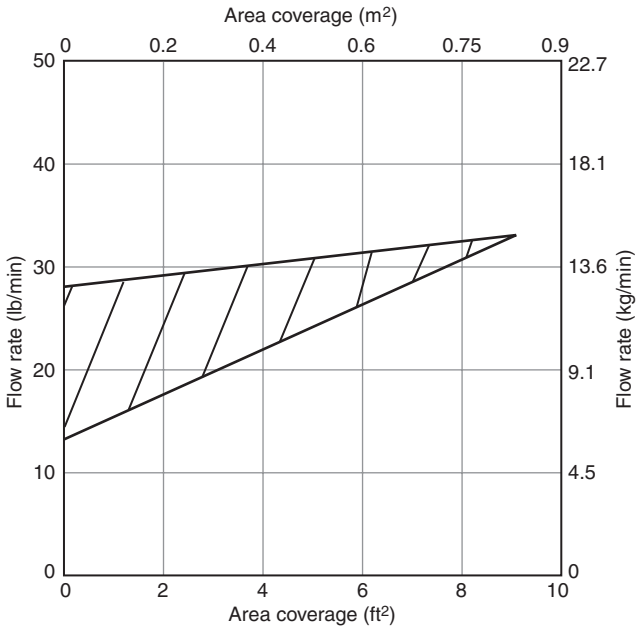

FIGURE 17.1.8 Typical Listing or Approval Curve of a Tankside Carbon Dioxide Nozzle Showing the Flow Rate Versus Area Coverage

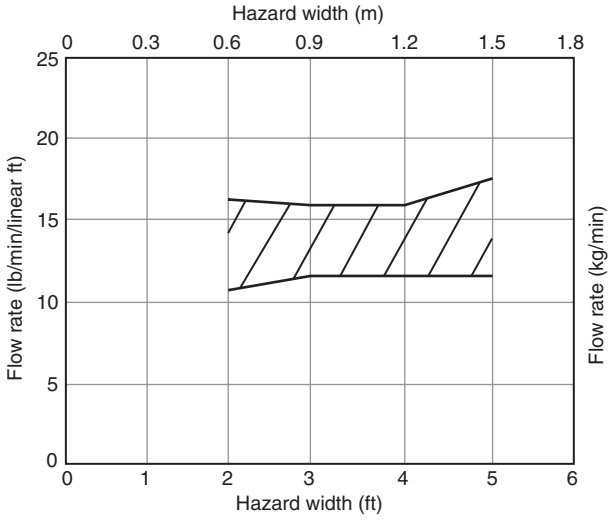

FIGURE 17.1.9 Typical Listing or Approval Curve of a Linear Carbon Dioxide Nozzle Showing Flow Rate Versus Hazard Width

Normal Manual Operation. Normal manual operation is actuation of the system requiring human action to initiate the operation. In modern carbon dioxide systems, normal manual operation is typically by a manual pull station connected to an electrical control panel.

Emergency Manual Operation. In emergency manual operation, the emergency manual release must function independently of electrical power and must be fully mechanical in nature. It can incorporate use of system carbon dioxide pressure to cause discharge. Emergency manual operation is intended for use only if both the automatic and normal manual operations have failed to cause a required discharge. Because most emergency manual operations cause immediate discharge of carbon dioxide without any alarm, it is essential that anyone who operates an emergency manual release be certain that the hazard area is evacuated and secured against entry of personnel prior to operation.

Control Panels

In modern carbon dioxide systems, fire detectors and manual electrical control stations (pull stations) are connected to an electrical control panel. Operation of a fire detector or pull station puts the control panel into an "alarm" condition. The control panel will cause a sequence of events leading to a discharge of carbon dioxide.

A relatively recent change to NFPA 12 requires pneumatic predischarge time delays and pneumatic predischarge alarms to be incorporated into most carbon dioxide systems. This is a retroactive requirement. Normally carbon dioxide from the system storage containers is used to power both the pneumatic time delays and the pneumatic audible alarms.

As part of the discharge sequence, the control panel opens a control valve to initiate carbon dioxide flow to the pneumatic predischarge time delay and pneumatic alarms. The control

panel will also provide power to electrically operated alarm devices. After the pneumatic time delay has expired, the discharge of carbon dioxide begins. If the system uses high-pressure storage containers, the discharge will continue until the containers are emptied. If the system uses a low-pressure storage container, the discharge is continued for a predetermined length of time after which a control valve is shut, ending the discharge.

The control panel may also cause required equipment shutdown and fuel line shutoffs, control dampers and fans, and send alarm signals to personnel responsible for response to fire situations. It is essential that electrical control panels that are intended to control carbon dioxide systems be designed such that a system discharge will not occur without the required predischarge time delay and alarms. The sequence of operation for the carbon dioxide system must be documented in writing and maintained in a protective enclosure with the system.

When the system is in "standby" condition, the control panel supervises the interconnections between all electrically powered components necessary for control of the systems and life safety. Connections between the control panel and detectors, manual electrical release stations, system valve actuators, and alarms should be supervised. The control panel also monitors the condition of system lockout valves and electrical power sources.

Some older carbon dioxide systems used timer-driven cams to operate switches that controlled the various discharge functions. Totally pneumatic systems using pneumatic detection and control were also common. Many of these systems are still in service.

Alarms

Both audible and visual predischarge alarms are generally required for carbon dioxide systems. Various types of sirens or horns are used for audible alarm. NFPA 12 requires that most total flood systems and some local application systems be equipped with pneumatically powered predischarge time delays and pneumatically driven predischarge audible alarms. Existing systems which lack such pneumatic alarms are required by NFPA 12 to be retrofitted with them. Whatever type of audible device is used, its sound should be distinctive and capable of being heard above background noises. Strobe lights or rotating beacons are often used as visual alarms. It is essential that the alarms function to warn people against entry into all areas made hazardous by a carbon dioxide discharge for as long as the hazard exists or until the areas are secured against entry by personnel.

CARBON DIOXIDE SYSTEM DESIGN CONSIDERATIONS

To organize basic components into a carbon dioxide fire protection system, a number of factors must be considered. These include the quantity of stored carbon dioxide, the method of actuation, the location of predischarge alarms, ventilation shutdown, pressure venting, and anything else involved in ensuring safe, prompt, and effective fire extinguishment and personnel safety.

Quantity Requirements

The quantity of carbon dioxide required for extinguishment depends on the type of fire, the type of extinguishing system, and conditions in the fire area. Where continuous protection is required, the quantity of carbon dioxide on hand should be at least twice that needed for extinguishment. Detailed methods of determining the quantity required for extinguishment are covered in NFPA 12.

Total Flooding Systems. The design concentration for a given enclosure should be sufficient to extinguish fires in all the fuels that are present in the hazard. The minimum concentration used in total flooding systems is 34 percent carbon dioxide by volume. Minimum design concentrations for various liquids and gases are given in Table 17.1.1. NFPA 12 requires a 50 percent concentration for electrical wiring hazards, including small electrical machines; 65 percent for bulk paper and fur storage vaults; and 75 percent for dust collectors. These are specific hazards for which there is a background of test experience. Other materials should be tested to determine minimum carbon dioxide concentrations and holding time.

The quantity of carbon dioxide must be sufficient to achieve a minimum design concentration and to maintain it until the fire is extinguished or a trained and suitably equipped fire brigade responds to complete the extinguishment. A series of specific flooding factors has been established for surface fire hazards. These factors include an allowance for distributed leakage due to cracks around doors, porosity of the walls, and other small openings based on room size. The factors are greater for smaller rooms, because the anticipated leakage would be greater relative to volume (Table 17.1.2 and Figure 17.1.10).

Note: If a hazard requires a design concentration greater than 34 percent, the basic quantity of carbon dioxide needed would be calculated by multiplying the appropriate flooding factor from Table 17.1.2 by the conversion factor determined from Figure 17.1.10.

If the enclosure has obvious openings that cannot be closed, or ventilating systems that cannot be shut off in the event of a

TABLE 17.1.2 Flooding Factors to Achieve 34 Percent Design Concentration

Volume of Space (ft^3)	Volume Factor		*Calculated Quantity Not Less Than (lb)*
	(ft^3/lb CO_2)	*(lb CO_2/ft^3)*	
Up to 140	14	0.072	—
141–500	15	0.067	10
501–1,600	16	0.063	35
1,601–4,500	18	0.056	100
4,501–50,000	20	0.050	250
Over 50,000	22	0.046	2500

For SI units: 1 ft^3 = 0.0283 m^3; 1 lb = 0.454 kg.

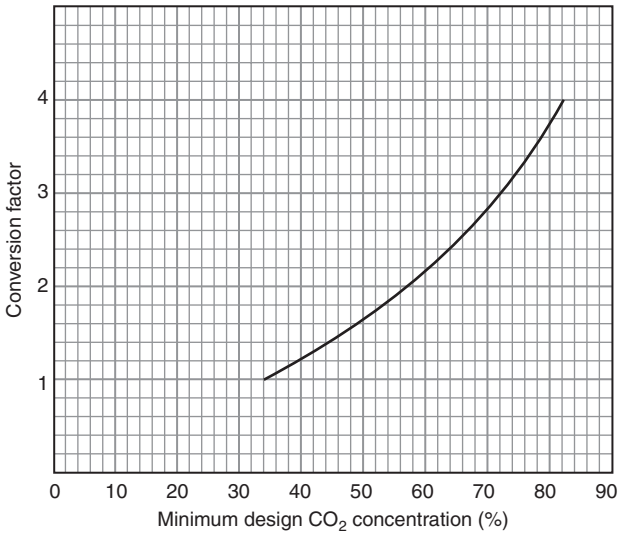

FIGURE 17.1.10 Minimum Design Carbon Dioxide Concentration Conversion Factors

fire, additional carbon dioxide must be added to the "basic quantity" calculated using the flooding factor and material conversion factor.

Surface burning fires, such as flammable liquid fires, are normally extinguished during a 1-minute carbon dioxide discharge. Leakage compensation must be in addition to the basic quantity.

Deep-seated fires require higher concentrations and much longer holding times. The rate of discharge must be high enough to develop a concentration of 30 percent in not more than 2 minutes, and the final design concentration must be achieved in not more than 7 minutes. Enclosures for deep-seated fires should be relatively tight, or it may be uneconomical to maintain the carbon dioxide design concentration. The basic quantity of carbon dioxide needed for deep-seated fire hazards is calculated using flooding factors given in NFPA 12. Some deep-seated fires can smolder for very long periods of time, even in the presence of a high carbon dioxide concentration. An example is fire in baled cotton stored in the cargo hold of a ship. For these fires, carbon dioxide may be used to suppress the open flaming and reduce the rate of fire spread. Complete extinguishment must be done by trained fire fighters using manual fire-fighting techniques. For such hazards, the carbon dioxide concentration should be maintained for sufficient time to permit response by a properly equipped and trained fire brigade.

Extended Discharge Systems. The most efficient way to compensate for leakage where the concentration must be maintained for a substantial time is to use an extended discharge at a reduced rate equal to the rate of leakage. The quantity of carbon dioxide required is based on the rate of discharge multiplied by the time that the concentration must be maintained. This is in addition to the quantity required to develop the design concentration.

Local Application Systems. These systems may be designed using either "rate-by-area" or "rate-by-volume" methods. When rate-by-area is used, the hazard is considered as a number of equivalent surface areas, each protected by a single nozzle. The rate of discharge from each nozzle is determined from listing information, and the total discharge rate for the system is the sum of the design rates required for each nozzle.

Where the hazard consists of three-dimensional irregular objects that cannot be reduced easily to equivalent surface areas, the rate-by-volume method may be used. In this case, the discharge rate of the system is based on the volume of an assumed enclosure entirely surrounding the hazard. Because this method is not as precise as the rate-by-area procedure, it usually results in more carbon dioxide discharge, unless the hazard is nearly enclosed with walls.

A discharge of vapor is not considered effective for local application. The liquid portion of the discharge should be continued for a minimum of 30 seconds, or longer if required for cooling. If a liquid fuel has an autoignition temperature lower than its boiling point (e.g., paraffin wax and some cooking oils), the mass of liquid can become "superheated" above its autoignition temperature. For such fuels, a minimum local application time of 3 minutes is required to permit the mass of liquid fuel to cool.

Additional carbon dioxide must be added to storage to compensate for any initial vapor discharge produced in cooling the piping. In high-pressure systems, only about 70 percent of the stored quantity will leave the storage cylinder as liquid. Therefore, the quantity calculated by rate and time must be increased by a factor of 1.4 to help ensure a 30 second liquid discharge.

Hand Hose Line Systems. The carbon dioxide supply depends upon the type and size of the hazard to be protected. As a practical matter, however, sufficient carbon dioxide should be available to counteract possible waste by inexperienced users. In any case, there should be sufficient carbon dioxide to permit operation of the system for at least 1 minute. The possible use of these hoselines by inexperienced personnel should be considered and enough carbon dioxide should be provided to permit extinguishment of a fire by such personnel. When more than one hose reel may possibly be used on a single hazard, sufficient carbon dioxide should be available to support the maximum number of hose reels that are likely to be used simultaneously for 1 minute.

Venting Requirements

When liquid carbon dioxide is discharged into a closed room, the atmosphere may shrink initially due to the sudden refrigerating effect. At a later flooding stage, the combined volume of the carbon dioxide and air may become greater than the initial room volume. Thus, although the first result may be to create a vacuum, or draw in air, the final result will be to increase the pressure or to exhaust the excess volume through vent openings. Actual air temperatures are greatly reduced during the discharge, but they soon return to normal as heat is absorbed from solid surfaces in the room.

Most ordinary rooms have sufficient leakage through cracks around doors and windows and through general porosity to prevent noticeable vacuum or pressure buildup. From the viewpoint of efficient total flooding, it is better to have major vent openings in or near the ceiling rather than near the floor.

In rooms that may be tightly sealed, a safe vent area can be estimated on the basis of calculated discharge flow rate and the strength of the enclosure:

$$X = \frac{Q}{1.3\sqrt{p}}$$

where

X = Vent area in in.^{2}

Q = Flow rate in lb/min

p = Allowable strength of the enclosure in lb/ft^2

For SI units:

$$X_m = \frac{239 Q_m}{\sqrt{p_m}}$$

where

X_m = Vent area in mm^2

Q_m = Flow rate in kg/min

p_m = Allowable strength of the enclosure in kg/m^2

More information on room venting can be found in NFPA 12.

System Control

Total flooding and local-application carbon dioxide systems normally should be designed to operate automatically. The detection device may be any of the listed or approved devices that are actuated by heat, smoke, flame, flammable vapors, or other abnormal process conditions that could lead to a fire or explosion. Automatically operated systems are required to have an independent means of manual actuation (emergency manual operator).

It is essential that electrical control panels intended to control carbon dioxide systems be designed such that a system discharge will not occur without the required predischarge time delay and alarms. NFPA 12 requires pneumatically powered predischarge time delays for most total flood systems and some local application systems. Existing systems must be retrofitted with pneumatic time delays to meet the NFPA 12 requirements. If a control panel fails to discharge the carbon dioxide system, the emergency manual operator is available to cause a discharge independently of the control panel. An unwanted discharge without proper predischarge alarms may endanger life.

Whether supplemental to automatic actuation or the sole means of placing a system in operation, manual controls must be easy to operate, accessible in case of fire, and located close to the valves they control. Remote manual controls usually are located near an exit for a total flooding installation or near a hazardous area for local application installations. Instructions for safe operation of the manual controls must be prominently displayed at the control.

Marine Systems

Systems used on offshore platforms and marine vessels are subject to different regulations and design procedures. Quantity calculations, piping design, nozzle sizing, and system control requirements can vary from those discussed in this chapter. The guidance of the authority having jurisdiction over the vessel must be followed for such systems.

TESTING AND MAINTAINING CARBON DIOXIDE SYSTEMS

An elaborate fire protection system could be ineffective or even dangerous unless it is properly tested to demonstrate adequate performance and maintained in good working condition.

Acceptance Testing

No newly installed system should be accepted until it has been inspected properly and tested to prove performance in accordance with design specifications. The inspection should ascertain whether the system is installed in accordance with approved plans. The piping is particularly important, because any changes might affect the flow rates that were calculated on the basis of the pipe sizes shown on the plans.

NFPA 12 requires a "full discharge test" of all newly installed systems. The final proof of performance is to discharge the system and, for total flooding hazards, to measure the concentrations of carbon dioxide and the holding time in the fire zone. Local application systems cannot be subjected to concentration testing. Their effectiveness is judged by observation during the test discharge. NFPA 12 gives the minimum requirements for approval of new installations.

Figure 17.1.11 shows a local application discharge test on a printing press. The effectiveness of the local application discharge is judged by observation during the discharge test. It is helpful to videotape the discharge of large local application systems. This photo taken from such a videotape reveals that carbon dioxide coverage on the front press stations was inadequate. Post-test inspection showed that the left nozzle for the station was plugged.

FIGURE 17.1.11 Local Application Discharge Test on Printing Press (Source: Photo Courtesy of Guardian Services, Inc.)

Inspections

To maintain a system in proper operating condition, it is essential to conduct periodic inspections. At least once a month, the system must be inspected to verify its operational status. The status of the carbon dioxide supply should be checked at least weekly for low-pressure supplies, at 6 month intervals for high-pressure cylinders, and immediately after the system has operated. The entire system should be inspected annually. In particular, inspectors should look for changes in the scope of the hazard, changes in the condition of any enclosure, and other changes that could affect the adequacy of the fire protection system.

Maintenance

All operating devices should be tested annually. Although much of this testing can be accomplished without discharging the system, a partial discharge may be necessary in some cases. Any required maintenance found by testing should be performed without delay.

Training

Personnel must be made aware of the importance of the fire protection as well as the potential effects of exposure to high concentrations of carbon dioxide. Training should include how the system extinguishes fire, physiological effects of exposure to carbon dioxide, how the system is actuated, proper response to alarms (including a detailed evacuation plan), and proper safety precautions that are to be observed before manually actuating the system. New personnel should be trained before they are permitted to enter spaces that could be affected by a carbon dioxide discharge or areas where carbon dioxide system controls are located. Periodic "refresher" training courses should be mandatory.

Persons who are not normally associated with the protected hazard and adjoining spaces, but who are given temporary assignment there, must also be briefed on the safety issues related to the fire protection system, including proper response to alarms and evacuation procedures. This applies likewise to outsiders, such as construction and maintenance people.

SUMMARY

Carbon dioxide is a widely used fire-extinguishing agent that is especially effective on flammable liquid fires, gas fires, and fires involving electrically energized equipment. It can also be used on ordinary combustibles such as cloth and paper. Carbon dioxide has several properties that make it a desirable fire-extinguishing agent; for example, it is noncombustible, does not conduct electricity, and is easily spread in its gaseous form. Total flooding systems may not be effective in enclosures incapable of retaining an extinguishing concentration. The CO_2 should not be used on fires involving chemicals that contain their own oxygen supply or on fires involving reactive metals. A variety of methods can be used to apply carbon dioxide, including total flooding and local application systems. Because concentrations resulting from the discharge of a carbon dioxide system can endanger life, it is essential that safety features be installed and kept in operating condition and that personnel be properly trained with respect to system safety. These systems must be properly designed, tested, and maintained by trained personnel in order to ensure that the systems work effectively and safely.

Overview of Dry Chemical Extinguishing Agents
Uses and Limitations of Dry Chemical Systems
Wet Chemical Extinguishing Agents
Uses and Limitations of Wet Chemical Extinguishing Systems
Inspection, Testing, and Maintenance Procedures for Chemical Systems

Key Terms

dry chemical, dry chemical extinguishing system, fixed extinguishing system, flammable liquid fire, portable fire extinguisher, saponification, total flooding, wet chemical, wet chemical extinguishing system

Although water is the most common fire extinguishing agent available, it is understood that for many types of fires water may not be the most effective, efficient, or even the safest agent to use. Flammable liquids, combustible metals, and various machining processes present special hazards that may best be protected by chemical extinguishing agents.

For the purposes of this chapter, chemical extinguishing agents are divided into two categories: dry and wet. Dry chemical fire extinguishing systems first appeared on the market in the mid-1950s, and wet chemical fire extinguishing systems began receiving listings for the protection of commercial cooking operations in the late 1960s. Both types of systems are addressed by the NFPA Technical Committee on Dry and Wet Chemical Extinguishing Systems, which outlines the two standards that address these systems: NFPA 17, *Standard for Dry Chemical Extinguishing Systems,* and NFPA 17A, *Standard for Wet Chemical Extinguishing Systems*.

This chapter contains information on the properties of both dry and wet chemicals that contribute to their use as extinguishing agents. The limitations, methods of application, system design, and the inspection, testing, and maintenance associated with these systems will also be addressed in this chapter.

Portable dry and wet chemical fire extinguishers are discussed in Section 17, Chapter 5, "Fire Extinguisher Use and Maintenance." For other related topics, see Section 9, Chapter 5, "Metalworking Processes."

OVERVIEW OF DRY CHEMICAL EXTINGUISHING AGENTS

Dry chemical is defined as a powder composed of very small particles, usually sodium bicarbonate–, potassium bicarbonate–, or ammonium phosphate–based with added particulate material supplemented by special treatment to provide resistance to packing and moisture absorption (caking) and to provide the proper flow capabilities. It is intended for application by means of portable extinguishers, hand hose line systems, or fixed systems.

Dry chemical extinguishing agents are commonly listed for use on Class B and Class C fires. However, ammonium phosphate–based agents may also be referred to as *multipurpose dry chemical* because they are listed for use on Class A, B, and C fires. Dry chemical extinguishing agents are not effective on Class D fires as the heat developed by combustible metals consumes the agent prior to extinguishment. Furthermore, application of multipurpose dry chemical may result in a violent reaction with some types of combustible metals. Therefore, the terms *dry chemical* and *multipurpose dry chemical* should not be confused with *dry powder* and *dry compound,* which identify powdered extinguishing agents developed primarily for use on Class D fires. See Section 9, Chapter 5, "Metalworking Processes," for a discussion on combustible metal fires.

James D. Lake is a senior fire protection specialist at NFPA and the staff liaison for the Technical Committee on Dry and Wet Chemical Extinguishing Systems. He also works with the Technical Committee on Venting Systems for Cooking Appliances.

The first dry chemical agents were borax- and sodium bicarbonate–based dry chemicals. Sodium bicarbonate eventually became the standard because of its greater effectiveness as a fire-extinguishing agent and was even modified to make it compatible with protein-based low-expansion foams for a dual agent attack in the 1960s. The mid-1960s saw the development of the monoammonium phosphate–based *multipurpose dry chemical;* the potassium bicarbonate–based *Purple K*, originally developed to be used with aqueous film forming foam (AFFF) in a dual system but is commonly used on its own for flammable liquid fires; and the potassium chloride–based *Super K*, which has extinguishing properties that are roughly equivalent to potassium bicarbonate but was developed as a dry chemical that would be compatible with protein-type foams.

As a group, dry chemical agents are noted for their efficiency in extinguishing fires in flammable liquids. They can also be used on fires involving some types of electrical equipment. Sodium bicarbonate– and potassium bicarbonate–based agents have certain limited applications in extinguishment of flash surface fires with ordinary combustibles, but the chemical requires water to put out deep-seated smoldering fires. Multipurpose dry chemical can be used on fires in flammable liquids, fires involving energized electrical equipment, and fires in ordinary combustible materials and seldom needs the help of water to completely extinguish fires in Class A materials.

In the late 1960s a urea-potassium bicarbonate–based dry chemical was developed in Great Britain but is not as widely used as the other agents.

Physical Properties

The principal base chemicals used in the production of currently available dry chemical extinguishing agents are sodium bicarbonate, potassium bicarbonate, potassium chloride, urea-potassium bicarbonate, and monoammonium phosphate. Various additives are mixed with these base materials to improve their storage, flow, and water repellency characteristics. The most commonly used additives are metallic stearates, tricalcium phosphate, or silicones, which coat the particles of dry chemical to make them free-flowing and resistant to the caking effects of moisture and vibration.

Because some of the additives in dry chemical agents may melt and cause sticking at higher temperatures, an upper storage temperature limit of 120°F (49°C) is recommended for dry chemical. (Temperatures up to 150°F [66°C] may be acceptable for very short durations.)

Most dry chemicals are alkaline (sodium bicarbonate, potassium bicarbonate, and potassium carbonate), one is neutral (potassium chloride), and the multipurpose type (monoammonium phosphate) is acidic. Inadvertent mixing of different base dry chemicals can initiate undesirable reactions, generating carbon dioxide gas and resulting in equipment failure or loss of discharge capability.

- *Sodium bicarbonate* is an odorless white crystalline powder that decomposes at 140°F (60°C), has a pH ranging from 8.3 to 8.6, is partly soluble in water, and is the mildest of all sodium alkalis. As an extinguishing agent, it commonly has a white or blue appearance. It is the original dry chemical extinguishing agent and may also be referred to as regular dry chemical. The production of sodium bicarbonate is more economical than any of the other dry chemicals, resulting in its being the most widely used of the group.
- *Potassium bicarbonate* is an odorless white powder that decomposes at 248°F (120°C), has a pH in the range of 8.4, and is not soluble in water. Purple K is given its characteristic hue by the addition of violet pigments during production.
- *Potassium chloride* is an odorless white crystal with a melting point of 1422°F (772°C), has a pH of 7, and is completely soluble in water. It was developed as a dry chemical that would be compatible with protein-type foams. Its extinguishing properties are about equal to those of potassium bicarbonate. One drawback is its tendency to cause corrosion after it has extinguished a fire.
- *Monoammonium phosphate* is a white crystal solid with a slight odor of ammonia. It has a melting point of 350°F (190°C) and is slightly soluble in water (0.04 oz/0.08 oz [1g/2.5mL]). As an extinguishing agent, it may have an off-white or yellow color.

Monoammonium phosphate is called a multipurpose dry chemical because it can be effective on Class A, B, and C fires. Ammonium salts interrupt the chain reaction of flaming combustion. The phosphate changes into metaphosphoric acid, a glassy fusible material, at fire temperatures. The acid covers solid surfaces with a fire-retardant coating. Therefore, this agent can be used on fires involving ordinary combustible materials such as wood and paper, as well as on fires involving flammable oils, gases, and electrical equipment. However, it may only control, but not fully extinguish, a deep-seated fire.

Toxicity. Dry extinguishing chemical agents are stable at both low and normal temperatures and are considered to be nontoxic and noncarcinogenic. However, other physiological conditions such as minor skin and respiratory irritations may occur on exposure to the agents. No chronic medical conditions have been reported from long-term exposure. The acute effects of exposure are irritation to mucous membranes, with the possibility of chemical burns of the skin, eyes, and mucous membranes lining the respiratory system. Moist skin may enhance this effect. In all cases, self-contained breathing apparatus (SCBA) should be worn to protect against smoke, fumes, and the dust created by fixed system discharge. Consult the appropriate material safety data sheets (MSDSs) for detailed information, instructions, and special precautions.[1]

Particle Size. Particles of dry chemical range in size from less than 10 microns up to 75 microns (1 micron = 0.000029 in.). Particle size has a definite effect on extinguishing efficiency, and careful quality control is necessary to prevent particles from exceeding upper and lower limits of this performance range. Each dry chemical has a unique size limiting factor, below which the particles completely decompose and vaporize, and above which the particles do not completely decompose or vaporize.[2] The best results are obtained by a heterogeneous mixture with a median particle size of 20 to 25 microns. Particle size also has an effect on the flow characteristics of dry chemical. Solid particles suspended in a gas stream present higher pressure losses than

does gas alone. Coarse powders cause excessive surging, low flow rates, and will require larger expellant gas quantities. Fine powder will produce similar results but not to the same degree. Particle size is also responsible for the aerodynamic drag phenomenon (ADP). The momentum gained by larger particles will transport smaller particles to penetrate the updraft of a flame. Ordinarily, smaller particles would decompose or vaporize prior to penetration.[3] Underwriters Laboratories Inc. (UL) and Factory Mutual Research Corporation listings and ratings are based on the specified use of the particular type of dry chemical set forth by the equipment manufacturer.

Extinguishing Properties

When introduced directly to the fire area, dry chemical causes extinguishment almost at once. Fire tests on flammable liquids have shown potassium bicarbonate–based dry chemical to be more effective than sodium bicarbonate–based dry chemical in extinguishment. Similarly, monoammonium phosphate has been found equal to or better than sodium bicarbonate in extinguishment effectiveness.[4] The effectiveness of potassium chloride is about equivalent to that of potassium bicarbonate, and urea-potassium bicarbonate exhibits the greatest effectiveness of all the dry chemicals tested.

Smothering, cooling, and radiation shielding contribute to the extinguishing efficiency of dry chemical, but studies suggest that a chain-breaking reaction in the flame is the principal cause of extinguishment.[5]

Cooling Action. It cannot be substantiated that the cooling action of dry chemical is an important reason for its ability to promptly extinguish fires. The heat energy required to decompose dry chemicals plays an undeniable role in contributing toward their individual extinguishing abilities, but the effect, per se, is minor. To be effective, any dry chemical must be heat sensitive and, as such, absorb heat in order to become chemically active.[6]

Radiation Shielding. Discharge of dry chemical produces a cloud of powder between the flame and the fuel; this cloud shields the fuel from some of the heat radiated by the flame. Tests to evaluate this factor concluded that the shielding factor is of some significance.[6]

Smothering Action. For special applications, such as kitchen range, hood, duct, and fryer fire protection, the extinguishing mechanism for dry chemical is based on the process of saponification. Saponification is the process of chemically converting the fatty acid contained in the cooking medium to soap, or foam, and it accomplishes extinguishment by forming a surface coating that smothers the fire.[7]

The soap produced by saponification is readily broken down by exposure to heat. As a result, because dry chemicals do not offer a substantial cooling effect, the cooking medium may reflash after a brief period of time. It is due to this lack of cooling and the resultant potential for reflashing of the cooking medium that dry chemical extinguishing agents are no longer listed for the protection of commercial cooking operations. Wet chemical extinguishing agents are currently the only agents listed for the protection of this hazard.

For many years it was widely held that regular dry chemical extinguishing properties relied primarily on the smothering action of the carbon dioxide released when sodium bicarbonate was heated by fire. The carbon dioxide does undoubtedly contribute to the effectiveness of dry chemical, as does the like volume of water vapor released when dry chemical is heated. However, tests have not supported the belief that these gases are a major factor in extinguishment.

Chain-Breaking Reaction. The preceding extinguishing actions, when combined, exert a minimal effect. The rapidity of extinguishment is due to the interference of the dry chemical particles with the propagation of the combustion chain reaction, which reduces the concentration of "free" radicals present within the flames. To accomplish this, the dry chemical must become thermally decomposed.

The discharge of dry chemical into the flames prevents reactive particles from coming together and continuing the combustion chain reaction. The explanation is referred to as the chain-breaking mechanism of extinguishment.[8,9]

When multipurpose dry chemical is discharged into burning ordinary combustibles, the decomposed monoammonium phosphate leaves a sticky residue (metaphosphoric acid) on the burning material. This residue seals glowing material from oxygen, thus helping to extinguish the fire and prevent reignition.

USES AND LIMITATIONS OF DRY CHEMICAL SYSTEMS

Dry chemical is primarily used to extinguish flammable liquid fires. Because it is electrically nonconductive, it can also be used on flammable liquid fires involving live electrical equipment. Regular dry chemical extinguishers have been tested and found suitable for use on flammable liquid and electrical fires (Class B and C fires) by fire equipment testing laboratories.

Due to the rapidity with which dry chemical extinguishes flame, dry chemical is used on surface fires involving ordinary combustible materials (Class A fires). There are several areas in the textile industry, notably opener-picker rooms and carding rooms in cotton mills, where regular dry chemical has been used effectively. However, wherever regular dry chemical is provided for use on surface-type Class A fires, it should be supplemented by water spray for extinguishing smoldering embers or in case the fire gets beneath the surface. In some baled cotton storage areas, the tops of bales can be covered with regular dry chemical to prevent surface spread should fire break out. This preventive measure does not eliminate the need for automatic sprinkler protection in such areas. Because multipurpose dry chemical becomes sticky when heated, it is not recommended for textile card rooms or other locations where removal of the residue from fine machine parts may be difficult.

Dry chemical does not produce a lasting inert atmosphere above the surface of a flammable liquid; consequently, its

use will not result in permanent extinguishment if reignition sources, such as hot metal surfaces or persistent electrical arcing, are present.

Dry chemical should not be used in installations where relays and delicate electrical contacts are located (e.g., in telephone exchanges and computer equipment rooms), as the insulating properties of dry chemical might render such equipment inoperative. Because some dry chemicals are slightly corrosive, they should be removed from all undamaged surfaces as soon as possible after fire extinguishment.

Specifications have been established by fire equipment testing laboratories to ensure the positive and consistent performance of dry chemical as an extinguishing agent. These specifications control moisture content, water repellency, electrical resistivity, storage at elevated temperatures, flow capability, caking resistivity, and abrasive action. The discharge characteristics of the device in which the dry chemical is to be used are also evaluated. Extinguishing effectiveness is determined by performance tests of the application to standard fires under conditions recommended by the manufacturer.

Dry chemical extinguishing systems can be used in those situations where quick extinguishment is desired and where reignition sources are not present. Dry chemical systems are used primarily for flammable liquid fire hazards, such as dip tanks, flammable liquid storage rooms, and areas where flammable liquid spills may occur. Systems have been designed for kitchen range hoods, ducts, and associated rangetop hazards, such as deep-fat fryers. However, due to its limited ability to prevent reflashing of a fire, no dry chemical agents or system has been able to meet the new listing criteria for the protection from these hazards. Where it is necessary to extinguish a flammable liquid or gas fire being fed by fuel under pressure, dry chemical hand hose line systems can be used, followed by closure of fuel shutoff valves.

Because dry chemical is electrically nonconductive, extinguishing systems using this agent can be used on electrical equipment that is subject to flammable liquid fires, such as oil-filled transformers and oil-filled circuit breakers. Dry chemical system protection is not recommended, however, for delicate electrical equipment, such as telephone switchboards and electronic computers. Such equipment is subject to damage by dry chemical deposit and, because of the insulating properties of the dry chemical, may require excessive cleaning to restore operation.

Regular dry chemical will not extinguish fires that penetrate beneath the surface or fires in materials that supply their own oxygen for combustion. Dry chemical may be incompatible with mechanical (air) foam unless the dry chemical has been specially prepared to be reasonably foam compatible.

Method of Application

Fixed systems are of two types: (1) total flooding and (2) hand hose line/local application. In total flooding applications, a predetermined amount of dry chemical is discharged through fixed piping and nozzles into an enclosed space or enclosure around the hazard (Figure 17.2.1). On actuation of the system by a heat detector, nitrogen is discharged into the 150 lb (68 kg) storage container and dry chemical is expelled through eight nozzles in the roof. Total flooding systems are applicable only when the hazard is totally enclosed or when all openings surrounding a hazard can be closed automatically, before or simultaneously when the system is discharged. In some instances, additional dry chemical can be included in the system design to compensate for unclosable openings. Total flooding can be used only where no reignition is anticipated, because the extinguishing action is transient.

FIGURE 17.2.1 A 15 ft by 24 ft (4.6 m by 7.3 m) Flammable Liquids Storage Building Protected by a Total Flooding Dry Chemical System

Hand hose line systems containing regular or ordinary dry chemical have been used to a limited extent for quick-spreading surface fires on ordinary combustible material. In such applications, the dry chemical system only stops or prevents a rapid surface spread, and must be supplemented by a water-type extinguishing device to put out deep-seated smoldering fires. Fixed systems containing multipurpose dry chemical are available and are suitable for the protection of ordinary combustibles, provided the dry chemical can reach all burning surfaces.

Hand hose line systems consist of a supply of dry chemical and expellant gas with one or more hand hose lines to deliver the dry chemical to the fire (Figure 17.2.2). Dry chemical systems of this type range from 125 to 3000 lb (57 to 1361 kg); the 3000 lb (1361 kg) system shown has six nitrogen cylinders and two 1 in. by 100 ft (25 mm by 30.5 m) hoses with shutoff nozzles. The hose stations are connected to the dry chemical container either directly or indirectly by means of intermediate piping. They can provide a large quantity of extinguishing agent for quick knockdown and extinguishment of relatively large fires, such as might be experienced at gasoline loading racks, flammable liquid storage areas, diesel and gas turbine locomotives, and aircraft hangars.

Figure 17.2.3 illustrates methods of dry chemical application.

System Design

Dry chemical systems are called either engineered or preengineered, depending on how the quantity of chemical, rate of flow, size and length of piping, and number and size of fit-

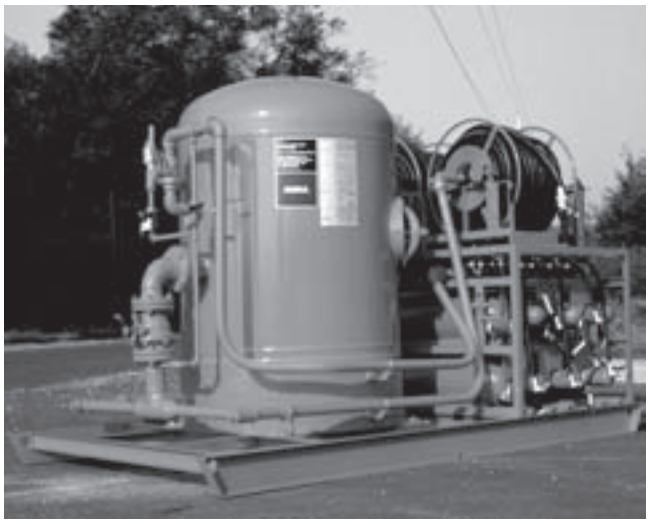

FIGURE 17.2.2 Dry Chemical Hand Hose Line System Consisting of an Expellant Gas Assembly, a Dry Chemical Storage Tank Assembly, and a Discharge Assembly (Source: Ansul Incorporated)

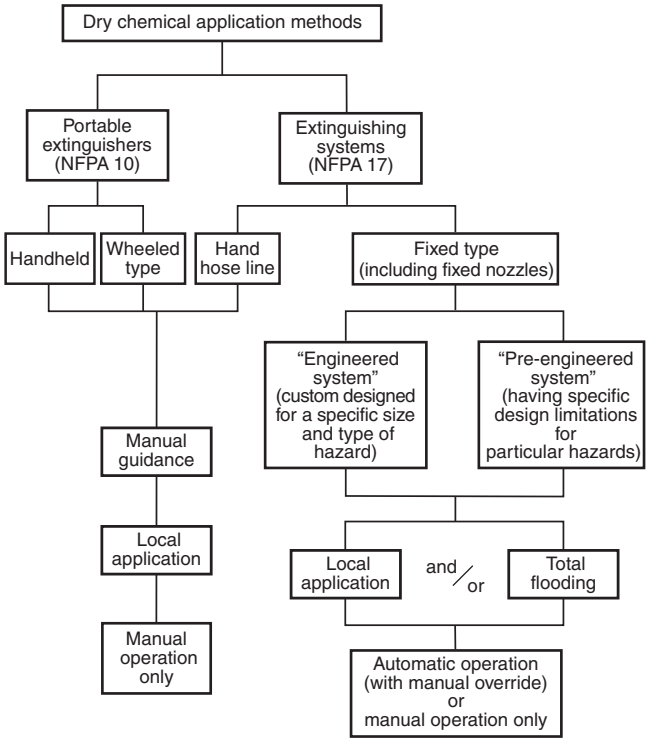

FIGURE 17.2.3 Methods of Dry Chemical Application

tings are determined. An engineered system is one in which individual calculation and design is needed to determine the flow rate, nozzle pressures, pipe sizes, quantity of chemical, and the number, types, and placement of nozzles for the hazard being protected. A pre-engineered system, sometimes called a package system, is one in which the size of the system (i.e., the quantity of chemical, pipe sizes, maximum and minimum pipe lengths, number of fittings, and number and types of nozzles) is predetermined by fire tests for specific sizes and types of hazards. Installation within these limits of hazard and system design ensures adequate flow rate, nozzle pressure, and pattern coverage without individual calculation (Figure 17.2.4).

In the past, pre-engineered systems were frequently used for kitchen range and hood fire protection, including deep-fat fryers. However, only alkaline dry chemicals (sodium bicarbonate, potassium bicarbonate, etc.) were used; multipurpose dry chemical was never used. It is important to note that dry chemical systems can remain in use provided the cooking equipment and the cooking medium have not changed from the time of the initial installation. Any changes in the system necessitate a change to a wet chemical system that has been listed in accordance with UL 300, *Standard for Fire Testing of Fire Extinguishing Systems for Protection of Restaurant Cooking Areas.*

Storage of Chemical and Expellant

Chemical agents are stored in pressure containers, usually of welded steel construction, either under atmospheric pressure until the system is actuated or under the pressure of the internally stored expellant gas.

Containers in which dry chemical is stored separately under atmospheric pressure are equipped with an expellant gas inlet, a moisture-sealed fill opening, and a dry chemical outlet. The gas inlet leads to an internal gas tube arrangement constructed so that, when it flows into the tank, it agitates and permeates the

FIGURE 17.2.4 A Double 30 lb (13.6 kg) Stored-Pressure Dry Chemical System with Pneumatic Release for Automatic Actuation. Each cylinder contains 30 lb (13.6 kg) of dry chemical pressurized to 350 psi (2413 kPa) with nitrogen.

powder, making it fluidlike. The dry chemical outlet is provided with a rupture disc or valve to permit buildup of proper operating pressure in the tank before the dry chemical can start to flow. The expellant gas assembly consists of a pressure storage vessel together with necessary valves, pressure regulators, and piping to deliver the expellant gas to the dry chemical storage tank at the correct pressure and rate of flow (see Figure 17.2.1). The expellant gas is usually dry nitrogen; however, dry air or other gases may be used. The volume and storage pressure of the expellant are dictated by the gas used and the requirements of the system. Containers in which dry chemical and the expellant gas are stored together are equipped with a moisture-sealed fill opening, a valve with integral discharge outlet and expellant gas charging inlet, and a pressure gauge.

It is desirable to locate the chemical expellant gas assemblies as near as practicable to the hazard to be protected. An area in which temperatures stay between –40 and +120°F (–40 and +49°C) is desirable to maintain the quality of the dry chemical.

System Actuation

Actuation of fixed systems is initiated by automatic mechanisms that incorporate sensing devices located in the hazard area and automatic, mechanical, or electrical releases that initiate the flow of the chemical, actuate alarms, and shut down process equipment. In systems with separate chemical and expellant gas containers, the flow of chemical is started by releasing the expellant gas, which pressurizes the chemical chamber to the point where the rupture disc in the container outlet operates. The chemical is then carried by the expellant gas through the distribution system to the hazard. In stored-pressure systems, however, the flow of chemical is started by merely opening the valve on the chemical chamber. If the expellant gas is used to pneumatically operate these devices, the gas shall be taken prior to its entry into the wet chemical tank.

Dry chemical systems have both automatic and manual methods of actuation. At least one manual actuator shall be provided for each system. It is important that the operating devices be designed, located, installed, or protected so that they are not subject to mechanical, environmental, or other conditions that could render them inoperative or cause inadvertent operation of the system. The automatic and manual means of system actuation must be separate and independent of each other so that a failure of one will not impair the operation of the other. Operation of any manual actuator is all that is required to operate the system. An easily accessible device for manual operation is required for all automatically operated systems.

A local signal is provided to indicate that the system has operated and is in need of recharging. The extinguishing system is also connected to the building fire alarm system, if one is provided, so that the actuation of the extinguishing system will sound the fire alarm throughout the building as well as provide the function of the extinguishing system.

System actuators are commonly mechanical and do not rely on electrical power for operation. However, it is permitted to have electrical actuators if there is a reserve power supply or the normal power supply is supervised. The means for mechanical actuator(s) shall be mechanical and shall not rely on electrical power for actuation.

When automatically actuated systems are used, consideration should be given to the reduced visibility and temporary breathing difficulty sometimes caused by quick discharge of large amounts of dry chemical in a restricted space. In all cases where there is a possibility that personnel may be stationed in such locations, suitable alarms and safeguards should be incorporated in the system to ensure adequate warning and prompt evacuation.

Operation of a hand hose line system requires two or, at the most, three steps. *Step one:* pressurizing the dry chemical chamber by opening the expellant gas valve (if the dry chemical and expellant gas containers are separate), or opening the main discharge valve if dry chemical is under stored pressure. *Step two:* operating the nozzle at the end of the hose line. *Step three:* if multiple hose stations are supplied by the same dry chemical supply, a distribution valve must be opened to direct the flow to the particular hose station to be used. It is extremely important to play out the hose fully (without kinks) to ensure the proper chemical discharge rate.

Fixed piping systems normally blow themselves clear. However, in hand hose line systems where the operator exercises control over the amount of dry chemical discharged, it is vital that all pipes and hose be independently blown clear before recharging to prevent blockage.

Distribution System

For fixed systems, the provisions for conveying the chemical to the hazard area and discharging it properly consist of piping or, for hand hose line systems, piping and hose lines or hose lines alone. Nozzles designed to emit wide, flat, or round streams in desired patterns are available to meet specific hazard requirements. Adjustable nozzles permitting an operator to vary the range and shape of the discharge are also available for use with hand hose line systems.

The piping and valving for dry chemical systems are of special design because dry chemical, while tending to behave as a fluid, has distinct flow characteristics.

Control of chemical flow starts at the chemical storage tank. In systems of separate dry chemical and expellant gas containers, expellant gas must be admitted to the tank in such a way as to properly fluidize the dry chemical while the pressure builds up equally throughout the entire volume of the tank before the dry chemical is released from the tank. Should the pressure increase too rapidly above the dry chemical, the powder will not be properly fluidized and, on release, the pressure drop in the piping or hose line will be excessive and result in a rate of dry chemical flow too low for proper extinguishing effectiveness.

If the expellant gas is permitted to channel to the outlet before the top of the dry chemical storage tank is properly pressurized, insufficient dry chemical will be carried by the flowing stream of gas, and the fire extinguishing effectiveness of the system again will be greatly reduced.

Pipe, Hose, and Fittings. After release from the storage tank, dry chemical is carried through the piping at high velocities by the expellant gas and is thrown to the wall of the piping by centrifugal force whenever the direction of flow is sharply altered, as by an elbow. Should an elbow be directly connected to a tee and lie in the same plane as the tee, it is obvious that the two branches of the tee will carry appreciably different proportions of gas and dry chemical. This condition is overcome by installing all tees in planes perpendicular to the planes of adjacent elbows, by allowing sufficient length of straight pipe between tees and elbows, or by inserting special venturi devices between tees and elbows to ensure proper redistribution of dry chemical in the stream of gas before the mixture enters the tee.

Another critical factor in dry chemical distribution system design is the pressure drop through various lengths of pipe, hose, or fittings. Consequently, the length and size of piping and hose, and the number and size of fittings, must be selected to provide the required rate of discharge and nozzle distribution. In pre-engineered systems, this is already ensured by virtue of the limitations established for piping and fittings. In engineered systems, this selection must be made on the basis of actual calculation of pressure drop and subsequent flow rate.

For engineered systems, pressure drop data have been obtained at various rates of flow for various sizes of pipe and fittings. In one manufacturer's system, the pressure drop through a standard elbow is equivalent to the pressure drop through 20 ft (6 m) of straight pipe of the same size.[10] Pressure drop through a tee is equivalent to that of 45 ft (14 m) of straight pipe of the same size.

Consideration must be given to the overall volume of the distribution piping. Excessive volume could result in agent remaining in the pipe due to insufficient pressure to move it through the system. Because these chemicals behave similarly to water in pipe, there is also a concern regarding hydraulic friction loss. Long runs and excessive numbers of elbow serve to reduce the velocity of the fluid as it travels through the pipe. Again, excessive pressure loss could result in agent being left in the piping and possibly resulting in an insufficient amount of agent being delivered to the fire.

Nozzles. Dry chemical agent is distributed through nozzles at predetermined flow rates and patterns depending on the hazard. Discharge nozzles are made of corrosion-resistant materials such as brass or stainless steel.

The selection of the proper types and sizes of nozzles for fixed systems is crucial to obtaining the proper coverage of the hazard. For example, total-flooding dry chemical agent nozzles are designed for a broadcast of turbulent agent flow. This is to achieve the fire-extinguishment mechanisms of smothering and shielding.[8] On the other hand, nozzles for local application, such as over deep fat fryers, are designed to get the liquid surface covered with agent while limiting the splashing effects, which could result in fire spread beyond the protected area. Consult the individual listing of the discharge nozzles to determine their intended use.

Due to the nature of the hazards protected and the extinguishing chemicals, it is necessary to protect the openings of discharge nozzles. Protection is provided against internal clogging by installing strainers in the distribution piping prior to the nozzles. Grease vapors, moisture, and other particles in the effluent from the processes may cause clogging at the nozzle or in the piping. For this reason, nozzles must have protective caps. These caps provide this protection and blow off or open when the system is discharged.

Nozzles for hand hose line systems may be of either a one- or two-position type. One-position nozzles provide a modified straight stream, whereas two-position nozzles provide a straight stream or a fan. Because the straight stream has a longer reach than the fan discharge, it is considered better for initial attack. The shorter, wider fan-shaped stream is usually preferred for a close-range attack to complete the extinguishment. However, the present state of the art seems to prefer the use of the modified straight stream only. It is more effective and less confusing in the hands of an experienced operator.

Quantity and Rate of Application of Dry Chemical

The quantity of chemical and rate of flow must be sufficient to create a fire-extinguishing concentration throughout all parts of the enclosure protected in a total flooding system, or over the specific fire area protected by a local application system. It must be realized that the fire-extinguishing concentration accomplished throughout an enclosure (total flooding) can occur only during discharge. Following discharge, dry chemical rapidly settles out and diminishes. This is in contrast to gaseous diffusion, where concentrations persist following discharge, such as in carbon dioxide and halon systems. Minimum rate of flow is critical because dry chemical will not extinguish a fire if applied too slowly. In local application systems, application at too high a rate may result in uneven discharge or complete discharge of chemical before extinguishment is accomplished.

Optimum quantities of chemical and application rates have been determined by experiment for engineered total flooding and local application systems. For pre-engineered systems, the maximum sizes of hazards that can be protected by the various sizes of systems within specific piping limitations have been determined.

The minimum flow rate in lb per second (kg/sec) is determined by multiplying the net volume in ft^3 (m^3) by 0.00125 (in SI units 0.020). These volume factors apply only to this manufacturer's equipment and are cited merely to illustrate a procedure used.[10] Quantities and flow rates determined in this manner are contingent on a nozzle arrangement that provides even distribution throughout the volume. The rates also assume that devices will be installed to close automatically all doors, windows, ventilators, or other openings through which dry chemical could escape from the enclosure.

In one manufacturer's pre-engineered total flooding system, a 1000 ft^3 (28 m^3) space not longer than 20 ft (6 m) can be protected by a 30 lb (14 kg) system with four nozzles and no more than 90 ft of ¾ in. pipe (27 m of 19 mm pipe), 13 elbows, three tees, and three venturi devices.[10] As with engineered systems, successful extinguishment is contingent on proper nozzle

location, shutdown of ventilation, and the closing of all openings, such as doors and windows, in addition to closure of fuel valves.

Although simultaneous shutdown of ventilation with the actuation of a total flooding system is the normal procedure, one exception exists. This exception is the special case of kitchen range hood and duct protection wherein pre-engineered systems are specifically designed to provide extinguishment, regardless of whether the ventilation is operating. Actually, this latter type of system is a combination of both total flooding and local application.

Quantities of dry chemical and flow rates for engineered local application systems are obtained from graphs plotted from tests using different flammable liquid surface areas, weights of dry chemical, and rates of application. These graphs are available from the manufacturer. For pre-engineered local application systems, the limitations of hazard size, system size, and piping arrangement are established by test and used in the same manner as for total flooding systems. The minimum recommended quantity of dry chemical for hand hose line systems is sufficient to permit use of the system for 30 seconds. Capacities of hand hose line systems range from 125 to 2000 lb (57 to 907 kg), and as many as four hose lines can be operated from a single system. As with fixed systems, a minimum flow rate must be maintained to prevent surging or interruption of flow. Minimum rates are determined by the equipment manufacturer and depend on the equipment used.

WET CHEMICAL EXTINGUISHING AGENTS

Wet chemical fire extinguishing agents consist of organic or inorganic salts mixed with water to form an alkaline solution that is capable of being discharged through piping or tubing when under expellant gas pressure. They are extremely effective and are currently the only agents listed for suppression of fires in commercial cooking equipment (Figure 17.2.5), such as deep-fat fryers, griddles, range tops, and broilers, because of their ability to retain the separation of the oil from air for a sufficient time to allow complete cooling.

Physical Properties

Wet chemical extinguishing agents are typically a proprietary mixture consisting of potassium carbonate, potassium acetate, potassium citrate, or a combination, mixed in water and other additives such as phenolphthalein, phosphoric acid, and/or dyes. As they are already liquid in character, wet chemical agents do not require additives to enhance flow. Wet chemicals range in other physical properties depending on the mixture used. Table 17.2.1 shows the ranges of values in the common properties associated with wet chemicals.

Compatibility. Wet chemicals are incompatible with any reactive metals, electrically energized equipment, lime dust (CaO), chlorine trifluoride (ClF_3), and any other material that is reactive with water. When in storage, it is also important that the containers be kept tightly closed and separated from acids.

Toxicity. Wet chemical extinguishing agents are stable at both low and normal temperatures and are considered to be nontoxic and noncarcinogenic. However, other physiological conditions such as minor skin and respiratory irritations may occur on exposure to the agents. No chronic medical conditions have been reported from long-term exposure. The acute effects of exposure are irritation to mucous membranes, with the possibility of chemical burns of the skin, eyes, and mucous membranes lining the respiratory system. Moist skin may enhance this effect. In all cases, self-contained breathing apparatus (SCBA) should be worn to protect against smoke, fumes created by fixed system discharge. Consult the appropriate material safety data sheets (MSDSs) for detailed information, instructions, and special precautions.[1]

Extinguishing Properties

When wet chemical extinguishing agents are sprayed on a grease fire, they interact immediately with the grease and saponify, forming a blanket of foam over the surface on which they are sprayed. This blanket extinguishes the fire by a combination of two primary methods: smothering and cooling.

(a)

(b)

FIGURE 17.2.5 Examples of Commercial Kitchen Cooking Equipment Protected by a Nozzle

TABLE 17.2.1 Characteristics of Wet Chemical Extinguishing Agents

Agent Property	*Value Range*
Storage life	12 years
Freeze point	10°F to –40°F –12°C to –40°C
Boiling point	215°F–230°F 102°C–110°C
Specific gravity	1.19–1.445
pH	7.8–13

Smothering Action. When wet chemical agent is applied to flammable liquid surfaces, the result is a rapid knockdown of flame and a spreading of foam on the fuel surface. This vapor-suppressing foam barrier extinguishes the flame by separating the liquid fuel and oxygen. The result is the inability of the flammable vapors from the fuel source to escape the surface and ignite. Because the primary use of wet chemical systems is for protection of commercial cooking equipment and this is a very localized protection area, it is critical that the fire be contained within the equipment involved. To achieve this end, wet chemical systems are specifically tested to determine that during the discharge process they do not splash burning grease.

Cooling Action. The effect of water vaporization by wet agents provides a cooling effect on the fuel. Furthermore, the application of the wet chemical solution and the resulting formation of foam on the surface of the fuel also provides a cooling effect, lowering the temperature of the flammable fuel, further decreasing flammable vapor release. Some wet chemical systems are designed to continue with an application of water through the nozzles after the wet chemical has been completely discharged. This serves to further cool the surrounding surfaces, thereby preventing reflash.

USES AND LIMITATIONS OF WET CHEMICAL EXTINGUISHING SYSTEMS

Commercial cooking operations have undergone major changes in recent years in two areas that have produced an increased challenge to chemical fire extinguishing systems.

First, there has been a change in the cooking medium from animal fats to vegetable oils. These newer cooking oils change their makeup after ignition. This change results in an ignition temperature that is considerably lower (50°F, or 28°C) than that of the original oil. Therefore, to prevent reflash of the oil, the entire volume of the oil must be cooled below the autoignition temperature. Vegetable oils also have less fatty acids than do animal fats. It is the fatty acids that interact with the alkaline solution of the chemical agent that produces the saponification that eventually smothers the fire. Because of the amount of fatty acids in animal fats, dry chemical agents were capable of producing a sufficient foam blanket to smother the fire. Vegetable oils, with their lower fatty acid content, do not provide as much of this catalyst and, therefore, the foam blanket is not as well developed. This results in the compromise of the smothering foam blanket and the potential for reflash of the fuel involved.

Second, new, energy-efficient cooking equipment allows the oils to retain their heat for greater lengths of time. The autoignition temperature of the majority of vegetable oils is 685°F (363°C), which is as much as 135°F (57°C) higher than that of animal fats. This temperature, combined with the ability of new cooking equipment to retain the heat, produces a fire that dry chemical agents cannot effectively suppress. Because heat breaks down the foam that is produced through saponification, it is also necessary to provide a sufficient cooling effect on the fuel. Dry chemical has limited saponification and cooling capabilities, and, as a result, is ineffective on present-day commercial cooking equipment fires. Wet chemical, because of the added cooling effect of its water base, is far more effective on these types of fire. As a result, only wet chemicals can be used to protect new commercial cooking systems in order to sufficiently saponify fats and oils. It is still possible for dry chemical systems to protect kitchen equipment that has not been changed since the original installation of the system.

Commercial cooking equipment is typically stainless steel, aluminum, or galvanized metal. As such, it is resistive to the corrosive effect of wet chemical agents. Caution must be exercised in the installation of other equipment near the cooking equipment as wet chemical extinguishing agents are not acceptable for use in areas where fires involve energized electrical equipment. However, wet chemical extinguishing agents may be used to protect other equipment within the commercial cooking exhaust system. The manufacturer's listed installation and maintenance manual should be consulted for the appropriate applications and limitations for which the specific wet chemical extinguishing system is considered satisfactory protection.

Methods of Application

Wet chemical is applied through fixed systems, but also may be applied in portable fire extinguishers that are used to provide additional support to the extinguishing system. The hardware components are similar to dry chemical systems insofar as there is an agent supply and expellant gas and an actuating method. The agent is delivered through piping to specially designed nozzles that atomize the solution and distribute the agent over the hazard area.

Wet chemical systems are local application systems. Local application systems are practical in those situations where the hazard can be isolated from other hazards so that fire will not spread beyond the area protected, and where the entire hazard can be protected. In this type of system, the nozzles are arranged to discharge directly onto the fire or burning surface such as

deep-fat fryers, griddles, and stoves. It is especially critical in commercial cooking operations that the cooking equipment not be rearranged after the installation of the extinguishing system. Most wet chemical systems apply the agent through nozzles that are specifically designed to protect the equipment under them. It is therefore critical to note that any rearrangement of the cooking equipment after installation of the extinguishing system could result in unprotected surfaces. That being said, there are wet chemical systems available that are designed with overlapping spray patterns. The overlapping spray allows coverage of the entire space below exhaust hood, permitting greater flexibility in the location and relocation of equipment, provided it is always located under the hood.

System Design

Wet chemical systems are proprietary, pre-engineered systems. Pre-engineered systems are defined by predetermined flow rates, nozzle pressures, and quantities of agent required. They have specific pipe sizes and maximum and minimum pipe lengths. Further specifications are provided in the manufacturer's installation manual for flexible hose, the number of fittings, and the number and types of nozzles to be used. An important point is that pre-engineered systems are limited to the protection of hazards for which they have been specifically listed.

Part of the listing process requires the system to perform satisfactorily any one or number of types of commercial cooking equipment. UL 300 contains testing protocols deep-fat fryers, griddles, range tops, charbroilers, including gas radiant, electric charbroilers, lava, pumice or synthetic rock, natural charcoal, mesquite wood, upright and chain broilers and woks. The standard tests also include splash tests specifically for deep-fat fryers, range tops, and woks.

The objectives of these tests are to prove that the agent is effective in complete extinguishment. For deep-fat fryers, woks, and ranges, there is an additional objective that the agent prevents reignition for 20 minutes or until the temperature of the grease decreases at least 60°F (33°C) below its autoignition temperature, whichever takes longer. For other types of equipment, the agent must prevent reignition for 5 minutes.

Storage of Chemical and Expellant

Wet chemical extinguishing agents are typically stored in plastic containers up to 5 gal (19 L) in capacity. Attention should be given to the freeze point of the particular agent. The agent storage life is approximately 12 years. System tanks containing wet chemical range in size between 1.5 and 3 gal (5.7 and 11.4 L), depending on the manufacturer's design. To expel that agent, most systems use pressurized cartridges of nitrogen or carbon dioxide. To ensure proper operation, the temperature ranges for wet chemical systems are between 32 and 130°F (0 and 54°C). This range is not normally a problem as wet chemical systems are primarily used in indoors.

System Actuation

Wet chemical systems are actuated by either automatic or manual means. Automatic actuation is provided by fusible link or heat detector operation (Figure 17.2.6). It is critical that the detector devices be placed in the proper locations. To ensure this, NFPA 17A requires detectors above each appliance or group of appliances protected by a single nozzle. Detectors must also be installed in the duct entrance and another above the electrostatic precipitator if one is installed near the base of the duct.

Manual actuation occurs by the use of a listed manual pull station located adjacent to the means of egress from the room. Manual pull stations provide a backup source of system operation and must be clearly identified (Figure 17.2.7).

Part of the listing for these manual actuators states that they not require a force of more than 40 lb (178 N) or a movement of more than 14 in. (35.6 cm) to secure operation. All remote manual operating devices must be identified as to the hazard they protect.

Actuation of the system punctures the seal on the expellant gas cartridge, and the gas flows to the agent cylinder and expels the liquid through the discharge piping and nozzles. Wet chemical systems that use a secondary water application also have a pneumatically controlled waterflow valve that allows water to flow into the system after the wet chemical is totally expelled. This assists in the overall cooling effect of the wet chemical agent.

NFPA 17A requires that all sources of fuel and power to equipment that produces heat be shut down on activation of the system. Other sources of electrical power that may be exposed to the spray pattern of the system must also be shut down so as not to react with the wet chemical agent. To achieve this, actuation of the system also trips gas valves and electrical switches that interrupt fuel and power to any heat-producing appliances under the hood (Figure 17.2.8).

Distribution

Piping and fittings must be of noncombustible materials and compatible with the characteristics of wet chemical. Distribu-

FIGURE 17.2.6 Typical Heat Detector Located in Exhaust Hood

FIGURE 17.2.7 Clearly Identified Manual Pull Station

FIGURE 17.2.8 Typical Gas Shut-Off Valve That Closes on Actuation of the Extinguishing System

tion piping should be either Schedule 40 black iron, chrome plated, or stainless steel. Galvanized piping is not used for the distribution piping. It is not necessary to calculate the flow rate, pressure drop, or nozzle pressure as the system has been pre-engineered for the specific protection and confirmed by testing by a listing laboratory. The manufacturer provides the necessary information on minimum and maximum piping limitations in the listing information and installation manual.

Nozzles

Discharge nozzles must be specifically listed for their intended use, and there may be many different nozzles manufactured for a given system (Figure 17.2.9). Each nozzle is designed to distribute the extinguishing agent in a specific pattern. It may not be possible to determine the type of nozzle from a cursory glance. Many of the nozzles appear to be identical; the differences are primarily in the tips of the nozzles that create the unique coverage characteristic. Nozzles carry permanent stampings that can be used to identify the type and spray pattern. This is very important when determining whether the system provides complete coverage. It is also critical that the nozzle be aimed in the

FIGURE 17.2.9 Wet Chemical Nozzles with Required Caps Protecting Against Clogging from Grease-Laden Vapors

proper direction. A specialized nozzle-aiming device is used for this purpose. This device clamps on the nozzle and uses a laser light that indicates the spray direction of the nozzles on the surface below. The nozzle can then be adjusted and tightened to hold the appropriate location.

Nozzles are typically chrome plated; however, they may constructed of any corrosion-resistant material such as brass or stainless steel. To prevent clogging, internal strainers or separate listed strainers are required to be located immediately upstream of the nozzle. Blow-off caps (either metal or rubber) are provided to protect the interior of the nozzle from clogging due to grease vapors, moisture, or other foreign materials.

Quantity and Rate of Application

The quantity and rate of application has been determined in the pre-engineering design process. Manufacturer's guidelines provide specific and detailed diagrams indicating the proper protection and coverage necessary for any component of the cooking operations, from the individual stove, wok, or broiler, to the hood and plenum areas, to the duct work. The quantity of extinguishing agent required is based on the number of flow outlets in the system. The number of nozzles in the system is then matched to the tank and cartridge requirements provided in the manufacturer's installation manual.

INSPECTION, TESTING, AND MAINTENANCE PROCEDURES FOR CHEMICAL SYSTEMS

Owners of chemical extinguishing systems should conduct monthly inspections to determine whether the system is in proper operating condition. This inspection is not intended to be detailed, but is rather a visual check of the system and should include determination of the following items:

- The extinguishing system is in its proper location.
- The manual actuators are unobstructed.
- The tamper indicators and seals are intact.
- The maintenance tag or certificate is in place.

- There is no obvious physical damage or condition that might prevent operation.
- There is no damage to, or obstruction of, fusible links or actuating devices.
- The pressure gauge(s), if provided, are in operable range.
- The nozzle blow-off caps are intact and undamaged.
- The hood, duct, and protected cooking appliances have not been replaced, modified, or relocated.

Systems subjected to process deposits (such as paint, dust, and grease) and corrosive conditions may require more frequent inspection of components. This inspection should be recorded in a report form and made available for review by the local authority having jurisdiction. Any deficiencies should be corrected immediately. For example, grease buildup on a link can severely delay the actuation of the system (Figure 17.2.10). Obstructed pull stations must be cleared to allow manual operation (Figure 17.2.11).

On a semiannual basis, routine maintenance, in addition to a more detailed inspection, should be performed. During this inspection, the hazard should be reviewed to determine whether it has been expanded or otherwise modified to extend beyond the capabilities of the system. A thorough examination of all system components is necessary. Each component should be inspected for wear, contaminant loading, corrosion, or any other condition that may render the component or system inoperable. The dry chemical agent is normally inspected at this time for evidence of caking. If caking is present, the dry chemical must be discarded and the system recharged in accordance with the manufacturer's instructions. In stored-pressure systems, the dry chemical must be checked every 6 years.

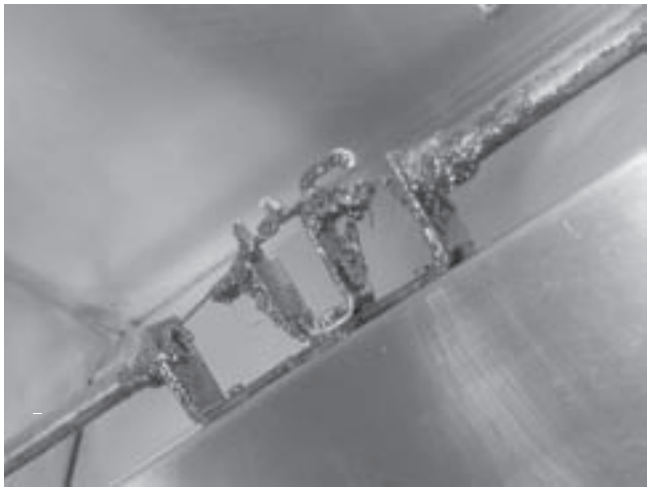

FIGURE 17.2.10 Grease Buildup on Link

FIGURE 17.2.11 Obstructed Pull Station

The distribution piping should be checked for obstructions during this procedure. This inspection can be accomplished by several means. If the system is small and accessible, the piping can be dismantled and inspected visually. If this is not practical, then purging with nitrogen or compressed air may be done. A full or partial discharge test may also be performed to verify the condition of the piping; however, all of the agent must be removed from the piping following the test to prevent caking and subsequent blockage of the pipe.

Periodically, a discharge test may be required during the performance of routine maintenance procedures. In this case, a "bag" test may be performed. During a bag test, the discharge nozzles are covered with a collection bag (a burlap bag or pillowcase) to retain discharged dry chemical. Following discharge of the system, the chemical should be weighed to determine the quantity of chemical contained. This can be compared to the amount required by the manufacturer's listed maintenance manual. Insufficient amounts may indicate possible piping obstructions.

Testing of wet chemical systems includes the operation of the detection system signals and releasing devices, including manual stations and other associated equipment. However, a discharge of the wet chemical normally is not part of this test.

The amount of expellant gas should be checked semiannually to ensure that there is sufficient gas to provide an effective discharge, and to automatically clean out the piping after the dry chemical has dissipated. In systems with separate expellant gas containers, this testing is accomplished by checking the pressure (if nitrogen) or weight (if carbon dioxide) against the manufacturer's recommended minimums. In stored-pressure systems, the pressure gauge is checked to see that it is in the operable range.

The inspection and maintenance of hand hose line systems will vary with the location and climate conditions. Equipment located in extremely hot or humid areas will require more frequent checking because the heat can cause cylinder pressure to increase and possibly cause leakage. Inspection of hand hose line systems consists primarily of checking the pressure of the expelling gas container, or the pressure of the unit itself (if it is of the pressurized type). It is also advisable to inspect all hose lines and nozzles to be sure that they are unobstructed and in good operating condition.

At least semiannually, maintenance should be conducted in accordance with the manufacturer's listed installation and maintenance manual. A trained person who has undergone the instructions necessary to perform the maintenance and

recharge service should conduct maintenance of the system. This can be determined by requiring proof of training by the manufacturer.

As a minimum, maintenance should include a check to see that the hazard has not changed, and an examination of all detectors, the expellant gas containers, the agent containers, releasing devices, piping, hose assemblies, nozzles, signals, all auxiliary equipment, and the liquid level of all nonpressurized wet chemical containers.

It is also important to verify that the agent distribution piping is not obstructed. This verification will require the disassembly of all piping and conducting at least a partial discharge test in accordance with the instructions from the manufacturer. Other obstructions may occur in the conduit carrying the cable that activates the system. Grease can cause plugging and moisture can cause corrosion that will inhibit proper operation.

Special attention is given to the fixed temperature-sensing elements. NFPA 17 and NFPA 17A both require these components to be replaced at least annually from the date of installation.

After maintenance and testing occurs, the system should tagged or labeled, indicating the month and year the maintenance and testing has been performed and identifying the person performing the service.

Chemical containers, auxiliary pressure containers, valve assemblies, hoses, fittings (not including field piping), check valves, directional valves, manifolds, and hose nozzles, in addition to the dry chemical chambers and hose assemblies of both dry and wet chemical systems, must be hydrostatically tested every 12 years. The dry or wet chemical removed from the chambers should be discarded. Care must be exercised to ensure that all equipment tested is thoroughly dried prior to recharging. If there is no automatic, connected reserve supply, alternative fire protection should be provided.

SUMMARY

Both dry and wet chemicals are used to extinguish fires. Multipurpose dry chemical is used on fires in flammable liquids, fires involving energized electrical equipment, and fires in ordinary combustible materials. Dry chemical causes extinguishment primarily through the chain-breaking reaction and also through smothering, cooling, and radiation shielding. Wet chemical extinguishing agents are used for suppression of fires in commercial cooking equipment, such as deep-fat fryers, griddles, range tops, and broilers. Wet chemical causes extinguishment because of its ability to retain the separation of the oil from the air for a sufficient time to allow complete cooling.

The installation of a complete chemical extinguishing system requires that various factors be determined, including the method of application, storage of chemicals, system actuation, distribution system, and quantity and rate of application. The system must undergo a regimen of periodic inspection, testing, and maintenance to ensure proper operating condition.

Water is the most widely used and most readily available extinguishing agent. Water is readily available and inexpensive. Water also possesses many advantages over other liquids in fire-fighting characteristics. However, it is not the proper extinguishing agent for all types of fires. It has some disadvantages; for example, it freezes at 32°F (0°C). This chapter discusses the properties of water as an extinguishing agent, including its advantages and limitations.

The principles of fire extinguishment are discussed in Section 2, Chapter 1, "Physics and Chemistry of Fire"; Section 2, Chapter 7, "Theory of Fire Extinguishment"; and in Section 17, Chapter 8, "Explosion Prevention and Protection." The systems and devices used for the transportation and application of water as a fire-extinguishing agent are addressed in other chapters in this section of the handbook. For the use of water as a suitable extinguishing agent on specific materials, such as chemicals, flammable liquids, gases, and metals, see Section 6, Chapter 9, "Metals"; and Section 6, Chapter 12, "Flammable and Combustible Liquids." For related topics, see Section 9, Chapter 16, "Mining and Mineral Processing"; Section 15, Chapter 2, "Water Supply Requirements for Public Supply Systems"; Section 16, Chapter 8, "Water Mist Fire Suppression Systems"; Section 16, Chapter 9, "Water Spray Protection"; and Section 17, Chapter 4, "Foam Extinguishing Agents and Systems."

INTRODUCTION TO WATER

Water is the most widely used and most readily available fire-extinguishing agent. Water is inexpensive, abundant, and effective in fire suppression. Water is transportable and can be pumped from a source to the fire. Water is available from domestic water distribution systems (fire hydrants), streams and rivers, wells, ponds, lakes, swimming pools, and in some cases is taken from the ocean.

Water is a very effective agent for controlling and extinguishing combustion. Water is the most abundant and available substance on the earth's surface and exists in three states: (1) liquid (water), (2) vapor (steam), and (3) solid (ice).

Life safety considerations must be weighed when choosing an effective fire-extinguishing agent. Water as an agent is safe, nontoxic, relatively noncorrosive, and stable. Water (H_2O) remains stable when applied to a fire and does not, except in very special circumstances, break down into its basic elements of hydrogen (H) and oxygen (O), both of which would encourage fire growth. Water can be applied as an extinguishing agent with building occupants in compartments, unlike some

John A. Frank, P.E., is a loss prevention training leader with Swiss Re. He is the former chair of the NFPA Technical Committee on Water Additives for Fire Suppression and Vapor Migration and was formerly a fire protection specialist with the United States Air Force.

gaseous extinguishing agents, which could cause asphyxiation or adverse side effects.

PROPERTIES OF WATER

The physical properties that allow water to be an effective extinguishing agent are as follows:

1. At ordinary temperatures, water exists as a stable liquid. Water's viscosity in the temperature range of 34 to 210°F (1 to 99°C) remains consistent, which allows it to be transported and pumped.
2. Water has a high density, which allows it to be discharged from and projected from nozzles. Water's surface tension allows it to exist from small droplets to a solid stream.
3. The latent heat of fusion is the amount of energy required to change the state of water from solid (ice) at 32°F (0°C) to a liquid. Water absorbs 143.4 Btu per lb (333.2 kJ/kg) in this process.
4. The specific heat of water is 1.0 Btu per lb(°F) (4.186 kJ/kg(°C)). For example, raising the temperature of 1 lb (0.45 kg) of water 180°F (100°C) from 32°F (0°C) to 212°F (100°C) requires 180 Btu. Raising 1 kg of water from 0°C to 100°C requires 418.6 kJ.
5. Water is effective as a cooling agent because of its high latent heat of evaporation (changing water from a liquid to vapor), which is 970.3 Btu per lb (2260 kJ/kg) as described in Section 2, Chapter 1, "Physics and Chemistry of Fire." Some authors are giving "credit" to additional heat absorption from the steam as it is heated beyond the boiling point of water when water is applied in small droplets. The specific heat of steam is 2.01 kJ/kg(°C).[1]
6. Water expands in its conversion from a liquid state to a vapor state to 1600 to 1700 times the liquid volume. One gallon (3.8 L) of liquid (which occupies 0.1337 ft^2 [0.004 m^3]) produces over 223 ft^3 (6.3 m^3) of steam. Therefore, it follows that 1 gal (3.8 L) of water at room temperature applied to a fire and converted to steam (complete conversion) will absorb heat both in rising to the temperature at which it becomes a vapor and in the phase change from liquid to vapor. (For SI units: °F = °C × ⅘ + 32; 1 Btu = 1.055 kJ; 1 lb = 0.45 kg; 1 gal = 3.785 L; 1 ft^3 = 0.0283 m^3.)

   Heat required to raise temperature of water to boiling:

   - 212°F – 68°F (room temperature) = 144°F
   - 144Δ°F × 1 Btu/lb × 8.33 lb (weight of 1 gal) = 1200 Btu

   Heat required to change water from a liquid to a vapor:

   - 970.3 Btu/lb × 8.33 lb (weight of 1 gal) = 8083 Btu
   - Total heat absorbed is 1200 + 8083 = 9283 Btu/gal of water

Using SI units in the preceding example, the total heat absorbed by 1 kg of water raised from 20°C (room temperature) to its boiling point is 2594.9 kJ/kg of water. A figure of 2600 kJ/liter is commonly used.

Therefore, a fire department hose stream discharging at 100 gpm will absorb 928,300 Btu per minute in a complete conversion. The same fire department hose stream will create 22,300 ft^3 per minute of steam in a complete conversion. In SI units (using 2600 kJ/liter), this same hose stream (discharging 378.5 L/min) will absorb 984,100 kJ/min or 16,402 kJ/sec or 16.4 MW. Likewise, 631 cubic meters of steam will be created.

When reviewing the international literature recommended in this chapter, the reader is cautioned to carefully note the units being used. Minor differences may be noted due to unit conversions. Also note that the preceding example does not give credit to heat absorbed by the heating of steam above the boiling point of water. Some international authors are giving this credit in their suppression models if small water drops (e.g., smaller than 1 mm) are used. Some models also give credit to the observation that it is not necessary to absorb all of the heat released by diffusion flames. After these credits are applied, the models may then assign another factor that accounts for less than optimum performance, as discussed later in this chapter. As is the case with all models, it is essential that the user understand the model's inputs and outputs to make appropriate decisions.

EXTINGUISHING PROPERTIES

Water is a very effective extinguishing agent because of its ability to cool the fuel, remove or displace the oxygen supply, and separate/dilute the fuel source. See the discussion on the principles of fire in Section 2, Chapter 1, "Physics and Chemistry of Fire," and Section 2, Chapter 7, "Theory of Fire Extinguishment."

The dominant mechanism of extinguishment, or combination of mechanisms of extinguishment, depends on several interrelated factors, including the fuel's physical and chemical properties, the geometry of the compartment (if one exists), ventilation, ambient conditions, the form of the water applied (e.g., fog versus solid stream), and the application technique.

Knowledge of the influence of these factors and the interaction of the mechanisms of extinguishment vary widely with the extent of scientific research conducted on a given application method. Section 16, Chapter 8, "Water Mist Fire Suppression Systems," provides a good example of the extent of the body of knowledge that exists regarding the interactivity of these mechanisms for fixed water mist systems. For manually applied hose streams, see Grimwood et al.[2]

Extinguishing by Cooling

Water principally extinguishes solid fuel fires by cooling the fuel surface. In addition to the cooling of a solid fuel itself, water is effective as a cooling agent because of its high latent heat of evaporation (item 5 under properties). Water introduced to a fire promotes heat loss via the heat transfer from the fire to the water. When the heat loss exceeds the fire heat gain, the fuel surface will begin to cool until the flame can no longer exist at the surface. Water is an effective coolant for solid fuel surfaces.

Besides the direct cooling of a solid fuel, water can cool solid fuels indirectly by the reduction of the radiant heat flux from the flame, and from the hot upper gas layer (if present), to the fuel surface. This action reduces the rate of pyrolysis of the fuel, which reduces the heat release rate of the fire. This cooling results from the cooling effects of the water droplets and steam.

Conceptually, when the heat absorption rate of water approaches the total heat release rate of the fire, fire control begins. When the heat absorption rate of water exceeds the heat release rate of the fire, fire suppression and, ultimately, fire extinguishment are achieved. Other factors to consider in fire control and extinguishment include heat losses through openings and heat losses to walls, ceilings, and floors.

As discussed in Section 2, Chapter 7, "Theory of Fire Extinguishment," it is theoretically not necessary to absorb all of the heat being released, but only enough to effect the combustion reaction. Because of the difficulty of applying water in the manner described in Section 2, Chapter 7, the actual application needed for extinguishment may be 10 to 100 times the critical application rate. Mawhinney indicates that absorbing 30 to 60 percent of the heat released from a fire may be enough to extinguish the fire.[3] Some manual suppression models now account for this observation.

The amount of water required to extinguish a fire depends on the heat release rate [Btu/sec (kW)] of the fire. How quickly a fire is extinguished depends on how the water is applied, how much is applied, and in what form water is applied.

As shown in water mist applications, the smaller the droplet, the higher the rate at which water extracts heat from the fire and fire gases, resulting in using a lower volume of water. Grimwood[4] reports on the findings of Rasbash that a 2 mm droplet moving at 0.07 m/sec will extract heat at a rate of 167 kW/m^2 of droplet surface area. Decreasing the droplet size to 50 microns (0.05 mm) and increasing the velocity to 0.5 m/sec increased the heat transfer rate to 2500 kW/m^2 of droplet surface area. Calculations show that for many applications, the optimum diameter of a water droplet is in the range of 0.01 to 0.04 in. (0.3 to 1.0 mm), and that the best results are obtained when the droplets are fairly uniform in size. However, a water droplet approaching the fire can evaporate in the fire plume, thus only cooling the fire plume but not effectively cooling the fuel surface, which, as shown in Section 2, Chapter 7, "Theory of Fire Extinguishment," can be critical. The need for direct fuel surface cooling varies with the application. Actual delivered density (ADD) is the actual water application rate to a fire at the surface of the burning fuel. Research facilities at Underwriters Laboratories and FM Global are capable of measuring the ADD in warehouse applications. This figure is then compared to the required delivered density (RDD) for suppression. Fire suppression is achieved when the ADD > RDD.

The amount of water reaching a fire is affected by the fire's burning rate and associated upward plume velocity. The water droplets must overcome the effects of the upward momentum of the fire plume and air currents in order to reach the burning fuel and provide effective fuel cooling. For example, droplets, once produced at a sprinkler, are subject to high temperatures that evaporate the small droplets at the ceiling. If the small droplets survive the ceiling temperature, they may not have the mass or momentum to be able to penetrate the fire plume. Yao and Williams reported that 1 mm drops can penetrate a 20 ft/sec (6.1 m/sec) fire plume, 1.5 mm drops can penetrate a 30 ft/sec (9.1 m/sec) plume, and 2 mm drops can penetrate a 40 ft/sec (12.2 m/sec) plume, which occurs in high-challenge fires.[5] Drops smaller than 0.3 mm are found in some water mist applications. See Isman[6] for a complete discussion. For manual application from hose streams, see Clark[7,8] and Grimwood et al.[2]

As the preceding discussion indicates, the high heat absorption of a fine mist must be balanced against the need for water to reach the fuel surface to cool the fuel. The relative importance of these competing characteristics depends on several factors. These factors can be specifically accounted for in engineered systems. For example, engineered water mist systems emphasize general cooling whereas large drop sprinklers emphasize penetration of the fire plume to directly cool the pyrolyzing fuel.

For manual application from hose streams, the literature reports successful extinguishment from techniques that emphasize general cooling (as from a fog stream), from techniques that emphasize direct cooling of the fuel (as from a solid stream), and from various combinations of these techniques. As is the case with engineered systems, the high heat absorption characteristics of a fog stream must be balanced against the penetrating characteristics of a solid stream. Major texts discussing the advantages of solid stream applications are by Clark[7] and by Fornell.[9] A major text on fog streams entitled *The Safe and Effective Use of Fog Nozzles* was published in 2003.[10]

An application method known as fog attack or gas phase cooling has gained widespread acceptance in Europe and is gaining acceptance in Australia and the United States. A major text on this subject entitled *3D Fire Fighting, Training, Techniques, and Tactics* was published in 2005.[4] This text also gives a historical overview of all methods of manual application as well as where each is most effectively used. The limits of the fog attack technique are explained as well. See Grimwood[11,12] or http://www.firetactics.com.

Extinguishing by Smothering

When water is applied to a fire or a hot compartment surface, steam is formed. The dilution of the air (oxygen) supply around the fuel sources provides suppression by a smothering action. Suppression by this method is more effective if the steam and water droplets are confined around the fuel source. The steam and water droplets also continue to extinguish a fire by cooling as the water droplets continue to evaporate around the heated area of a fire.

Fires in ordinary combustibles are normally extinguished by the cooling effect of water—not by the smothering effect created by steam. Water mist systems, which may be used as an alternative to sprinkler systems or certain gaseous extinguishing systems, have been found to be effective in controlling *and* extinguishing fires by cooling and by smothering, as discussed in Section 16, Chapter 8, "Water Mist Fire Suppression Systems." The advantages and disadvantages of steam generation from manually applied water streams have been fiercely debated for many years.

Water may be used to smother a burning liquid when the liquid has a flashpoint above 100°F (37.8°C), a specific gravity greater than 1.0, and is not water soluble. To achieve this most effectively, a foam concentrate is added to the water to form a foam-water solution. The foam-water solution must then be applied gently to the surface of the flammable liquid. Water

mist systems have been used to extinguish fires in liquids with a flashpoint below 100°F (37.8°C). Heptane is a common test liquid. In cases where oxygen is produced while a burning material decomposes, smothering by any agent is not possible.

Systems based on the use of industrial process steam are sometimes used in industrial ovens. Design applications are discussed in NFPA 86, *Standard for Ovens and Furnaces*, and in insurance company guidelines.

Extinguishing by Emulsification

An emulsion is formed when immiscible liquids are agitated together and one of the liquids is dispersed throughout the others. Extinguishment by this process can be achieved by applying water to certain viscous flammable liquids, since the effect of cooling the surfaces of such liquids prevents the release of flammable vapors. With some viscous liquids (such as No. 6 fuel oil), the emulsification is a froth that retards the release of flammable vapors. Care must be used on liquids of appreciable depth, however, because frothing may spread the burning liquids over the sides of the container. A relatively strong, coarse water spray is normally used for emulsification. A solid stream of water should be avoided, as it will cause violent frothing. These techniques are rarely used. Additives that promote emulsification are discussed later in this chapter.

Extinguishing by Dilution

Fires in water-soluble, flammable materials may, in some instances, be controlled or extinguished by dilution. The percentage of dilution necessary varies greatly, as does the volume of water and the time necessary for extinguishment. For example, dilution can be used successfully in a fire involving an ethyl or methyl alcohol spill if it is possible to get an adequate mixture of water and alcohol and if the mixture can be contained while it is being diluted. Details for ethyl alcohol can be found in FM Global Data Sheet 7–74 *Distilleries*.

Dilution is not a common practice when tanks are involved. The danger of overflow because of the amount of water required and the danger of frothing should the mixture become heated to the boiling point of water seldom make this form of extinguishment practical.

MANUAL APPLICATION RATES

In the United States, three methods are widely used to determine the manual water application rate needed to extinguish a fire. These are the Iowa Flow Formula, the National Fire Academy (NFA) Formula, and the Insurance Services Office (ISO) method. A fourth method—the Illinois Institute of Technology method—is not as widely used. (See Section 15, Chapter 2, "Water Supply Requirements for Public Supply Systems," for detailed information on the Illinois Institute method.) Although useful for fire service preplanning and for municipal water supply planning, none are readily adapted for fire protection engineering applications and performance-based design. The Iowa Flow Formula and the ISO formula are more fully discussed in Section 15, Chapter 2, "Water Supply Requirements for Public Supply Systems." See Burns and Phelps[13] for further information on the NFA formula. Grimwood et al.[14] introduced a tactical flow rate based on extensive analysis of international research as well as extensive practical experience in London. A detailed comparison of the tactical flow rate to the Iowa and NFA methods is also provided.

The Iowa State Method has scientific research behind it that emphasizes both the cooling effect of water and the smothering effect of steam. Measurements focused on the reduction of ceiling and compartment temperature. Fire protection engineering calculations are driven by heat release rates or their constituent components of the mass loss rate of the fuel and the heat of combustion of the fuel. The effect of the rate of cooling and steam smothering on these engineering parameters was not measured, which limits the usefulness of the method. Further, the formula is meant to be applied to the largest open area in a structure, not to partially involved areas. The amount of water needed for adjacent areas and for exposures is not addressed. For additional information see Clark,[7,8] Fornell,[9] and Royer.[15] Wiesman and Iowa State University Bulletin No. 18 should be read in their entirety.

The NFA formula was developed from the experience of structural incident scene commanders. The formula can be applied to partially involved structures; however, there is no method for fire protection engineers to determine a footprint of a fire that can be substituted into the percent involvement portion of the formula.

The ISO formula is based primarily on how much water (in increments of 250 or 500 gpm [946.25 to 1892.5 L/min]) is needed to contain a fully involved structure (or a predefined portion of a multistory facility) and to prevent fire spread to adjacent structures. It is not suitable to determine the manual application rate needed to extinguish a growing fire within a structure. For further information see Hickey.[16]

It may seem desirable to use knowledge of the heat absorption rate of water and knowledge of the heat release rate of a fire to determine if the flow rate is adequate. This is being discussed more and more in the international literature. As previously discussed, a 100 gpm (378.5 L/min) stream will absorb 928,300 Btu per min (16.4 MW) in a complete conversion. The same 100 gpm (378.5 L/min) hose stream will create 22,300 ft^3/min (631 m^3/min) of steam in a complete conversion. The difficulty in applying this knowledge to fire protection engineering problems is based on the compound effect of the following unknowns:

- The amount of water that is converted to steam
- The amount of water that reaches the flame
- The amount of water that actually reaches the fuel surface
- The combined effect of steam's smothering and cooling
- The criticality of water reaching and cooling the fuel surface versus general area cooling for the given fire
- The amount of heat that must be removed to cause a collapse of the combustion reactions

Kimball observed that two to four times the flow rate suggested by the Iowa State study tends to be used.[17] Recently, factors have been introduced to account for the unknowns listed previously. When reviewing such factors, it is important not to mix the reduction factors with the theoretical heat absorption in

other models. This is because, as discussed earlier in this chapter, some heat absorption models give additional credits for heat absorption as the steam is heated beyond the boiling point of water and for the observation that it is not theoretically necessary to absorb 100 percent of the heat that is being released. Table 17.3.1 gives some of the values used in the international literature.

OPACITY AND REFLECTIVITY

Tests conducted at Underwriters Laboratories Inc. (UL), using water spray to provide exposure protection to a sheet metal surface from a gasoline fire, indicate that when the spray is applied as a thin film of water over the sheet metal, the temperature of the metal was contained within limits that protected the metal from significant damage. This did not occur, however, when the water spray was adjusted so that it did not touch the sheet metal, but it did provide a water curtain between the metal and the fire. In this latter case, the temperature of the metal was three to four times greater than when the water flowed over the metal. These tests indicate that, because of its lack of opacity, water does not prevent the passage of radiant heat very well. The principal value of water used to protect exposures is from the cooling obtained by evaporation of a water film on the exposed surfaces.

NFPA 13, *Standard for the Installation of Sprinkler Systems,* calls for outside sprinklers for protection against exposure fires to be positioned so that the water will thoroughly wet exposed glass windows and run down over the window sash

TABLE 17.3.1 Literature Values for Heat Absorption Efficiency of Water Applied by Fire Fighters

Researcher	*Reference*	*Efficiency (%)*	*Theoretical Heat Absorption Used (MW per kg/sec) (Same as L/sec)*[a]	*Conditions/Comments*
Barnett[b]	Draft SFPE *Engineers Guide to Fire Department Intervention* citing New Zealand Fire Engineering Guide and National Research Council of Canada	33	2.6	Based on first principles of heat absorption. The 33% factor includes an increase over heat absorption efficiencies alone to account for the effect of steam
Grimwood et al.[c]	*3D Fire Fighting, Training, Techniques, and Tactics*	32	2.6	Heat absorption a rounded conversion from 9.8 MW/gal/sec. Applies to direct attack

and the glass, wetting the entire window as much as possible. Similar recommendations require that as much of the cornice as possible be wetted when cornice sprinklers are installed. These recommendations reflect the experimental evidence.

In England, tests measured the transmission of radiant heat through water sprays from two types of nozzles.[18] The tests proved that the transmission of this kind of heat depends mostly on nozzle design, and that, with certain nozzles, a water curtain of low transmission could be produced for waterflows comparable to those of sprinkler installations. Fire fighters have, of course, used water curtains in situations where it was too hot or dangerous for them to remain exposed to flames and heat.

WATER AS AN EXTINGUISHING AGENT

It is recognized that fires involving various fuels and materials react differently to various extinguishing agents and that water is *not* the best agent for all types of fuels.

Water is not suitable for all types of fires. There are four typical classifications of fire: (1) Class A—ordinary combustibles, (2) Class B—flammable and combustible liquids, (3) Class C—electrical, and (4) Class D—combustible metals. A fifth class, Class K, has been added for cooking oils. Water is most effective and most commonly used for Class A fires. Water is not appropriate or the most desirable agent of choice for Class B, Class D, or Class K fires. (Water mist systems have been successful on tests of some Class B and Class K fires.) Using water for Class C fires must be considered carefully before the water is applied. Water may not be an acceptable agent where collateral water damage is deemed unacceptable.

A good reference to consult for recommendations on use of water on specific materials where problems could be encountered is the NFPA *Fire Protection Guide to Hazardous Materials.*[19]

Water applied to fires by certain types of water mist fire suppression systems has been found to be effective with fires involving flammable liquids and live electrical equipment. Water mist systems can be used to protect shipboard engine enclosures, valuable artwork, and computer room subfloors. Water mist is especially effective in confined spaces when a detection system operates the water mist fire suppression system. Water mist systems are also an attractive option for applications where the storage or discharge of water is to be minimized. Direction on the use of water mist as a suppression system is given in NFPA 750, *Standard on Water Mist Fire Protection Systems.* More information can be found in Section 16, Chapter 8, "Water Mist Fire Suppression Systems."

Water can be used in some instances for fires involving chemicals and combustible metals, where the quantity of water can overcome some adverse chemical reactions and extinguish the fire.

The following possible personnel hazards must be considered when choosing water as the extinguishing agent: (1) exposure and/or inhalation of steam in all fires, (2) electrocution or shock injury in electrical fires, and (3) adverse or explosive reactions in chemical and combustible metal fires.

Wetting Agents

Information in this section is based on NFPA 18, *Standard on Wetting Agents*. Wetting agents are compounds that are added to water to change some or all of the water's characteristics, for example, surface tension or viscosity. Experience as well as testing indicates that the addition of a proper wetting agent to water will, when properly applied, increase the extinguishing efficiency of that water with respect to quantity used and time to achieve fire control or suppression. The value of such a factor may well become important, especially in rural areas where adequate quantities of water are not always available for fire fighting.

Certain types of fires, such as those in baled cotton, stacked hay, some rubber compounds, and some flammable liquids that do not ordinarily respond to treatment with water may be extinguished when a proper wetting agent is used. This may be attributed to an increase in the penetrating, spreading, and emulsifying capability of water due to lowered surface tension. This decrease in surface tension can be described as a disruption of the forces holding the surface film of water together, permitting it to flow and spread uniformly over solid surfaces. The treated water possesses the ability to penetrate into small openings and recesses that nontreated water would flow over by the simple bridging action of the surface film. The treated water exhibits not only penetrating and spreading qualities but also increased absorptive speed and superior adhesion to solid surfaces.

Some wetting agents have foaming characteristics when mixed with water and air. The foam retains the wetting and penetrating characteristics of the wetting agent and provides an efficient smothering action for the extinguishment of Class A and some Class B fires. It also provides a fluid insulation for protection against fire exposure. The foam produced in this manner has the additional advantage of breakdown at approximately 175°F (79.4°C), then returns to its original liquid state and retains the penetrating and wetting qualities.

Although wetting agents can be used on some Class B fires, they do not perform as well as foam and in many cases the performance of a wetting agent on Class B fires may be unsatisfactory with respect to extinguishment or burnback resistance. A wetting agent that has been listed for Class B fires by UL has not undergone testing as rigorous as the testing required to be listed as a foam under UL 162, *Foam Equipment and Liquid Concentrates.*

There are numerous chemicals that fulfill the primary function of a wetting agent, which is to lower the surface tension of water. However, very few of these chemicals are suited to fire protection because their application is complicated by hazard considerations, such as toxicity, corrosive action on equipment, and stability in water.

Wet water is water plus a wetting agent. Wet water has the same limitations as water on fires in chemicals that react with water. The use of wet water on flammable and combustible liquid fires is not common. Wet water should not be used on flammable or combustible liquid fires if the liquids are water soluble, such as the alcohols, glycols, and some ketones.

Because of its conductivity, the application of wet water solutions on live electrical equipment requires the same precau-

tions as application of water on Class C (electrical) fires. Wet water applied by spray or fog might be used with caution due to its penetrating characteristics. Wet water may have more harmful effects on motors, transformers, and similar equipment than plain water. Any electrical equipment that has been penetrated by wet water should be thoroughly flushed and cleansed before it is returned to service.

A specific use of wet water is to penetrate combustible materials. One objective is to use less agent than if plain water were used, especially in Class A fuels with the potential for a deep-seated fire. This increased water absorption can increase the potential for structural or commodity collapse if too much agent is absorbed, thereby increasing the weight of the commodity.

Wetting agents may be either premixed with water or added to the water through suitable proportioning equipment at the time the water is being used. Mixing wetting agents from different manufacturers, or mixing a wetting agent with mechanical or chemical foam concentrates, is not recommended. Distinction must be made between wetting agents and wetting-agent foams and other detergent-type foams (high-expansion foam) and film-forming foam agents. Guidance for the use of wetting agents is given in NFPA 18, *Standard on Wetting Agents.*

Class A Foam

Water additives known as Class A foams have become extremely popular in recent years. Fornell describes seven advantages of Class A foam over water alone.[20] Colletti and Liebson should be read in their entirety. Also see NFPA 1150, *Standard on Foam Chemicals for Fires in Class A Fuels,* and NFPA 1145, *Guide for the Use of Class A Foams in Manual Structural Fire Fighting.*

Modern Water Additives

Manufacturers have developed water additives that appear to be much more effective on Class A and Class B fires than traditional wetting agents. These manufacturers often promote the environmental benefits of their agents as well. As of this writing, the Technical Committee on Water Additives for Fire Suppression and Vapor Mitigation is working on a new document, NFPA 18A, *Standard on Water Additives for Fire Control and Vapor Mitigation.* The challenge before the committee was how to quantify the improvements that these agents purport to offer. The proposed standard will provide quantifiable performance requirements. These requirements can be compared to other agents for the intended use.

For example, an agent meeting the minimum requirements of NFPA 18A is required to be applied at a greater density than a UL-listed Aqueous Film Forming Foam (AFFF) to extinguish a Class B fire. But the NFPA 18A agent may have additional listings and capabilities that AFFF does not have. Specifically, NFPA 18A requires that agents demonstrate improved performance over water on Class A fires.

Agents listed under NFPA 18A have the option of being listed for long-term vapor mitigation and for use on three-dimensional (flowing) fuel fires. AFFF is not listed for these applications. Agents listed under NFPA 18A must meet the requirements of UL 162 if they are intended to be used on Class B fuels in extreme depth such as tank fires. Some agents that would be covered under the NFPA 18A agent have found a niche market in the protection of Powder River Basin coal at power plants and have become the standard in that industry. Powder River Basin (PRB) coal refers to low-sulfur coal. Its name comes from the region along the Montana-Wyoming border where it is mined. Powder River Basin coal is a greater fire protection challenge than more traditional coals and warrants extra fire protection precautions. For more information visit the Powder River Basin coal users group at http://www.prbcoals.com. For related topics, see Section 9, Chapter 16, "Mining and Mineral Processing."

Additional information on the differences between agents covered under NFPA 18A and traditional Class B foams can be found in the annex of NFPA 18A. It is up to the user to carefully evaluate the intended application(s), the cost and amount of agent needed to meet those needs, and potential environmental impact before selecting the agent that best meets those needs.

Two additives, along with two types of aqueous film-forming foam and a film-forming fluoroprotein foam, were tested in sprinkler and water mist systems by the UK Royal Navy. Liu and Kim reported that "test results showed that all five types of additives improved the performance of both sprinklers and water mist but such improvement was much more significant for water mist."[21]

WATER AND FLAMMABLE AND COMBUSTIBLE LIQUIDS—CLASS B FIRES

Care must be exercised when using water as an extinguishing agent with Class B (flammable and combustible liquid) fires. Water density can create problems with flammable and combustible liquids. When the liquid is lighter (specific gravity less than 1.0) than water, the water can submerge beneath the liquid and can cause the flammable or combustible liquid to flow from its containment, spreading the fire. With crude oil, water can submerge to the bottom of the container and cause the crude oil to "boil over." Other hazards are slopover and frothover. (See Section 6, Chapter 12, "Flammable and Combustible Liquids.") Water is immiscible with hydrocarbon fuels, does not provide an effective coating of the fuel surface, and does not dilute the flammable or combustible mixture below the flammable limits. However, when properly mixed with certain types of foam concentrate, water is an effective fire-suppressing agent for certain types of flammable and combustible liquids.

Heavy fuel oil, lubricating oil, asphalt, and other high-flashpoint liquids do not produce flammable vapors unless heated. Once ignited, the heat of the fire will cause pyrolysis for continued burning. If water in spray form is applied to the surface of such high-flashpoint burning liquids, cooling will slow down the rate of pyrolysis enough that it may extinguish the fire. If water is applied to high-flashpoint burning liquids by means of a coarse spray, extinguishment may be obtained by emulsification.

Foam concentrate used for flammable and combustible liquids are commonly called Class B foams to distinguish themselves from the previously discussed Class A foams. Fire

department pumpers are now commonly equipped with one tank for Class A foam and another for Class B foam.

Fire-fighting foam for Class B liquids is (1) an aggregate of air-filled bubbles forming from aqueous solutions (water and foam concentrate) and (2) lower in density than flammable liquids. It is used principally to form a cohesive floating blanket on flammable and combustible liquids and prevents or extinguishes fire by limiting the amount of air and cooling the fuel. It also prevents reignition by suppressing formation of flammable vapors. (See Section 17, Chapter 4, "Foam Extinguishing Agents and Systems.")

Fire-fighting foams for Class B liquids consist of a combination of water, foam concentrate, and air. Low-expansion-type foams typically utilize a ratio of 1, 3, or 6 percent concentrate to 99, 97, or 94 percent water, respectively, to make a foam-water solution. Water remains the principal component in fire-fighting foams.

The ability of water without additives (foaming agents) to extinguish a fire is limited on low-flashpoint flammable liquids, such as Class I flammable liquids (flashpoints below 100°F [37.8°C]), as defined in NFPA 30, *Flammable and Combustible Liquids Code.* Sprinklers and water spray are usually effective in extinguishing fires in combustible liquids with flashpoints of 200°F (93.3°C) and higher, in flammable liquids with a specific gravity greater than 1.0, and in water-soluble liquids. Water can be effective with high-flashpoint hydrocarbon fires when introduced as a high-velocity spray causing penetration of the droplets and cooling of the surface layer.[22] If water does not evaporate and cool the fuel surface, it can accumulate and submerge and can displace the hydrocarbon. Control of fire, but not extinguishment, is possible in low-flashpoint (under 200°F [93.3°C]) flammable liquids. Any water that reaches the surface of a burning, low-flashpoint flammable liquid in a tank may sink and cause the tank to overflow. In the case of a spill fire, the water may cause the fire to spread. Special handling of certain types of water spray nozzles can result in extinguishment of fires in these liquids or, at a minimum, effective fire control.

Water can be used as an effective cooling agent in Class B fires; it can also (1) protect against flame-exposure of the storage container and (2) protect exposures as a cooling agent.

See Section 6, Chapter 12, "Flammable and Combustible Liquids," for characteristics and fire preventive methods for Class B fires.

WATER AND LIVE ELECTRICAL EQUIPMENT—CLASS C FIRES

Water in its natural state contains impurities that make it conductive. If water is applied to fires involving live electrical equipment, a continuous circuit might be formed that would conduct electricity back to the user and cause a shock, especially if there are high voltages or potentials. Foam-type extinguishing agents are also conductive. The amount of current, rather than the voltage, determines the extent of the shock. Conductivity of water when used on live electrical equipment depends on several variables:

1. The voltage and amount of current flowing
2. The "breakup" of the stream as a result of the nozzle design, the pressures used, and the wind conditions. This breakup influences the conductivity of the stream because the air spaces formed between the droplets interrupt the electrical path to ground. Water spray nozzles and combination straight-stream spray nozzles (in the spray position) provide for effective dispersion of the water droplets. The hazards of these are less than those of solid streams of water.
3. The purity of the water and the relative resistivity of the water
4. The length and cross-sectional area of the water stream
5. The resistance to ground through a person's body as influenced by location (whether on wet ground or not), skin moisture, the amount of current the body can endure, the length of exposure to the current, and other factors, such as protective clothing.
6. The resistance to ground through the hose

Conductivity and Hazard of Shock

There is some danger to fire fighters directing streams of water onto wires of less than 600 V to ground from a distance likely to be encountered under ordinary fire-fighting conditions. It is more dangerous if fire fighters, standing either in puddles of water or on moist surfaces, come into contact with live electrical equipment. In such cases, the fire fighters' bodies complete an electrical circuit, and the current from the electrical equipment relayed through their bodies is more readily grounded than if it were conveyed through dry, nonconductive surfaces. Rubber boots often contain enough carbon black to permit the passage of current through the body and do not provide reliable protection.

Research conducted by UL on electric fences indicates that there are differences in the electric current to which individuals may be safely subjected and that the maximum continuous (uninterrupted) current to which an individual may be safely subjected is 5 mA (milliamperes) AC applied on the surface of the body.[23]

Impurities in water (mostly the mineral content) also affect its conductivity. Tests of the resistivity of public water supplies in Indiana showed results ranging from 710 to 5400 ohms per cm^3; the lowest values were found in supplies from deep wells. The resistivity of deep well supplies ranged from 1000 to 2000 ohms per cm^3; and the resistivity of river waters was about 4000 ohms per cm^3. In tests conducted by the Commonwealth Edison Company in cooperation with the Chicago Fire Department, the resistivity of Chicago River water ranged from 1671 to 2393 ohms per cm^3.[24] At the time the tests were made, the normal hydrant water in the Chicago area had a resistivity of about 3800 ohms per cm^3.

Safe Distances from Live Equipment

From time to time, authorities have tried to determine safe distances between nozzles and live electrical equipment. The bibliography at the end of this chapter cites more papers on this subject.

The conductivity of water streams varies according to the type of equipment from which they are expelled, such as

(1) handheld or manually supported solid-stream nozzles, (2) handheld water spray (water fog) nozzles, (3) fixed water spray systems for fire protection services, and (4) plain water and water-solution portable fire extinguishers.

Data available on the minimum safe distances between manually supported solid-stream hose lines and live electrical equipment carrying voltages higher than 600 V are not entirely consistent because the results of different tests vary. These variations may be attributed to the different testing methods used, the variances in the purposes of the tests, the limitations of the tests caused by the physical circumstances and available equipment, and the fact that the same voltages were not used in all of the tests.

Data from the American Insurance Services Group (AISG), a unit of Insurance Services Offices, Inc. (formerly AIA), was published in the 18th and earlier editions of this handbook. At AISG's request, this information was removed from the 19th edition of this handbook because the data are based on an AIA bulletin that is no longer in print and is considered obsolete. AISG does not recommend the information published in Table 6-1A in the 18th edition of this handbook. Some limited tests made in 1958 by the Hydroelectric Power Commission of Ontario, in cooperation with the Office of the Fire Marshal of Ontario, Canada,[25] resulted in recommendations for minimum safe distances from live electrical equipment for a ⅝ in. (16 mm) solid-stream nozzle (Table 17.3.2). The report recommends that solid streams greater than ⅝ in. (16 mm) should not be used near live electrical equipment, but the tests were limited to a maximum stream distance of 30 ft (9.1 m). Larger nozzles might produce sufficient stream dispersion over longer distances, which would permit their use.

TABLE 17.3.2 Limit of Safe Approach to Live Electrical Equipment

Voltage to Ground	*Voltage Between Conductors*	⅝ in. (16 mm) Solid-Stream Nozzle:[a] Minimum Safe Distance	
		ft	*m*
2,400	4,160	15	4.6
4,800	8,320	20	6.1
7,200	12,500	20	6.1
8,000	13,800	20	6.1
14,400	24,900	25	7.6
16,000	27,600	25	7.6
25,000	44,000	30	9.1

The results of tests made in 1934 for the Fire Brigade of Paris, France, present perhaps the most comprehensive guide[26] (Table 17.3.3). The distances are based on preventing the transmission of a 1 mA current to a fire fighter in contact with a nozzle or hose. The tests covered only voltages to ground ranging from 115 to 150,000 V, and the groupings of the voltages do not correspond to current standard U.S. voltages. The maximum size of the nozzle used is also nonstandard in the United States.

The preceding information indicates that definite shock hazards exist unless adequate distances are maintained, and these distances can only be estimated from the available data. It is difficult for fire fighters in the field to know precisely what electrical potentials exist in any given situation. For this reason, and those given next, it is best, whenever possible, to use water spray streams rather than solid streams.

As noted previously, water spray reduces the conductivity hazard. The design of the nozzle and the characteristics of the spray determine the amount of leakage current that can actually flow in the stream, and each nozzle should be tested to determine precisely the characteristics it possesses. Tests on various commercial water spray nozzles indicate that a minimum

TABLE 17.3.3 Minimum Safe Distances Between Hose Nozzles and Live Electrical Equipment Recommended for the Paris, France, Fire Brigade

distance of 4 ft (1.2 m) should be maintained for voltages to ground up to about 10 kV. This distance is actually no greater than is sensible to prevent personnel from getting dangerously close to live electrical equipment. Distances should be increased when attacking fires involving live electrical equipment operating above this voltage. Figure 17.3.1 shows the results of four researchers, as analyzed by the U.K. Fire Offices' Committee, Joint Fire Research Organization.[27]

The Toledo Edison Company conducted tests in which water was discharged onto a screen at a potential to ground of 80,500 V (equivalent to a system or line voltage of 138 kV phase-to-phase). As a consequence, the Edison Electric Institute in 1967 adopted the following safety rules. (The distances in these rules will limit leakage currents to less than 1 mA):

1. Using all handheld water spray nozzles, the minimum approach distance is 10 ft (3 m).
2. Using handheld, 1½-in. (38-mm) straight (solid) stream nozzles, the minimum approach distance is 20 ft (6 m).
3. Using handheld, 2½-in. (64-mm) straight (solid) stream nozzles, the minimum approach distance is 30 ft (9 m).

When combination straight-stream spray nozzles are used on live electrical equipment, fire fighters should be sure they have the desired spray pattern before applying the stream. The use of spray nozzles on "applicators" increases the possibility of accidental contact between the nozzle and live electrical equipment, and most authorities recommend that they not be used.

Clearance from Fixed Water Spray Systems

Fixed water spray systems are used extensively to protect high-value and/or critical electrical equipment, such as transformers, oil switches, and motors. These systems are designed to provide effective fire control, extinguishment, prevention, or exposure protection. NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection,* gives installation recommendations for such systems and includes a table of recommended clearances between water spray equipment and unenclosed or uninsulated live electrical components at other-than-ground potential (Table 17.3.4). Modern practice is to coordinate the required clearance with the electrical design. The basic insulation level (BIL) values of the equipment are used as the basis, although the clearance between uninsulated live parts of the equipment and any portion of the water spray system should not be less than the minimum clearances provided elsewhere for electrical system insulation on any individual component (the minimum unshielded straight-line distance from the exposed electrical parts to nearby grounded objects). The BIL (expressed in kilovolts [kV]) is the crest value of the full wave impulse test. (See Section 16, Chapter 9, "Water Spray Protection.")

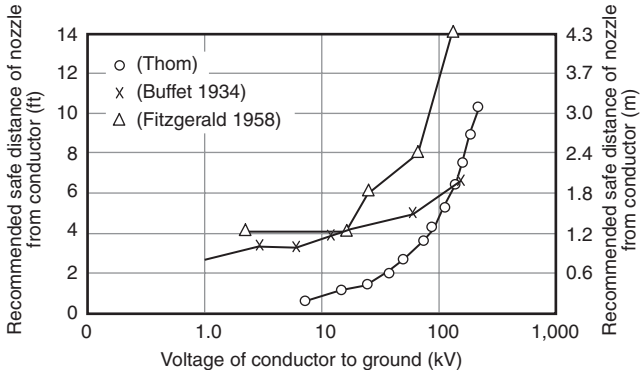

FIGURE 17.3.1 Variation of Safe Distance with Conductor Voltage for Spray Nozzles

TABLE 17.3.4 Clearance from Water Spray Equipment to Live Uninsulated Electrical Components

Nominal System Voltage (kV)	*Maximum System Voltage (kV)*	*Design BIL (kV)*	Minimum* Clearance	
			in.	*mm*
To 13.8	14.5	110	7	178
23.0	24.3	150	10	254
34.5	36.5	200	13	330
46.0	48.3	250	17	432
69.0	72.5	350	25	635
115.0	121.0	550	42	1067
138.0	145.0	650	50	1270
161.0	169.0	750	58	1473
230.0	242.0	900	76	1930
		1050	84	2134
345.0	362.0	1050	84	2134
		1300	104	2642
500.0	550.0	1500	124	3150
		1800	144	3658
765.0	800.0	2050	167	4242

Note: BIL values are expressed as kilovolts (kV), the number being the crest value of the full wave impulse test that the electrical equipment is designed to withstand. For BIL values that are not listed in the table, clearances can be found by interpolation.

*For voltages up to 161 kV, the clearances are taken from NFPA 70, *National Electrical Code.* For voltages 230 kV and above, the clearances are taken from Table 124 of ANSI C2, *National Electric Safety Code.*

Portable Extinguishers and Hazard of Shock

Water-based or water-solution portable fire extinguishers are not recommended for use on live electrical equipment, that is, Class C fires. NFPA 10, *Standard for Portable Fire Extinguishers,* recommends that extinguishers specifically tested for use on Class C fires be used for such fires. When electrical equipment is de-energized, water-based extinguishing agents and extinguishers for Class A or B fires may be used safely. Conductivity tests of portable fire extinguishers containing water indicate that soda-acid (now discontinued), loaded-stream (now discontinued), foam, and antifreeze solution extinguishers, all of which produce solid streams and have a short range, are particularly hazardous. One test involving an antifreeze solution extinguisher

showed a current of 157 mA for a potential of 1 kV with a 3/32 in. (2.4 mm) stream at a distance of 1 ft (0.3 m). To reduce the current to below 1 mA, it would be necessary to use the device from a distance at which the stream is dispersed; it is generally agreed that for such extinguishers the minimum distance should be 4 ft (1.2 m) for voltages up to 1 kV. Extinguishers containing plain water might, in theory, be used at shorter distances, but it is best to maintain a 4 ft (1.2 m) distance if it is necessary to use this kind of extinguisher.

Water on Electrical, Electronic, and Computer Equipment

Automatic sprinkler protection and water spray fixed systems are valuable for fire control, even where electrical, electronic, or computer equipment may be present. There should be little concern about the possibility of shock or of the water causing excessive damage to the equipment. Experience has proved that, if a fire activates sprinklers, the sprinklers, if properly installed and maintained, provide effective protection, with regard to electrical shock, with no measurable increase in damage to the equipment, as compared with the damage done by heat, flame, smoke, and the manual hose streams.[28]

NFPA 75, *Standard for the Protection of Information Technology Equipment,* recognizes the importance of automatic sprinkler protection in computer rooms. It recommends that, where sprinklers are installed to protect electronic computer equipment, the power to the equipment should be disconnected prior to the application of water.

WATER AND COMBUSTIBLE METALS—CLASS D FIRES

The reaction between water and combustible metals ranges widely from minor reactions to an explosive reaction. In some instances, water can be used to overcome some adverse chemical reactions if a large quantity is applied. As a rule, water should not be used on fires involving combustible metals, for example, magnesium, titanium, metallic sodium, and hafnium, or on metals that are combustible under certain conditions, for example, calcium, zinc, and aluminum. However, water can be utilized to protect exposures as a cooling agent. NFPA 484, *Standard for Combustible Metals*, specifies when sprinklers may and may not be used when magnesium is present.

USE OF WATER ON SPECIAL HAZARDS

Although water is generally a universal extinguishing agent, there are certain prohibitions and precautions that must be observed when it is applied manually on some burning materials that either react chemically or explosively on contact with water. In other instances, the mechanical action of applying water must be carefully monitored to avoid creating conditions that intensify the hazard rather than controlling it.

The following paragraphs give guidance on using water on different materials that can present problems if water is used arbitrarily as an extinguishing agent. See Section 6, "Characteristics of Materials and Products," for specific information on chemicals and gases.

Chemical Hazards

As a general rule, water should not be used on materials that react with water and may release oxygen, flammable gases, and heat. Examples include alkalies, anhydrides, carbides, hydrides, nitrates, and peroxides (organic and inorganic) to list a few. When wet, certain materials, such as unslaked lime, will heat spontaneously over a period of time if heat cannot be dissipated due to storage conditions.

Radioactive Metals

Water should not be used continuously on radioactive metals. The requirements for fire protection for radioactive metals are generally consistent with their nonradioactive counterparts (for all practical purposes, radioactivity does not influence, nor is it influenced by, the fire properties of a metal). Control of contaminated runoff water is a complicating factor in using water on radioactive metals.

Flammable Gases

In gas-fire emergencies, water is generally used for the control of heat from the fire while efforts are made to shut off, or stop, the flow of escaping gas. Water in the form of spray applied from hose lines or monitor nozzles, or by fixed water spray systems, is commonly used for dispersement or dilution of concentrations of flammable gases.

WATER ADDITIVES FOR SPECIALIZED USES

Freezing Temperatures and Antifreeze Additives

Because water freezes at 32°F (0°C), its use as an extinguishing agent is limited in climates or situations where freezing temperatures are encountered. There are several methods commonly used to prevent problems of freezing. These include using dry-pipe sprinkler systems instead of wet-pipe systems, circulation or heating tank water supplies held for fire protection purposes, adding freezing-point depressants to the water, or a combination of these.

The water-soluble freezing-point depressant most widely used in fire equipment is calcium chloride with a corrosion-inhibitor additive. Calcium chloride solutions are not used when fire protection systems are supplied by public water connections. Sodium chloride (common salt) is unsatisfactory because of its limited ability to depress the freezing point of water and its highly corrosive attribute.

Antifreeze Additives for Sprinkler Systems

Chemically pure glycerine (U.S. Pharmacopoeia 96.5 percent grade) or pure propylene glycol can be used to depress the

freezing point of water in portions of water suppression systems connected to public water supplies, if authorized by local health or water authorities. Diethylene glycol, ethylene glycol, or calcium chloride, as well as glycerine or propylene glycol, can be used for the same purposes where public water is not connected to the system. Both ethylene and diethylene glycol are poisonous and cannot be permitted to contaminate drinking water.

Antifreeze Additives for Water-Type Extinguishers

Alkali-metal salt solutions provide protection against freezing temperatures as low as –40°F (–40°C). Only the antifreeze solutions specified by the manufacturers should be used. Glycol solutions should not be used in extinguishers because the amount required to protect against freezing would be high; a 52.5 percent solution of ethylene glycol would be needed to depress the freezing point to –40°F (–40°C). Such amounts will alter the effectiveness of the extinguisher and may also lead to complications if the water should "boil off" and leave a strong concentration of the glycol, which, under certain conditions, could be ignited.

Efforts have been made to develop other additives that can be mixed with water to lower the freezing point to –65°F (–54°C). This work has been largely stimulated by increased activity in extremely low-temperature areas, with most of the research being done by the U.S. armed forces. To date, formulas of lithium chloride, lithium chloride–calcium chloride, and lithium chloride–anhydrous sodium chromate have been used successfully. No commercial use of these solutions is known; however, the U.S. Naval Research Laboratory has developed a lithium chloride solution for fire extinguishers exposed to low temperatures of –65°F (–54°C).

Additives to Modify Flow Characteristics

Friction loss in fire hose is always an obstacle for fire fighters. The longer the hose or the more water pumped through it, the greater the pressure loss. With a smooth fire hose lining, most of the pressure loss is the result of friction between particles of water generated by the turbulence in the flowing stream. When flow is either smooth or laminar, the friction loss tends to be very low with a slow stream of water. However, the amount of water delivered under laminar flow is generally too low for fire fighting. Fire fighting requires high-velocity streams that generate turbulence, which, in turn, results in friction between water particles. This friction accounts for about 90 percent of the pressure loss in fire hose. The friction between the flowing water and the interior hose wall accounts for only 5 to 10 percent of the loss.

Until 1948 it was generally believed that not much could be done to reduce friction loss. At the time, trace quantities of certain polymers were found to reduce friction loss of turbulent streams. Most researchers report that linear polymers (i.e., polymers that form a single straight-line chemical chain with no branches) are the most effective in reducing turbulent frictional losses. Of these, the poly-chain (polyethylene oxide) is the most effective. Friction-reducing efficiency is a direct function of polymer linearity.

Poly-chain synthetics are nontoxic, have no effects on plants or marine life, and will degrade in sunlight. A poly-chain synthetic is a long linear chain, high-molecular-weight polymer, and is two to three times more effective as a friction-reduction agent than other materials tested to date. It is an odorless, opaque, white slurry that weighs 9.1 lb per gal (1.1 kg/L) and must be kept within 0 to 120°F (–17 to 49°C). When it is injected into the hose stream, it dissolves completely and does not separate. It is compatible with all fire-fighting equipment and is useful in both fresh and salt water. One gallon (2.6 L) of additive treats 6000 gal (22,710 L) of water and achieves at least a 40 percent greater water delivery.

Tests conducted by the New York City Fire Department and Union Carbide Corporation found that a 1½ in. (38 mm) hose with an additive delivered 250 gpm (946 L/min), or as much as a 2½ in. (64 mm) hose without the additive. With the additive, a 2½ in. (64 mm) hose was able to deliver more water than a 3 in. (76 mm) hose, and nearly as much water as a 3½ in. (89 mm) hose. These tests also showed that the additive nearly doubled the nozzle pressure. The stream's reach was increased by nearly 30 percent, and the stream was more coherent.

The author is unaware of any fire departments that are currently using these additives. Certainly, they are not in widespread use.

Additives to Increase Water's Viscosity

The relatively low viscosity of water makes it tend to run off solid fuel surfaces quickly and limits the ability to blanket a fire by forming a barrier at the surface. Additives make the use of water more effective on certain types of fires. Most applications of viscous water have been directed at fighting forest fires.

Viscous water has had several thickening agents added to it. In proper proportions, viscous water has the following advantages over nontreated water: ability to cling and adhere to the fuel surface; provide a continuous coating over the fuel surface; provide a layer thicker than water; absorb heat proportional to the amount of water present; project farther when discharged from a nozzle; and resist movement due to wind and air currents.

Viscous water has the following disadvantages over water: it does not penetrate the fuel as well as water, it creates a higher friction loss in fire hose or piping, increases the water droplet size, makes surfaces slippery and difficult to walk on, and requires mixing prior to use.

The author is unaware of any systems currently using this additive. Certainly, they are not in widespread use.

CARE IN USE OF WATER AS AN EXTINGUISHING AGENT

There are numerous factors that must be considered before using water as an extinguishing agent, as this chapter has already discussed. It must be considered if the use of water will cause the fire to grow or spread, whether there will be a chemical reaction causing harm, or if live electrical equipment can endanger personnel.

Fire fighters must also consider water runoff when using water-based fire extinguishing agents. Water can carry pollut-

ants from a fire to a water supply or cause groundwater contamination. When using water to extinguish hazardous materials fires, such as pesticides and flammable liquids, some of the fuel will be carried off by the water vapor (steam), some of the water may be absorbed by the fuel, and some fuel may be carried by the runoff water.

SUMMARY

Water is the most widely used extinguishing agent because it is readily available and because of its ability to cool, to remove and displace the oxygen supply, and to separate/displace the fuel source. Although water is highly effective on Class A fuels, it is not usually the agent of choice on Class B, C, D, or K fires.

Several additives are available to improve water's performance. The most common are Class A and B foams, and an emerging class of additives collectively known as water additives for fire control and vapor mitigation.

Care must be exercised before using water on fires involving energized electrical apparatus, hazardous materials (including flammable and combustible liquids), and combustible metal fires. The effect of contaminated runoff on the environment should always be considered.

alcohol-type foaming agent, aqueous film-forming foam, chemical foam, crash-rescue vehicle, film-forming fluoroprotein (FFFP) agent, fire-fighting foam, foam extinguishing agent, high-expansion foaming agent, low-temperature foaming agent, protein foaming agent

Fire-fighting foams are used in fixed and portable fire extinguishing systems. They are used primarily to combat flammable and combustible liquid fuel fires. Aqueous foam solutions, created using foam concentrate mixed with water, are expanded with air to create foam. Foam is used to suppress liquid fuel vapors and cool the liquid surface. There are many NFPA standards and guidelines that address foam application for tank/dike protection, aviation spill hazards, aircraft hangar protection, and liquid warehousing applications.

Foams vary in terms of their chemical makeup, which affects the required rate of application and appropriateness for use on particular liquid fuel hazards. For example, protection of polar solvent hazards requires specially formulated alcohol-type concentrate (AR). High-expansion foams can, in some cases, be used to protect both Class A and Class B fire hazards; they are particularly suited as a flooding agent for large spaces. Foams may be tailored for combined use with dry chemical agents. This provides for both two-dimensional pool and three-dimensional spilling fuel fire scenarios.

Foam is generated by proportioning foam concentrate with water. Various fixed and portable proportioning devices are used. Discharge devices include nozzles, foam monitors, and sprinklers. Tank protection requires special nozzle and distribution systems. Specialized foam fire-fighting vehicles are described.

For related topics, see Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 13, Chapter 7, "Aircraft Rescue and Fire Fighting (ARFF)"; and Section 16, Chapter 1, "Principles of Automatic Sprinkler System Performance."

USES AND LIMITATIONS OF FIRE-FIGHTING FOAMS

Low-expansion foam is used principally to extinguish burning flammable or combustible liquid spill or tank fires by application to develop a cooling, coherent blanket. Foam is the only permanent extinguishing agent used for fires of this type. Its application allows fire fighters to extinguish fires progressively. A foam blanket covering a tank's liquid surface can prevent vapor transmission for some time, depending on the stability and depth of the foam. Fuel spills are quickly rendered safe by foam blanketing. The blanket may be removed after a suitable period of time; typically it has no detrimental effect on the product with which it comes into contact.

Foams can be used to diminish or halt the generation of flammable vapors from nonburning liquids or solids and may be used to fill cavities or enclosures where toxic or flammable gases may collect.

Foam is of great importance where aircrafts are fueled and operated. Sudden, large fuel spills resulting from aircraft accidents or malfunction require rapid foam application. Hangar fire protection is best accomplished by properly designed foam systems.

Increasingly, warehouses and buildings storing large quantities of combustible and flammable liquids are protected by foam-water sprinkler systems. The protection required is a function of the

Joseph L. Scheffey, P.E., is director of fire protection research and development at Hughes Associates, Inc., in Baltimore, Maryland.

type and quantity of liquid stored, building height, and storage configuration.

Foams of the medium- or high-expansion type (20 to 1000 times) may be used to fill enclosures such as basement room areas or holds of ships where fires are difficult or impossible to reach. Here foams act to halt convection and access to air for combustion. Their water content also cools and diminishes oxygen by steam displacement. Foams of this type (with expansion ratios of 400 to 500) may be used to control liquefied natural gas (LNG) spill fires and help disperse the resulting vapor cloud.

Many foams are generated from solutions with very low surface tension and penetration characteristics. Foams of this type are useful where Class A combustible materials are present. In such instances, the water solution draining from the foam cools and wets the solid combustible.

Foam breaks down and vaporizes its water content under attack by heat and flame. It therefore must be applied to a burning liquid surface in sufficient volume and rate to compensate for this loss, with an additional amount applied to guarantee a residual foam layer over the extinguished liquid. Foam is unstable and may be broken down easily by a physical or mechanical force, such as a water hose stream. Certain chemical vapors or fluids may also destroy foam quickly. When certain other extinguishing agents are used in conjunction with foam, severe breakdown of the foam may occur. Turbulent air or violently uprising combustion gases from fires may divert foam from the burning area.

The mechanisms of foam fire extinguishment on two-dimensional hydrocarbon fuel fires have not been fully developed. Recent theoretical and preliminary experimental work has attempted to correlate foam extinguishment with fundamental fluid spread mechanisms. More research is required to develop foam suppression theory.

Foam solutions are conductive and therefore not recommended for use on electrical fires. If foam is used, a spray is less conductive than a straight stream. However, because foam is cohesive and contains materials that allow water to conduct electricity, foam spray is more conductive than water spray.

Engineering design requirements and recommended application methods must be followed for successful use of foams. These requirements can be found in NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam;* NFPA 16, *Standard for the Installation of Foam-Water Sprinkler and Foam-Water Spray Systems*; and NFPA 403, *Standard for Aircraft Rescue and Fire-Fighting Services at Airports*. Additionally, NFPA codes and standards, such as NFPA 30, *Flammable and Combustible Liquids Code*, and NFPA 409, *Standard on Aircraft Hangars*, provide application rate and installation details on special hazard systems.

In general, the following criteria for the hazardous liquid must be met for a foam to be fully effective:

1. The liquid must be below its boiling point at the ambient conditions of temperature and pressure.
2. Care must be taken in application of foam to liquids with a bulk temperature higher than 212°F (100°C). At these fuel temperatures and above, foam forms an emulsion of steam, air, and fuel. This may produce a fourfold increase in volume when applied to a tank fire, with dangerous frothing or slopover of the burning liquid.
3. The liquid must not be unduly destructive to the foam used, or the foam must not be highly soluble in the liquid to be protected.
4. The liquid must not be water reactive.
5. The fire must be a horizontal surface fire. Three-dimensional (falling fuel) or pressure fires cannot be extinguished by foam unless the hazard has a relatively high flashpoint and can be cooled to extinguishment by the water in the foam.

TYPES OF FOAM

A number of types of foaming agents are available, known as foam concentrates, some of which are designed for specific applications. Some are suitable for extinguishing all types of flammable liquids, including water-soluble and foam-destructive liquids. Descriptions of the common types of foam follow.

Aqueous Film-Forming Foam Agents (AFFF)

Aqueous film-forming foam agents are composed of synthetically produced materials that form air-foams similar to those produced by the protein-based materials. In addition, these foaming agents are capable of forming water solution films on the surface of flammable hydrocarbon liquids, hence the term *aqueous film-forming foam* (*AFFF*). AFFF concentrates are available for proportioning to a final concentration of 1 percent, 3 percent, or 6 percent by volume, with either fresh water or seawater.

The air-foams generated from AFFF solutions possess low viscosity, have fast spreading and leveling characteristics, and, like other foams, act as surface barriers to exclude air and halt fuel vaporization. These foams also develop a continuous aqueous layer of solution under the foam, maintaining a floating film on hydrocarbon fuel surfaces to help suppress combustible vapors and cool the fuel substrate. This film, which can also spread over fuel surfaces not fully covered with foam, is self-healing following mechanical disruption and continues to spread as long as there remains a reservoir of nearby foam. Film effectiveness may be reduced on hot surfaces and aromatic hydrocarbons. To ensure fire extinction, an AFFF blanket should cover the fuel surface entirely, as with other types of foam.

AFFF fluidity and film strength on kerosene makes it particularly suitable for jet aircraft fuel spill fire fighting.

AFFF concentrates contain fluorinated, long-chain synthetic hydrocarbons with particular surface-active properties.

Because of the extremely low surface tension of the solutions draining from AFFF, these foams may be useful under mixed-class fire situations (Classes A and B), where deep penetration of water is needed in addition to the surface-spreading action of foam itself.

Foam-generating devices yielding stable, homogeneous foams are not necessarily needed in the employment of AFFF. Less sophisticated foaming devices, such as water spray nozzles and sprinklers (unlike with most other foaming agents), may be used because of the inherent rapid and easy foaming capability of AFFF solutions. However, such foams drain relatively rapidly, and they may provide less burnback resistance com-

pared to protein-based foams. AFFF also may be used, without compatibility problems, in conjunction with dry chemical agents. Although AFFF concentrates must not be mixed with other types of foam concentrates, foams made from them do not break down other types of foams in fire-fighting operations. The normal-use temperature range for these agents is 35 to 120°F (1.7 to 49°C).

Fluoroprotein (FP) Foaming Agents

The concentrates used for generating fluoroprotein foams are similar in composition to protein foam concentrates, but, in addition to protein polymers, they contain fluorinated surface active agents that confer a "fuel shedding" property to the foam generated. This makes them particularly effective for fire-fighting conditions where the foam becomes coated with fuel, such as in the method of subsurface injection of foam for tank fire fighting, and nozzle or monitor foam applications where the foam may often be plunged into the fuel. Fluoroprotein foams are very effective for in-depth crude petroleum or other hydrocarbon fuel fires because of this fuel shedding property. In addition, these foams demonstrate better compatibility with dry chemical agents than do the regular protein-type foams. They also possess superior vapor securing and burnback resistance characteristics. Fluoroprotein-type concentrates are available for proportioning to a final concentration of either 3 percent or 6 percent by volume, using either fresh water or seawater. They are nontoxic and biodegradable after dilution. The normal-use temperature range for these agents is 20 to 120°F (–7 to 49°C).

Film-Forming Fluoroprotein (FFFP) Agents

Film-forming fluoroprotein (FFFP) agents are composed of protein together with film-forming fluorinated surface-active agents, which make them capable of forming water solution films on the surface of most flammable hydrocarbons and conferring a fuel-shedding property to the foam generated.

Air-foams generated from FFFP solutions have fast-spreading and leveling characteristics and, just as other foams, act as surface barriers to exclude air and prevent vaporization. Like AFFF, they generate a self-healing, continuous floating film on hydrocarbon fuel surfaces that helps suppress combustible vapors. However, to ensure fire extinction, an FFFP blanket, as with other types of foam, should cover the entire fuel surface.

Because of the rapid and easy foaming capability of FFFP solutions, water spray devices may be used in many situations. However, the foams produced drain rapidly and may have less burnback resistance compared to protein-based foams.

Film-forming fluoroprotein-type concentrates are available for proportioning to a final concentration of either 3 or 6 percent by volume, using either freshwater or seawater. They may be used in conjunction with dry chemical agents without compatibility problems.

Protein (P) Foaming Agents

Protein-type air-foams use aqueous liquid concentrates proportioned with water for their generation. These concentrates contain high-molecular-weight natural proteinaceous polymers derived from a chemical digestion and hydrolysis of natural protein solids. The polymers give elasticity, mechanical strength, and water retention capability to foams generated from them. The concentrates also contain dissolved polyvalent metallic salts, which aid the protein polymers in their bubble-strengthening capability when the foam is exposed to heat and flame. Protein-type concentrates are available for proportioning to a final concentration of either 3 or 6 percent by volume, using either freshwater or seawater. In general, these concentrates produce dense, viscous foams of high stability, high heat resistance, and good resistance to burnback, but they are less resistant to breakdown by fuel saturation than are AFFF and fluoroprotein foams. They are nontoxic and biodegradable after dilution. The normal-use ambient temperature range for these concentrates is 20 to 120°F (–7 to 49°C).

Low-Temperature Foaming Agents

This type of foam concentrate is protected for storage and use at low temperature by the inclusion of freezing-point depressants. Low-temperature foaming agents may be used at ambient temperatures as low as –20°F (–29°C). They are available for use at either 3 or 6 percent by volume concentration in either freshwater or seawater, and may be of the AFFF or protein-based type.

Alcohol-Type Foaming Agents (AR)

Air-foams generated from ordinary agents are subject to rapid breakdown and loss of effectiveness when they are used on fires that involve fuels that are water soluble, water miscible, or of a "polar solvent" type. Examples of this type of fuel are alcohols, enamel and lacquer thinners, methyl ethyl ketone, acetone, isopropyl ether, acrylonitrile, ethyl and butyl acetate, and the amines and anhydrides. Even small amounts of these substances mixed with common hydrocarbon fuels, such as gasohol, may cause rapid breakdown of ordinary fire-fighting foams.

Therefore, certain special foaming agents, called alcohol-type concentrates, have been developed. These alcohol-resistant (AR) concentrates are proprietary compositions of several types, some containing a protein, fluoroprotein, or an aqueous film-forming foam concentrate base. The most common are usually described as polymeric alcohol-resistant AFFF concentrates which produce foams suitable for application to spill or in-depth fires of either hydrocarbon or water-miscible flammable liquids by any foam-generating device. They exhibit AFFF characteristics on hydrocarbons and produce a floating gel-like mass for foam buildup on water-miscible fuels. Agents of this type have no transit time limitations. Normal-use temperatures for any of the alcohol-type agents are 35 to 120°F (1.7 to 49°C).

Medium- and High-Expansion Foaming Agents

Medium- and high-expansion foams are agents for control and extinguishment of Class A and some Class B fires, and are particularly suited as a flooding agent for use in confined spaces. The foam is an aggregation of bubbles, mechanically generated by aspiration or a blower-fan, which forces air or some other gas through a net or screen that is wetted by an aqueous solution of

surface-active foaming agents. Under proper conditions, fire-fighting foams of expansions from 20:1 up to 1000:1 can be generated.

Medium- or high-expansion foam is a unique vehicle for transporting wet foam masses to inaccessible places, for total flooding of confined spaces, and for volumetric displacement of vapor, heat, and smoke. Tests have shown that when used under certain circumstances in conjunction with water from automatic sprinklers, the foam will provide more positive control and extinguishment than either extinguishing agent by itself. Optimum efficiency in any one type of hazard is dependent on the rate of application and the foam expansion and stability.

Liquid concentrates for producing medium- and high-expansion foams consist of synthetic hydrocarbon surfactants of a type that will foam copiously with a small input of turbulent action. They are generally used in approximately 2 percent proportion in water solution. Medium-expansion foam may also be generated from solutions of fluoroprotein, protein, or AFFF concentrates at 3 or 6 percent proportion.

Medium- or high-expansion foams are particularly suited for indoor fires in confined spaces. Their use outdoors may be limited because of the effects of weather. These foams have several effects on fires:

1. When generated in sufficient volume, they can prevent the air necessary for continued combustion from reaching the fire.
2. When forced into the heat of a fire, the water in the foam is converted to steam, which reduces the oxygen concentration by diluting the air.
3. The conversion of the water to steam absorbs heat from the burning fuel. Any hot object exposed to the foam will continue breaking down the foam, converting the water to steam, and being further cooled.
4. Because of its relatively low surface tension, foam solution not converted to steam will tend to penetrate Class A materials. However, deep-seated fires may require overhaul.
5. When accumulated in depth, high-expansion foam can provide an insulating barrier for protection of exposed materials or structures not involved in a fire, thereby preventing fire spread.

Research has shown that using air from inside a burning building to generate high-expansion foam has an adverse effect on the volume and stability of the foam produced. Combustion and pyrolysis products, when they react chemically with the foaming agent, can reduce the volume of foam produced and increase the drainage rate. The high temperature of the air breaks down the foam as it is generated. Physical disruption also takes place, apparently caused by vapor and solid particles from the combustion process. These factors that cause foam breakdown may be compensated for by higher rates of foam generation.

Entry to a foam-filled passage must not be attempted without use of self-contained breathing apparatus. The foam mass also reduces vision and hearing, and lifelines must be used for personnel entering the foam.

Foam of approximately 500:1 expansion can be successfully used for control of fires and reduction of vaporization from LNG spills. As water slowly drains from the foam in small amounts, it forms a thin ice layer which floats on the LNG and supports the high-expansion foam blanket. Fixed and portable high-expansion foam facilities of this type have been provided for LNG storage and manufacturing plants.

Other Synthetic Hydrocarbon Surfactant Foaming Agents

There are many synthetically produced surface active compounds that foam copiously in water solution. When these are formulated properly, they may be used as wetting agents or as fire-fighting foams and employed in much the same manner as other types of foam (see NFPA 18, *Standard on Wetting Agents*).

Hydrocarbon surfactant foam liquid concentrates are employed in 1 to 6 percent proportions in water. When these solutions are used in conventional foam-making devices, the resulting air-foam possesses low viscosity and spreads quickly over liquid surfaces. Its fire-fighting characteristics depend on (1) the volume of the foam layer on the burning surface, which halts access to air and controls combustible vapor production; and (2) the minor cooling effect of the water in the foam, which becomes available due to a relatively rapid breakdown of the foam mass. This water solution does not possess film-forming characteristics on the flammable liquid surface although, under some conditions, it may produce a temporary water emulsion due to its wetting agent or "detergent-type" properties. Because of the low surface tension and wetting properties of the water solutions of these foams, they also may be used as extinguishing agents for Class A fires, although they were primarily developed with medium- or high-expansion foam in mind.

Synthetic hydrocarbon surfactant foams are generally less stable than other fire-fighting foams. Their water solution content drains away rapidly, leaving a bubble mass which is highly vulnerable to fuel heat or mechanical disruption. Usually these foams must be applied at higher rates than other fire-fighting foams to achieve extinction. Many formulations of this type of foam concentrate break down other foams if used simultaneously or sequentially.

Caution should be used when using wetting agents described in NFPA 18 for Class B situations. The test criteria used to classify the wetting agent for use on Class B fires may be significantly different than that used to classify AFFF, fluoroprotein, and protein foams. Fire suppression of Class A, B, and D fires using wetting agents is the subject of ongoing investigation.

Foams for Vapor Suppression

Fire-fighting foams may be used to suppress vapors from unignited flammable liquids for which the foams are proven extinguishing agents. To ensure good vapor suppression, the foam must be applied gently, so as to not mix fuel with the foam, and must cover the entire fuel surface. Care should be taken not to agitate the fuel during foam application, because static spark ignition of volatile hydrocarbons can result from plunging and turbulence from a foam or water stream.

There are flammable, toxic, or otherwise hazardous liquids on which fire-fighting foams are unstable and are therefore

unsuitable for use either for fire fighting or vapor suppression. Special vapor-mitigating foams have been developed that are relatively stable on many hazardous liquids; one type is an alcohol-resistant fire-fighting foam of the low-expansion type, which can be additionally stabilized to enhance its effective foam life and stability on toxic, flammable, or corrosive liquids. Other types are medium-expansion foams especially formulated to be stable on either acidic or alkaline hazards. These medium-expansion foams are not effective fire-fighting foams.

In general, vapor-mitigating foams should be applied to spills of toxic liquids only by trained personnel wearing suitable protective gear. These foams require special engineering consideration, and, to date, no standards have been developed for their use. The manufacturers should be consulted for use, limitations, and application data.

Chemical Foam Agents and Powders

These foam-producing materials have become obsolete because of the superior economics and ease of handling of the liquid foam-forming concentrates previously discussed. Chemical foam is formed from the chemical reaction in aqueous solution between aluminum sulfate ("A," acidic) and sodium bicarbonate ("B," basic) which also contains proteinaceous foam stabilizers. Foam is formed by the generation of carbon dioxide gas trapped in the bubbles of the foaming solution.

GUIDELINES FOR FIRE PROTECTION WITH FOAMS

The following general rules apply to the application and use of ordinary air-foams:

1. The more gently the foam is applied, the more rapid the extinguishment and the lower the total amount of agent required.

2. Successful use of foam is also dependent on the rate at which it is applied. Application rates are described in terms of the amount by volume of foam solution reaching the fuel surface (in terms of total area) every minute. If the foam has an expansion rate of 8:1, an application rate of 0.1 gpm/ft^2 (4.1 Lpm/m^2) will provide 0.8 gal/ft^2 (32.8 L/m^2) of finished foam every minute. Increasing the foam application rate over the recommended minimum will generally reduce the time required for extinguishment. However, little time advantage is gained if application rates are increased more than three times the minimum recommended. If application rates are less than the minimum, extinguishment time will be prolonged or may not be accomplished at all. If application rates are so low that the rate of foam loss by heat or fuel attack equals or exceeds the rate of foam application, the fire will not be controlled or extinguished.

3. The minimum recommended application rate is the rate found by test to be the most practical in terms of speed of control and amount of agent required. The general curve in Figure 17.4.1 illustrates the rate-time relationship for foam application to a hazard. The curve may be displaced right or left depending on fuel, method of application, and type of foam concentrate; hence, the need for carefully engineered systems based on the appropriate standard and actual test information.

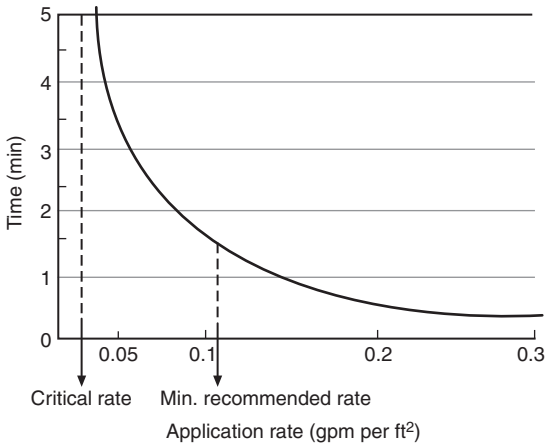

FIGURE 17.4.1 General Relationship of Foam Application Rate to Time of Application Necessary for Extinction (1.0 gpm/ft^2 equals 40.7 Lpm/m^2)

4. In general, air-foams will be more stable when they are generated with water at ambient temperature. Preferred water temperatures range from 35 to 80°F (1.7 to 27°C). Either freshwater or seawater may be used. Water containing known foam contaminants, such as detergents, oil residues, or certain corrosion inhibitors, may adversely affect foam quality.

5. Foams are adversely affected by air containing certain combustion products. Although the effect is minor with ordinary air-foam and ordinary hydrocarbon fuels, it is desirable to locate fixed foam-makers on the sides of, rather than directly over, the hazard.

6. Recommended pressure ranges should be observed for all foam-making devices. Foam quality will deteriorate if these limits (high and low) are exceeded.

7. Many air-foams are adversely affected by contact with vaporizing liquid extinguishing agents, their vapors, and by some dry chemical agents.

FOAM-GENERATING METHODS

The process of producing and applying fire-fighting air-foams to hazards requires three separate operations, each of which consumes energy. They are (1) the proportioning process, (2) the foam generation phase, and (3) the distribution method. A flow diagram illustrating the relationship of the three operations is given in Figure 17.4.2.

In general practice, air-foam generation and distribution occur nearly simultaneously within the same device. There are also many types of proportioning. In certain portable devices, all three functions are combined into a single device. The design and performance requirements of foam systems dictate the choice of types of proportioning, generating, and distributing equipment for the protection of specific hazards.

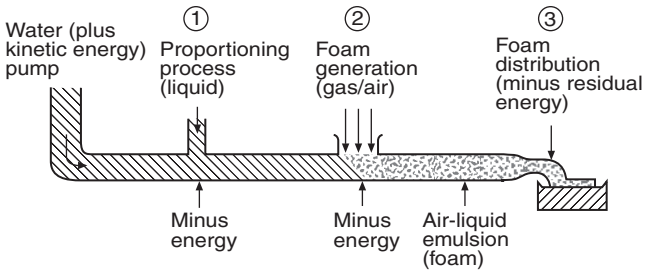

FIGURE 17.4.2 Steps in Air-Foam Generation

Foam Concentrate Proportioners

It is very important that foam concentrate be proportioned accurately into the water stream. Proportioning equipment, foam concentrate, and discharge equipment must be matched to produce the proper solution concentration at system design operating pressures. If proportioning is low, the foam will be relatively weak and unstable; if too high, the foam may be stiff and concentrate will be wasted, thus reducing effective system operating time.

So that a predetermined volume of liquid foam concentrate may be mixed with a water stream to form a foam solution of fixed concentration, the following two general methods are used:

1. Methods that use the pressure energy of the water stream by venturi action and orifices to induct concentrate
2. Methods that use external pumps or pressure heads to inject concentrate into the water stream at a fixed ratio to flow

Figures 17.4.3 and 17.4.4 illustrate the general principles of the two different proportioning methods. Figure 17.4.5 shows a section view of a proportioner. Specific system designs of proportioning equipment are given below.

The Nozzle Eductor. This type of foam concentrate proportioner is of simple design and is widely used in portable foam-making nozzles where foam concentrate is available in 5 gal (19 L) pails or drums as shown in Figure 17.4.6. Incorporating a modified venturi within the foam-making nozzle section, the nozzle eductor drafts concentrate from a portable container through a pickup tube. By using a properly sized orifice or pipe section at the low-pressure cavity, the concentrate is mixed in proper proportion to the fixed flow and operating pressure of the nozzle and foam generation proceeds.

In-Line Eductor. This type of proportioner educts or drafts foam concentrate from a container or tank by venturi action, using the operating pressure of the hose water stream on which it is installed, and injecting concentrate into that flow of water. Its correct operation is very sensitive to waterflow and pressure. Changes in either of these factors from those for which the eductor was designed will result in incorrect proportioning. Distances of more than 6 ft (1.8 m) elevation from the eductor to the lowest liquid level of the foam concentrate container also may result in incorrect proportioning. Foam-generation devices and

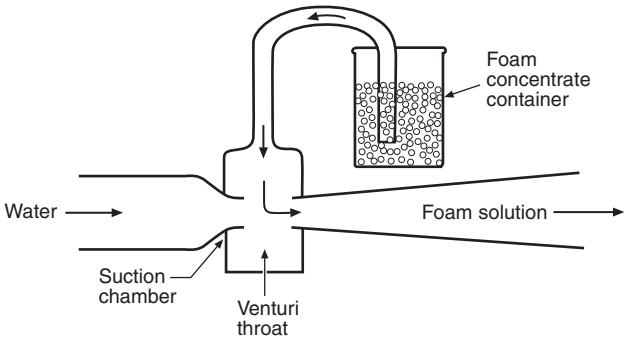

FIGURE 17.4.3 Venturi Induction (In-Line) Proportioner

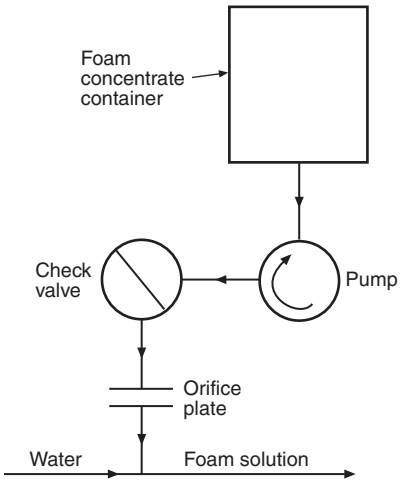

FIGURE 17.4.4 Foam Concentrate Pump Proportioner

FIGURE 17.4.6 Air-Foam Nozzle with Built-In Eductor

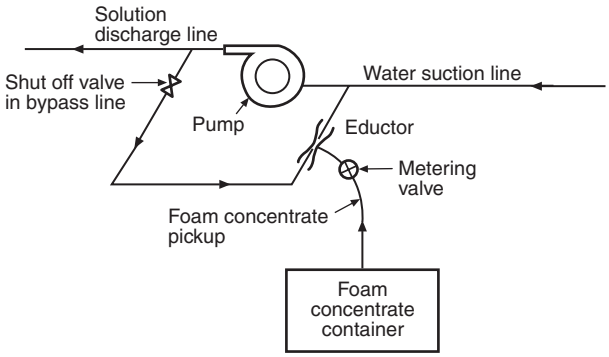

FIGURE 17.4.7 Around-the-Pump Proportioner

maximum downstream lengths of hose recommended for each eductor must be carefully adhered to. This proportioning device may be used in the hose line leading to the foam-generation device. An eductor of this type may also be installed at the foam concentrate tank in a fixed system or at the pump discharge of a mobile pumper.

Some designs of this proportioning device incorporate metering valves in the foam concentrate intake line so various volume percentages of concentrate in the water stream may be obtained. A check valve is usually placed in this intake so that water cannot flow back into the foam concentrate container if a blockage occurs or a valve is closed in the downstream hose. The use of this eductor requires an allowance for a pressure loss of approximately 30 percent in the system or layout.

Around-the-Pump Proportioner. This type of proportioner also operates on the venturi principle, except that this proportioner must be situated at the pump and connected to both suction and pressure sides. Its advantage is that pressure recovery of the venturi action is attained, and pump delivery pressures to the foam-making device or devices downstream require no compensation for pressure loss except for that in the layout hose length. The net delivery volume of the pump will be decreased by 10 to 40 gpm (38 to 150 Lpm) in this method of proportioning (Figure 17.4.7). The small portion of the pump discharge flows through a bypass line to the suction side of the pump. A venturi eductor in this line produces a negative pressure on the foam concentrate pickup line from the foam concentrate container. Foam concentrate is led to the eductor, where it mixes with water and is delivered to the suction side of the pump.

Multiple foam-makers may be supplied with foam solution by this type of proportioner when it is supplied with a multiported metering valve designed for the required flows.

Pressure Proportioning Tank. This type of proportioner may consist of one tank or of two tanks separately connected to the water and foam solution lines. The tank or tanks in the system may each be fitted with a flexible diaphragm or bladder to separate the "driving" water from foam concentrate. Tanks may rely simply on differences in density of the two liquids to retard mixing during operation (without diaphragm or bladder) when proportioning protein or fluoroprotein concentrate.

The principle of this device is simple. A small amount of the flowing water volumetrically displaces foam concentrate into the main water stream. The design pressure of the vessel must be above the maximum static water pressure encountered in the system.

Water is allowed to enter the foam tank from the main stream with as little friction loss as possible. An orifice meters liquid in the tank into the low-pressure area. Advantages of this system are its low-pressure drop, automatic proportioning over range of flows and pressures, and its freedom from external power. Its disadvantages are a long refill time (since it is a "batch" method, the tank must be drained of its driving water and the tank or the bladder refilled with concentrate) and an economic limit on size.

Coupled Water Motor-Pump Proportioner. This proportioner consists of two positive displacement rotary pumps mounted on a common shaft. Water delivered to the larger pump (motor) causes it to drive the smaller pump, which is used to draft concentrate from a container and deliver it (at line pressure) to the water discharge line from the larger pump. By proportioning the sizes of the two pumps, the correct volume of concentrate is delivered to the water stream.

This proportioner is manufactured in only two sizes for water throughputs of 60 to 180 gpm (227 to 680 Lpm) and 200 to 1000 gpm (757 to 3800 Lpm). Both sizes are designed for proportioning foam concentrates recommended for use at 6 percent concentration. A pressure drop of 25 to 30 percent in the water stream supplied to the device is required for its operation.

Balanced Pressure Proportioner. Foam proportioning into the water line supplying a foam suppression system can be accomplished by using a balanced pressure or positive-pressure injection-type proportioning system. These two methods provide the widest variations for operating flows, pressures, and operating ranges for systems having single and multiple supplies

to protected areas. Although these systems are widely used for fixed systems, they may also be used in mobile apparatus as shown in Figure 17.4.8. The following sections describe installations for fixed systems. Figure 17.4.9 shows a representative skid-mounted balanced pressure proportioner unit.

Balanced Pressure System Utilizing a Foam Concentrate Pump for a Single Injection Point. This method, illustrated in Figure 17.4.10, uses a separate pump for supplying foam concentrate that is delivered in the correct proportions into the flowing water. Foam concentrate to water percentage equals 1 percent (1:99), 3 percent (3:97), or 6 percent (4:96) for Class B foams protecting flammable liquids. Usually a modified venturi type proportioner that includes a fixed metering orifice is used at the injection point of foam concentrate into the water stream. A pressure-balancing valve senses the water and foam pressures entering the modified venturi during flowing conditions. The balancing valve maintains equal water and foam pressures entering the venturi device by sensing the water pressure and relieving the higher-pressure foam concentrate supply back to the foam tank reservoir. The foam pressure at the entry point to the metering orifice is maintained equal to the water pressure at all flowing conditions of the system. The modified venturi creates a low-pressure point. This metering pressure drop at the foam concentration entry point allows the concentrate to enter the water stream and mix as a solution, supplying the discharge devices in the protected area. As waterflow increases to system, the metering pressure drop increases, thereby maintaining proper proportions of foam concentrate to water.

Balanced Pressure System Using Diaphragm Bladder Tank for Single Injection Point. This simple system, illustrated in Figure 17.4.11, uses water power to operate. The system consists of a pressure vessel-type steel tank that includes a reinforced rubber bladder inside that is shaped to fit the inside geometry of the tank vessel. Foam concentrate is contained inside the bladder, and water is supplied to the outer shell of the bladder. As the water compresses the bladder, foam concentrate is forced out of the tank and supplied to the modified venturi proportioner and metering orifice in the same manner as used for the foam concentrate pump system described previously. As the waterflow increases through the venturi, a metering pressure loss is created. When this pressure loss reaches a point equal to the pressure loss in the supply and discharge piping of the foam concentrate tank, the proper foam concentrate flow will occur. This provides the proper solution mixture of foam water required to extinguish the fire at 1 percent (1:99), 3 percent (3:97), or 6 percent (6:94). The height of proportioner above the tank top must be considered in the friction loss calculations, as it will directly affect the foam concentrate percentage accuracy. This type of system proportions lean (lower foam concentrate than needed) below the approved or listed minimum flow rates. Consideration should be used before applying this system below these flow rates: the listed minimum flow rates should fall within the operating limits of the application. AFFF or nonviscous foam concentrates are generally acceptable considering the initial operation of the system discharge device. Most alcohol-resistant foam concentrates are very viscous and create much higher friction loss in foam concentrate piping. The higher friction loss results in a much higher minimum flow rate where the desired percentage of foam to water is developed. This is critical in closed sprinkler systems where initial operation of sprinklers will not result in enough flow to produce proper foam water so-

lution to extinguish a flammable liquid fire. In a deluge system, the proportioner should be sized to meet the desired hydraulic characteristics of the application.

Balanced Pressure System Using Positive Pressure Foam Injection and In-Line Balanced Pressure Proportioners (ILBP). Balanced pressure proportioning systems using positive-pressure foam injection and an ILBP device use two basic methods of foam concentrate supply (Figures 17.4.12, 17.4.13, 17.4.14, and 17.4.15). Foam concentrate can be supplied from a bladder tank or a foam concentrate pump as long as it is being supplied at a higher pressure than the water supply at the point of foam injection to the system.

In a bladder tank system, concentrate proportioning is accomplished by installing a pilot-operated pressure control valve (POPCV) upstream of the ILBP assembly (see Figures 17.4.12 and 17.4.13). The POPCV is adjusted to a lower outlet pressure differential that meets the required difference to operate the ILBP balancing valve (note: this differential is manufacturer dependent). The water supply to the bladder tank is taken upstream of the POPCV, which provides a higher outlet pressure of foam concentrate being supplied to the ILBP proportioner assembly (Figure 17.4.16). The ILBP balancing valve senses the water supply pressure entering the modified venturi proportioner device and lowers the foam concentrate pressure entering the metering orifice to that equal to the water pressure entering

the venturi proportioner. When the water pressure equals the foam concentrate pressure and the waterflow is such that the proper metering pressure drop is created across the venturi, the proper percentage of foam concentrate is injected into the water supply, thereby delivering the proper foam solution to the protected area.

Since this is a positive injection system, foam solution percentage will be rich (i.e., higher foam concentrate than needed) at lower flow rates. For example, this phenomemon will occur in a closed sprinkler system during the initial operation of several sprinklers. Also, the minimum listed flow rates for this type of system, compared to the balanced pressure bladder tank system, are typically much lower when alcohol-resistant foam concentrates are used.

In some installations, the total water supply pressure available is not adequate to create the proper pressure differential to allow the system to proportion within its operating limits. A foam concentrate pump can be used to supply the foam concentrate at a higher pressure than the water supply pressure at the point of foam injection to the system. Positive displacement foam pumps are generally used to supply the higher foam concentrate pressure. Accurate supply is maintained by using a pressure-relief-type valve in the foam supply line. The relief is piped back to the foam supply tank and is set to supply adequate pressure at the full range of system operating conditions (Figure 17.4.17).

A positive-pressure foam system using a bladder tank with POPCV or foam concentrate pump can supply multiple system proportioning points from a single foam supply source. Also, a longer distance from the foam concentrate supply is feasible. Large variations in system pressure are tolerable with the same accuracy of foam proportioning throughout the system. Multiple discharge devices and system sizes are adaptable to a single foam concentrate supply source.

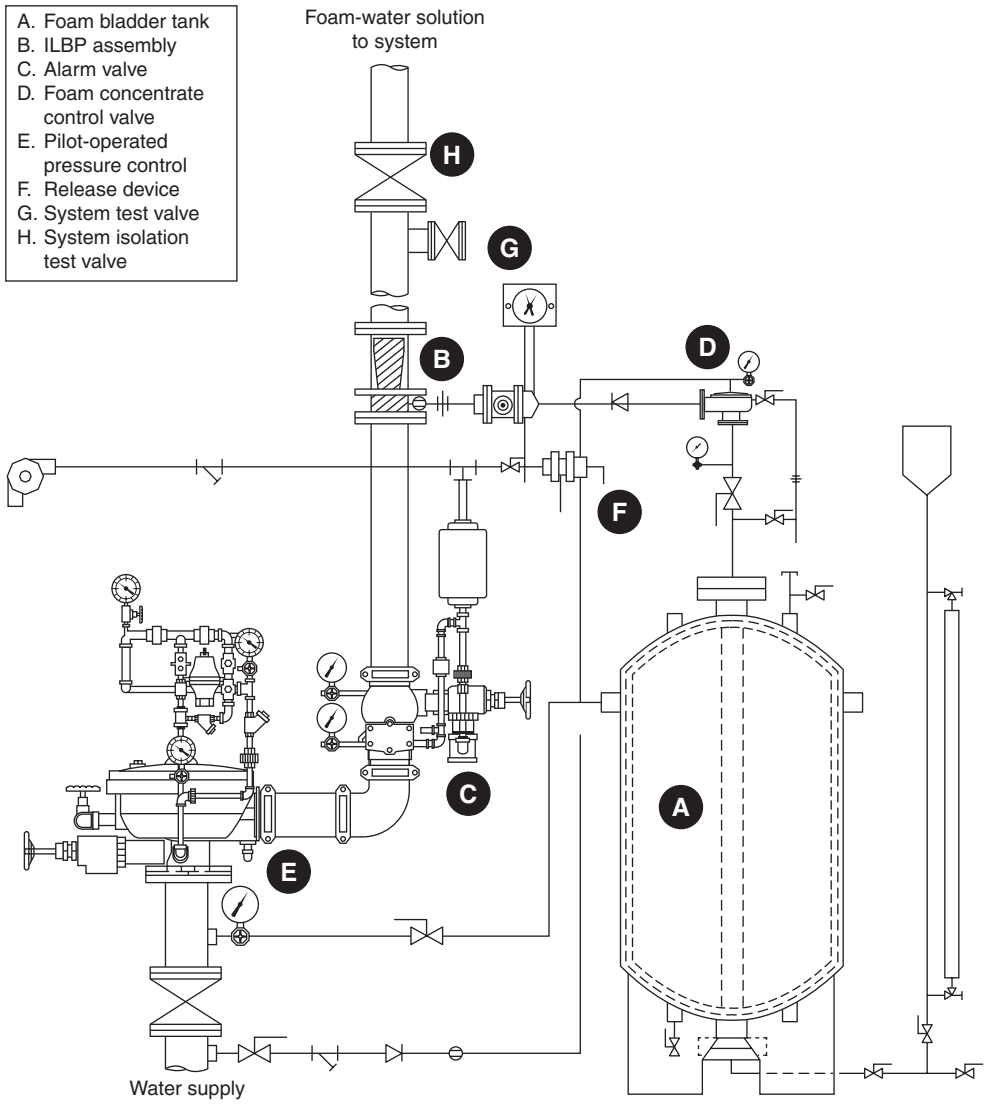

FIGURE 17.4.12 Wet Pipe Low-Flow Foam Proportioning System Bladder Tank Foam Supply (Source: The Viking Corp.)

Advantages and Disadvantages of Various Balanced Pressure Proportioning Systems. The different balanced pressure proportioning systems have advantages and disadvantages, depending on the particular design. The balanced pressure system with foam concentrate pump for single injection point has the following advantages and disadvantages:

Advantages

1. Foam concentrate can be pumped longer distances and the balancing valve can be kept adjacent to proportioner.
2. Foam supply can be replenished on the run by adding to the atmospheric tank.
3. The system will proportion at the correct percentage at lower flow rates due to less effect by friction loss.

Disadvantages

1. Maintenance and reliability requirements are relatively greater.
2. The cost is relatively high.
3. A backup power supply is required for electric systems.

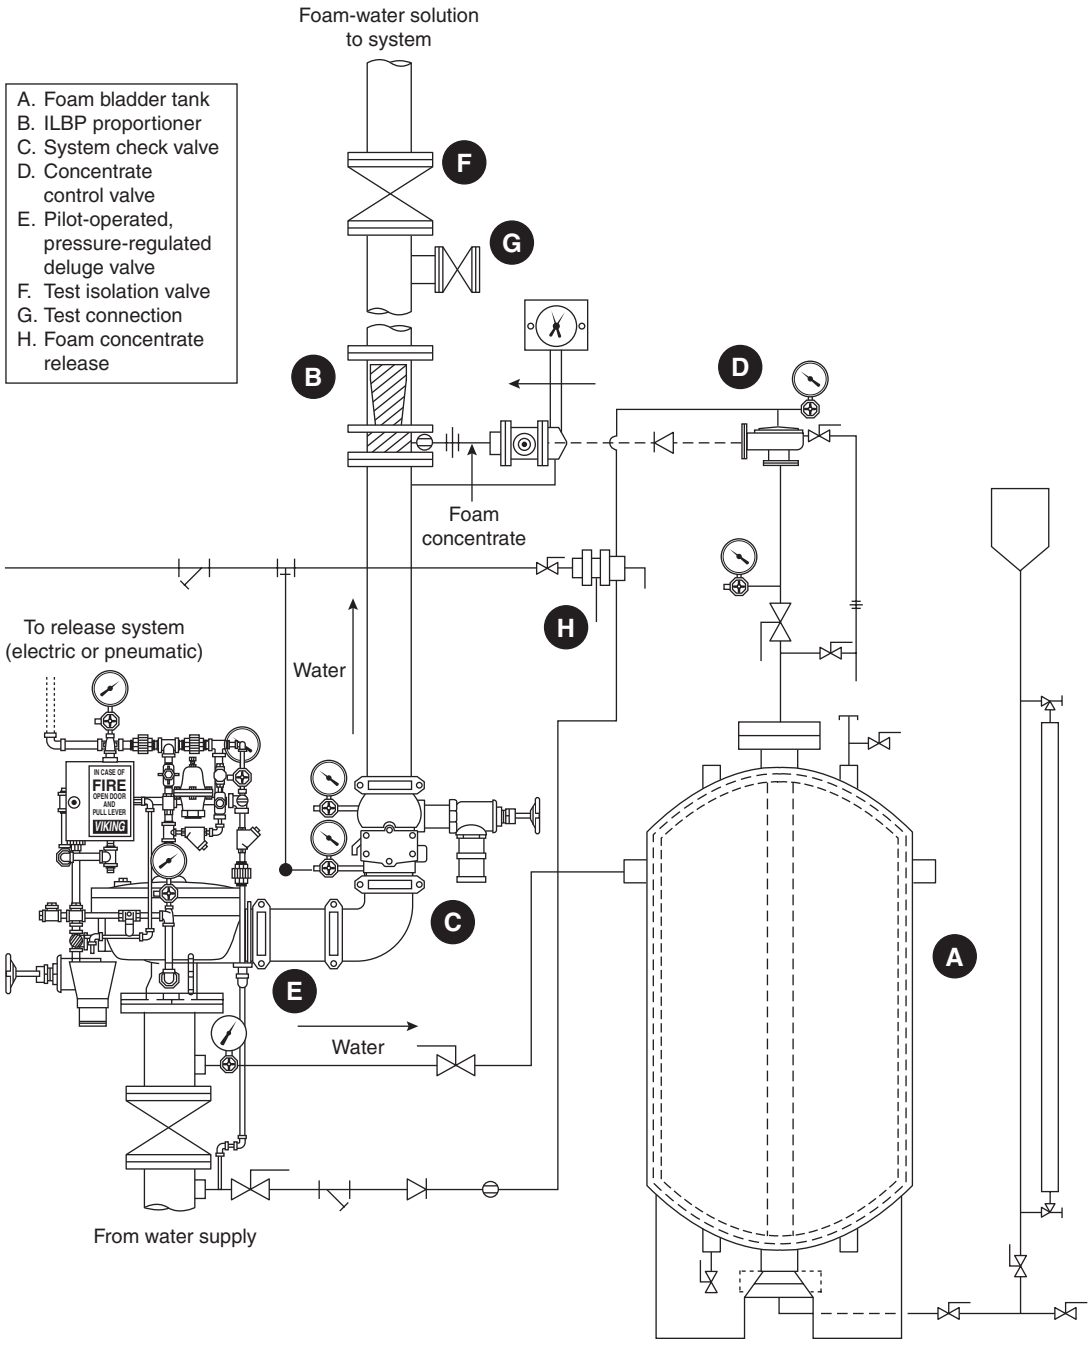

FIGURE 17.4.13 Low-Flow Preaction System with Bladder Tank (Source: The Viking Corp.)

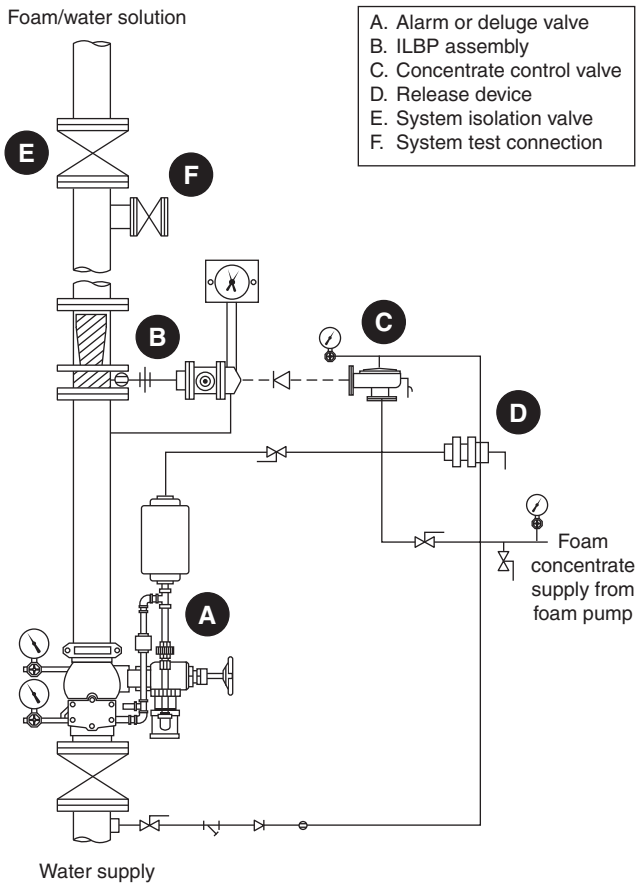

FIGURE 17.4.14 Wet Pipe Low-Flow System, Foam Supply from Foam Pump (Source: The Viking Corp.)

4. The balanced pressure proportioning systems require more space than other systems.
5. The system is limited to a single point of foam injection.

The balanced pressure system with bladder tank has the following advantages and disadvantages:

Advantages

1. No electrical power is required for the water-powered design.
2. Costs are lower for smaller systems and deluge applications.
3. Pre-engineered systems and foam storage are available.
4. Retrofitting into an existing system is relatively easy.
5. Maintenance costs are relatively low.

Disadvantages

1. Refill during a fire condition is not easy.
2. The bladder tank must be installed adjacent to proportioning equipment.
3. Proportioning of foam at low flows is lean, that is, has a lower concentrate percentage than needed or below listed rates.
4. The application is limited to a single proportioning source. (It is difficult to balance various flows that may be required in a multi-injection point system.)

The balanced pressure system with positive foam injection bladder or foam pump has the following advantages and disadvantages:

Advantages

1. The system can handle variable-pressure applications with the bladder tank design discharging a constant supply.
2. Multiple proportioning points and sizes can be accommodated from a single foam supply source.
3. Foam concentrate can be supplied a long distance to multiple points.
4. A wide flow range is available.
5. In closed head sprinkler systems, foam is supplied at the first sprinkler operation.
6. Multiple discharge devices and multiple areas of protection can be supplied.
7. Pressures and proportioning can be adjusted at the point of application.

Disadvantages

1. Refill during a fire condition is not easy.
2. Higher relative cost proportioning assembly compared to the system with only an injection pump or bladder.

Variable Orifice, Variable Flow Demand Proportioner. This type of balanced pressure system uses a specially designed, flow-sensitive, moveable piston section in the water supply that controls a variable orifice in the foam concentrate line. A pump supplies concentrate at monitored pressures to the metering orifice, which changes in size proportionally to the system demand for foam solution. The device is especially designed for large-capacity systems. Its design provides accurate proportioning over ranges of flow of water of approximately 2.3 to 1.

Premixed Foam Solution. This method of proportioning is a batch type of mixing of concentrate with water, usually in a container that can be pressurized. The measured volume of concentrate is poured into a measured volume of water to yield a foam solution of the recommended strength; for example, for a 3 percent solution in a container that holds 100 gal (378.5 L) of liquid, 97 gal (367 L) of water are poured into it and 3 gal (11.5 L) of foam concentrate are mixed with it to give a solution of 3 percent by volume. The final solution mixture is then educted from a tank to a pump or placed in a pressurizing vessel.

Some foam concentrates are not suitable for storage in premixed solution. Even those that are formulated for this use may show gradual loss of effectiveness. Manufacturers' recommendations should be followed carefully.

Portable Aspirating Equipment and Systems

Because of the difficulties associated with pumping or transporting generated foam in pipes or hoses and the familiarity of fire fighters with nozzles, the earliest designs of air-foam generators were devised to be used in much the same manner as water nozzles. They incorporated a crude venturi design whereby a jet or jets of foam solution enter an open contracted portion of a large-diameter foam tube. This action lowers the atmospheric

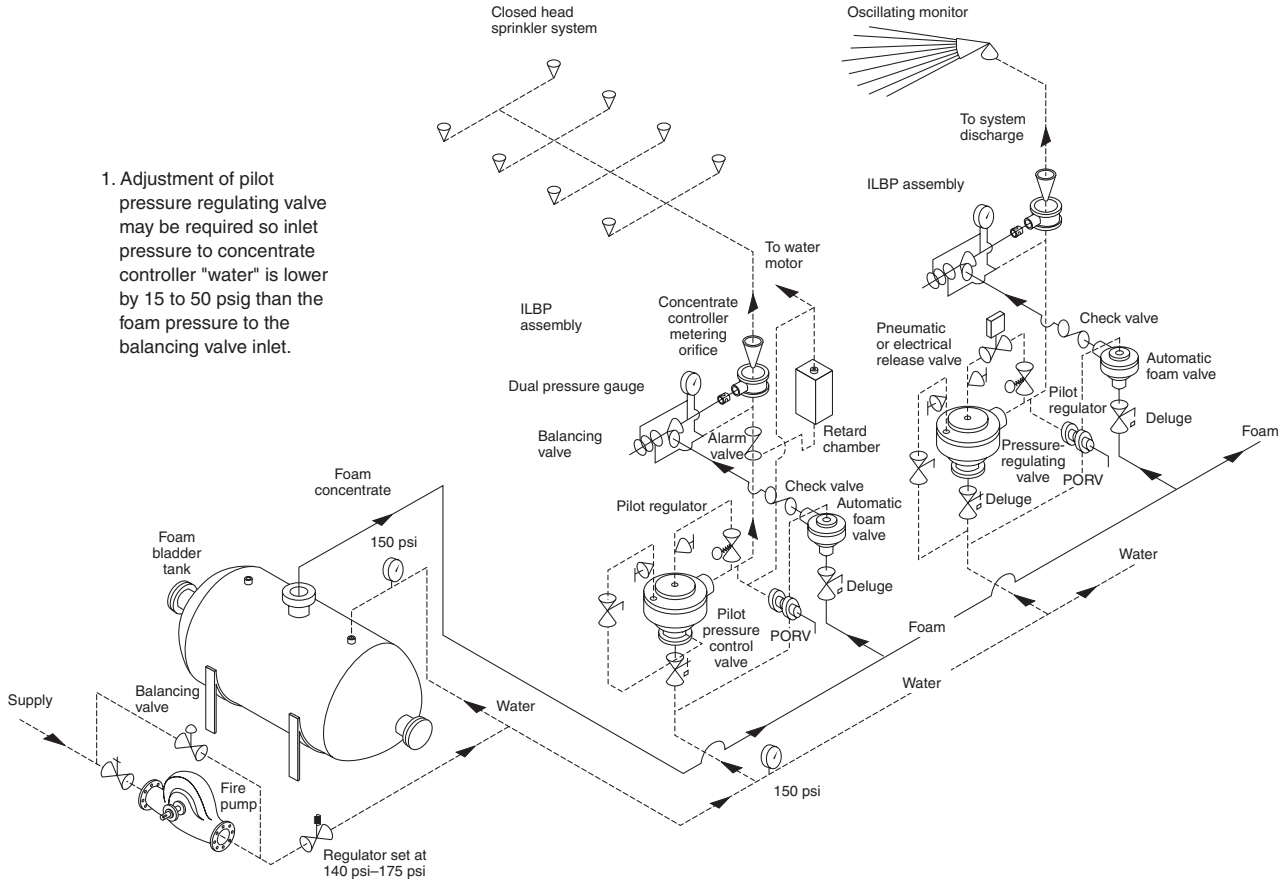

FIGURE 17.4.15 Low-Flow Foam System Schematic with Multiple Discharge Areas (Source: The Viking Corp.)

FIGURE 17.4.16 ILBP Assembly (Source: The Viking Corp.)

pressure surrounding the jets, and air is drawn or aspirated into the throat of the tube. Downstream of the contracted portion of the tube, a high turbulence and mixing of air and foam solution occurs. This turbulence may be increased by internal turbulence-accelerating devices, such as screens or baffles. The kinetic energy of the fluid contributes to this mixing action so that a useful, stable foam exits the tube at a relatively low pressure (Figure 17.4.18).

The basic design principles of this method of producing air-foam have been changed in many ways to yield, for many purposes, foams with greatly differing characteristics. However, all types of nozzles incorporating foam solution jets leading into free air-mixing cavities, followed by discharge apertures of one kind or another, use the aspirating action for making foam.

Hose Line Foam Nozzle. This is the most widely used portable, air-aspirating foam device for flammable liquid fire fighting. It is manufactured in a variety of capacities up to approximately 350 gpm (1325 Lpm) (Figure 17.4.19). Supplied with foam solution from a proportioner or by means of a pickup tube, it is used for combating fires resulting from spills of flammable liquid, or fires in tanks or fuel pits. To provide a variety of foam stream patterns that may be needed for the extinguishment operation, these nozzles often contain built-in devices that allow continuous foam pattern variation from a solid, straight stream to an inverted, filled umbrella shape (Figure 17.4.20). As with water streams, foam is employed in a solid, straight stream for range or reach. A flat or wide "bushy" shape is used for gentle

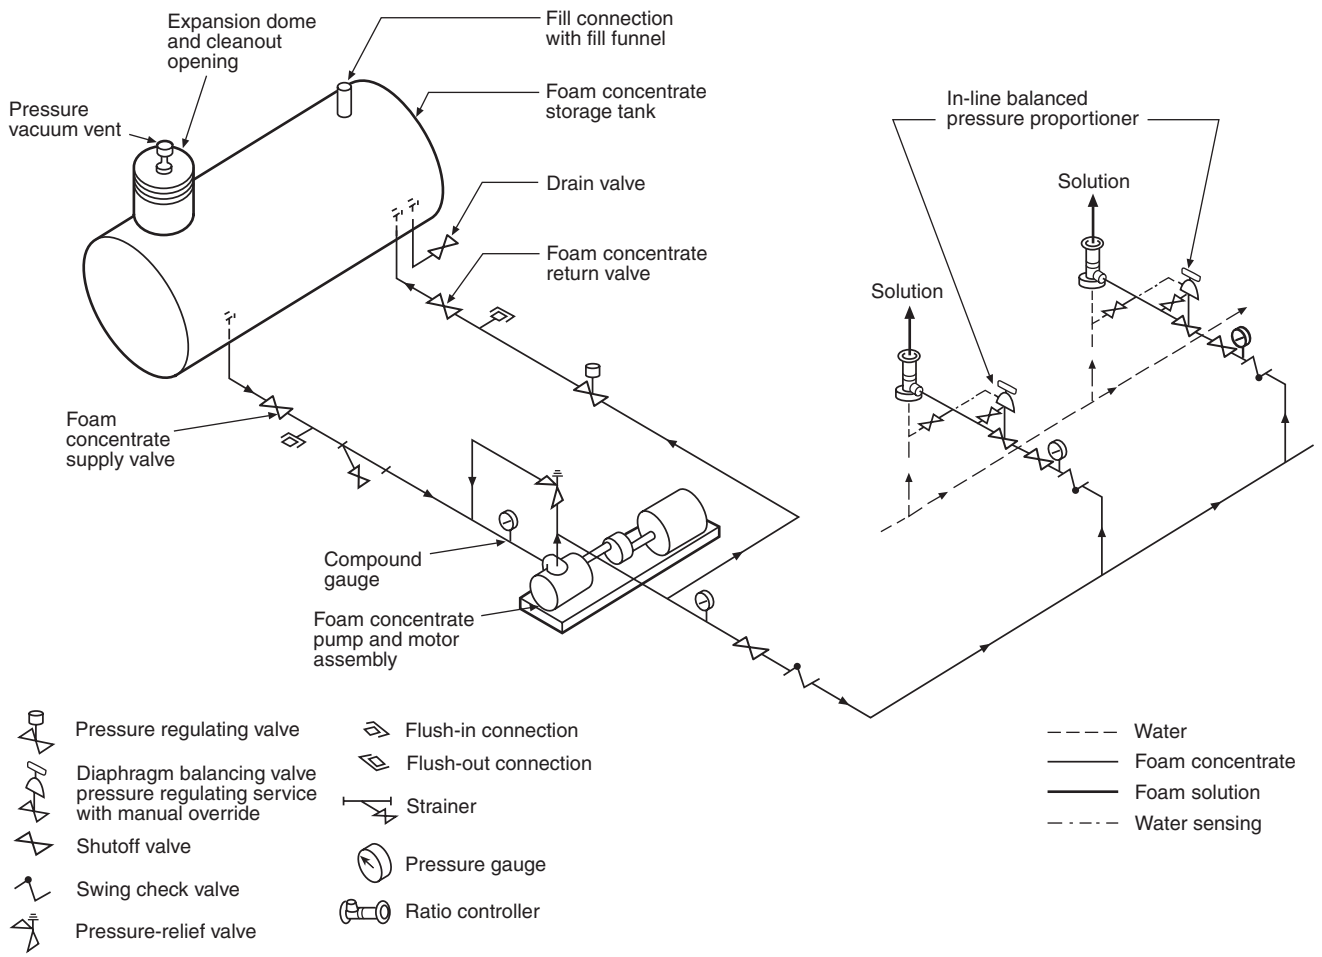

FIGURE 17.4.17 Balanced Pressure Proportioning with Multiple Injection Points

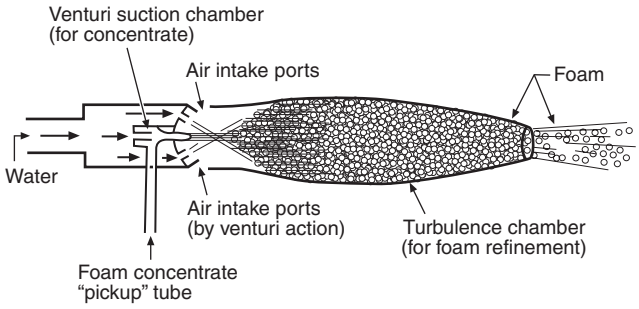

FIGURE 17.4.18 Aspirating Foam-Maker with a Concentrate Pickup Tube

FIGURE 17.4.19 Hose Line Foam Nozzle

FIGURE 17.4.20 Adjustable Hose Line Foam Nozzle (Source: Kidde Fire Fighting)

"snowstorm" application on the burning fuel surface, and a very wide, circular "bushy" shape is used for radiance shielding of the operator during fire extinguishment or penetration into the fire area.

Another type of hose line foam nozzle is especially designed for quick, portable, one-person use during emergency operations from airport crash-rescue vehicles. Customarily

called a handline foam nozzle, it is equipped with a foam pattern changing device, and some types are supplied with a valve control for converting the water or solution stream into a water spray for cooling purposes.

Foam and Foam-Water Monitors. In large-scale fuel-fire fire-fighting operations, it may become necessary to position a foam-making nozzle with a high discharge rate at an advantageous position for continuous application of foam to one point or over an area. Devices for this purpose are available in a variety of types, for example, as part of mobile truck apparatus, on a trailer, wheeled, or permanently mounted. The foam pattern change is accomplished by moving a deflector into the foam stream or by opening or closing the "jaws" at the exit end of the large tube.

This equipment has largely been replaced with non-air-aspirating monitor nozzles. Non-air-aspirating monitors are effective devices for extinguishing hydrocarbon pool fires.

High Back-Pressure Foam-Maker. Certain circumstances necessitate that foam be generated and supplied under pressure for transmission in pipes under a definite pressure head. The subsurface foam injection method for fuel tank fire extinguishment requires this type of foam-maker. The high back-pressure foam-maker, or "forcing foam-maker," is a venturi device that is carefully designed to make foam by air aspiration and to supply it under pressure at a carefully selected ratio (from 2:1 to 4:1) of air-to-foam solution. Approximately 20 to 40 percent of the inlet pressure is recoverable. In use, this foam device is usually brought to the fixed piping foam inlet, installed, and then supplied with foam solution by a portable or mobile pumper, or it may be permanently installed as part of a fixed system (Figure 17.4.21).

Medium- and High-Expansion Foam-Generating Devices. There are two principal methods used for the generation of these types of fire-fighting foams. One method uses a modified venturi action with air aspiration flow, whereas the other requires use of a blower and screen to form the finished foam. The latter system produces high-expansion foam containing sufficient residual kinetic energy to enable it to be forced through large tubes and passageways.

Figure 17.4.22 illustrates the operating principles of high-expansion foam-generating devices.

Water Fog or Spray Nozzles and Monitors. Several types of adjustable water fog or spray nozzles for portable use provide an acceptable fire-fighting foam of adequate characteristics when supplied with certain foam concentrates. The most universal design of these is shown in Figure 17.4.23. An adjustable water spray monitor nozzle designed for this purpose is shown in Figure 17.4.24.

These portable water spray nozzles are used with aqueous film-forming foam (AFFF) solutions for combating flammable liquid tank and spill fires and are used in this manner on crash-rescue vehicles. The foam resulting from the discharge of AFFF solution devices that do not aspirate air is generally fast draining and may not impart the same degree of burnback resistance as the foam produced from AFFF agents when foam-generating devices of an air-aspirating type are used.

Foam monitors using AFFF can be either air-aspirating or non-air-aspirating. Non-air-aspirating monitor nozzles have the advantage of increased stream reach compared to air-aspirated devices. Combined with the rapid-fire knockdown characteristics of AFFF, these monitors are very effective for large hydrocarbon pool fire suppression. In particular, foam monitors are effective in aviation fire protection, both as turrets on aircraft rescue and fire-fighting vehicles and in fixed systems protecting aircraft hangars (Figure 17.4.25).

Foam-Generating Equipment

Where flammable liquid fire protection is required for permanently installed hazards, such as fuel storage tanks or dip tanks containing flammable or combustible liquids, air-foam-generating and distributing devices are installed integrally with the hazard. These fixed devices, which are piped to a source of foam solution, may be arranged for manual control or automatic activation by fire detectors in the event of fire.

Open Dip Tank, Quench Tank System. This system consists of a small, aspirating foam-maker supplied by a water line and foam concentrate educted to the foam-maker. Foam discharges into a mixing box, which also acts as a surface distributor for gentle foam application.

Foam Chambers for Large Fuel Storage Tanks. Fire protection of large outdoor fuel storage tanks requires that several foam chambers with foam-makers be installed at equally spaced positions slightly below the curb angle on the top periphery of the tanks. These chambers are connected to lines on the ground that supply foam solution to each foam-maker simultaneously in case of ignition of the flammable contents of the tank. Frangible seals at the discharge outlet of the foam chamber prevent vapor from entering the foam piping. These seals are designed to burst when foam pressure is applied. A screen for the air inlet to the aspirating foam-maker prevents clogging from foreign matter, such as bird nesting material. A universal or swing pipe joint is installed at ground level in the foam solution inlet pipe to prevent fracturing of the supply piping if an explosion precedes a tank fire (Figure 17.4.26).

Internal Tank Foam Distributing Devices. A prime requirement for efficient fuel tank extinguishment by topside foam devices has always been that the foam must be applied to the burning surface without undue plunging into the fuel or allowing the foam to become coated with burning fuel. This gentle application of foam must be accomplished at any level of the contents of the tank. Many devices have been developed to gently apply foam from one point, regardless of burning fuel level. These devices are required for some alcohol-type foams. Alternatively, foam discharge into a tank may be deflected to run down the inside tank shell to the burning fuel surface.

Central "Foam House" Distributing Systems. These systems, as shown in Figure 17.4.27, consist of an enclosure housing a foam concentrate supply tank and a proportioning device of an automatic or balanced pressure type. Foam solution is supplied under adequate pressure from this foam house to the piping system and controlled by appropriate valves so that the foam chambers with foam-makers on the burning tank receive foam solution.

Semifixed systems of similar design are more frequently used with mobile foam concentrate supply from foam trucks. The truck proportions and pumps foam solution to the pipe laterals feeding the foam-makers from a safe location outside the dike.

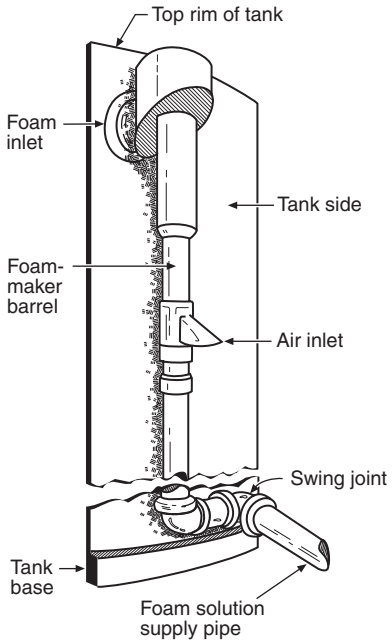

FIGURE 17.4.26 Air-Foam Chamber at Top of Storage Tank

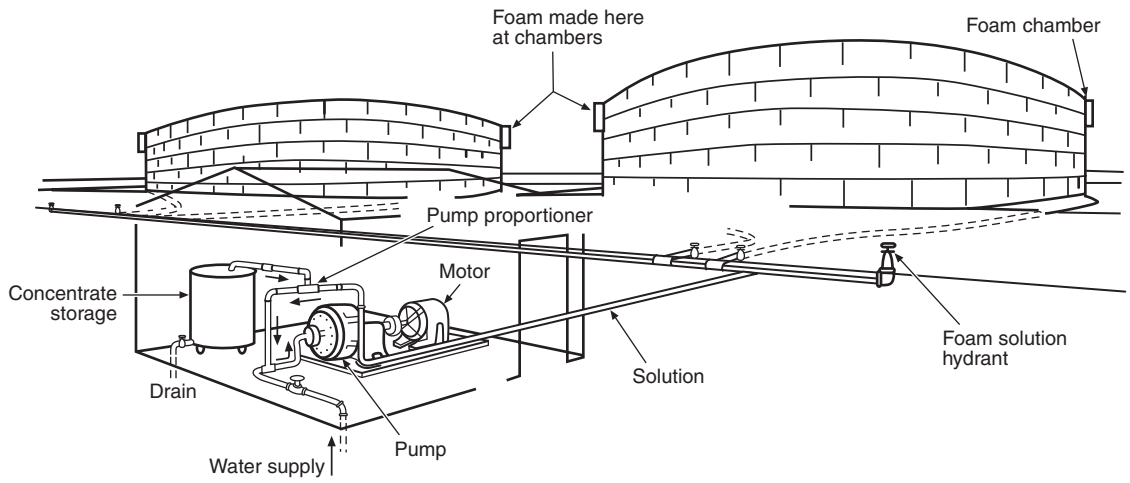

FIGURE 17.4.27 Schematic Arrangement of Foam Protection for Storage Tanks

Intermediate Back-Pressure System. Although this system of tank protection is similar to the preceding central foam house distributing systems, it utilizes strong and well-braced foam-delivery pipes on the side of the tank, which act as supports to prevent buckling of the tank from heat. This system also uses a foam truck to proportion and pump foam solution to the piping outside the dike or firewall of the burning tank.

Subsurface Foam-Injection Systems. The problems inherent with the application of foam from above the burning surface (topside) are sometimes difficult to combat. Problems may consist of explosion or fire damage to the foam-makers or tankside piping, forceful upward fire-drafted air currents that prevent the falling foam from reaching the burning surface, hazard to workers attempting to erect portable foam distributing devices near the burning tank, or inability of foam applied from the periphery of a large tank (greater than about 200 ft [61 m] in diameter) to flow and form a complete center seal during fire attack.

The obvious solution to these problems is to apply foam from the underside of the fire, causing it to come up through the contents of the tank. The subsurface foam-injection system accomplishes this by injecting foam under the pressure of the head of fuel in the tank, using the high back-pressure foam-maker referred to previously in this chapter.

Entry of foam may be provided at several points at the base of the tank (base injection), or it may be accomplished by means of the product line. Where large tanks are involved, a branched pipe foam distributor may be installed on or slightly above the floor of the tank above any expected water level and connected to a central foam-injection point outside the tank.

Mobile foam concentrate proportioning equipment is used with these systems, pumping from a protected position outside the tank dike (Figure 17.4.28).

Subsurface application of foam is recommended only for protection of cone-roof tanks containing hydrocarbon fuels. It is not recommended for use on floating-roof tanks or for protection of polar or water-miscible fuels.

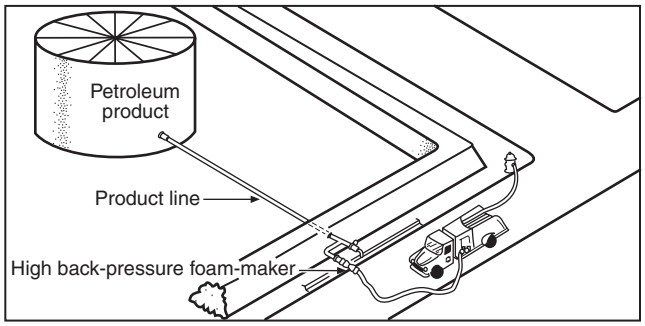

FIGURE 17.4.28 Semifixed Subsurface Foam Installation

These topside and subsurface injection systems require careful design. Their minimum installation requirements are found in NFPA 11.

Portable Foam Devices for Tank Protection. Mobile foam monitors of high-capacity discharge (foam cannon) may be used to direct a stream of foam over the open top rim of a burning tank so foam will fall into the burning area. These devices waste foam because of crosswinds, fire updrafts, and inability to place the equipment in an advantageous position. A foam-application rate 60 percent higher, therefore, must be included in the design; details are contained in NFPA 11. Nozzles of this type also are used to extinguish fires in the overflow space inside the dike surrounding the tank. Care is needed in directing the foam stream from such devices, as shown in Figure 17.4.29.

In recent years, mobile foam monitors with capacities up to 4000 gpm (15,144 Lpm) have been developed and used successfully for extinguishment of hydrocarbon fires in tanks up to 195 ft (60 m) in diameter.[1] Careful planning is required to ensure availability of adequate waterflow and pressure, foam concentrate, proportioning equipment, trained personnel, and safe accessibility to the hazard when relying on such devices.

FIGURE 17.4.29 Portable (Trailer) Foam Monitor (Cannon) (Source: Kidde Fire Fighting)

Other Considerations for Fuel Storage Tanks. The floating-roof storage tank has a good chance of freedom from fire; consequently, fixed foam systems are usually not required for their protection. Under certain circumstances, however, there may be a need for a foam-flooding system to flood the rim area.

As indicated by its name, the "covered" floating-roof tank is totally enclosed above the floating roof with a properly vented steel roof. Usually Class IB flammable liquids, such as gasolines and crudes, are stored in "open top" or covered floating-roof tanks. During storage operations, there is no vapor space between the bottom of the floating roof and the stored product surface. However, during periods of initial fill, a flammable vapor space will exist until the floating roof is buoyant. In the case of covered floating-roof tanks, the space between the fixed and the floating roof will be within the flammable range during periods of initial fill and longer, depending on atmospheric temperatures, wind, and vapor pressure of the stored product. Class II and III combustible liquids are usually stored in fixed-roof tanks.

In an open-top floating-roof tank, a rim of fire is all that can be expected. Rim fires may be caused by atmospheric disturbances, such as lightning, but usually do not occur if the floating roof is bonded properly to the shell as specified in NFPA 780, *Standard for the Installation of Lightning Protection Systems.* Rim fires due to atmospheric disturbances do not occur in covered floating-roof tanks because of the "Faraday effect" of the fixed roof. Rim fires may occur in either type of floating-roof tank due to a serious exposure fire.

Fixed foam fire protection for the open top floating-roof consists of aspirating-type foam-makers installed in such a way that when supplied with foam solution, their foam discharge floods the annular area covered by the seal around the tank periphery. A metal foam dam may be needed to restrict the foam to this area. Further details of such construction are contained in the Appendix to NFPA 11.

When foam protection is desired for covered floating-roof tanks, a foam system similar to those described for fixed-roof tanks may be provided. Subsurface injection systems are not recommended for open top or covered floating-roof tanks because of the possibility of tilted or sunken roofs resulting in improper foam distribution.

Fixed foam systems employing foam spray nozzles or monitors are used to protect large oil-water separators, pump areas, and oil piping manifolds. Fixed foam systems are not generally used to protect tank diked areas. Large wheeled monitors or trailer-mounted foam cannons, as shown in Figure 17.4.29, are used for this purpose.

Other Hazards. Certain hazardous areas, for example, aircraft hangars, may require additional foam-making and distributing devices, such as foam monitors mounted near floor level. Often these devices are provided with an automatic oscillator so that foam is continually distributed over the floor to extinguish burning spilled fuel under obstacles, such as aircraft wings. These are typically combined with air-aspirating or non-air-aspirating sprinklers installed at the roof of the hangar. Application rates for non-air-aspirating AFFF sprinklers are lower than air-aspirating sprinklers, in recognition of the fire plume penetration capability of AFFF discharged from ordinary sprinklers. NFPA 409 provides design details for overhead and low-level foam systems.

NFPA 409 also recognizes low-level AFFF application, combined with water-only sprinklers at the ceiling. A recently developed low-level AFFF nozzle can be installed in the floor

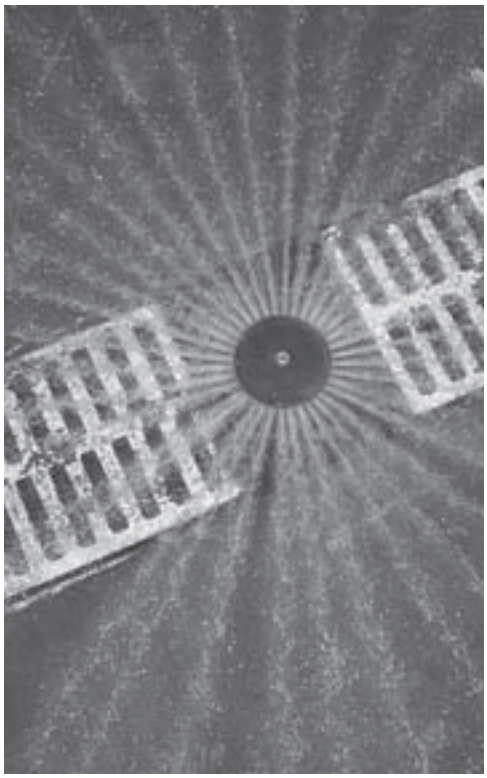

FIGURE 17.4.30 Low-Level AFFF Nozzle Installed in Aircraft Hangar Floor (Source: The Viking Corp.)

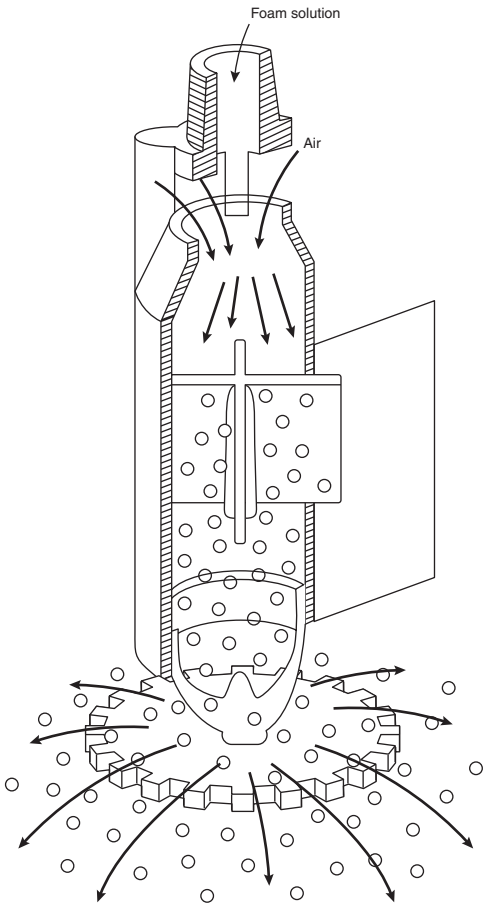

FIGURE 17.4.31 Air-Aspirating Foam Sprinkler (Source: Ansul Incorporated)

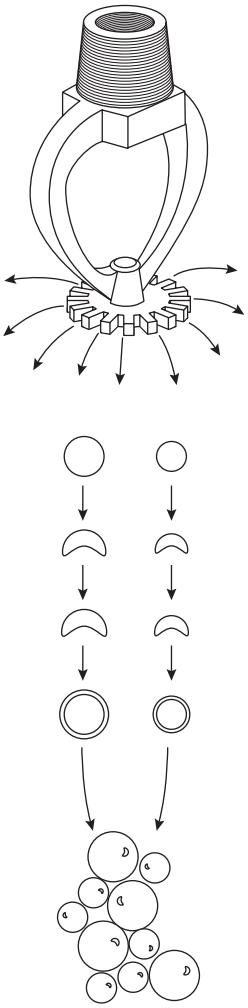

FIGURE 17.4.32 Non-Air-Aspirating Sprinkler (Source: Ansul Incorporated)

of a hangar (Figure 17.4.30). This design reduces AFFF spray to aircraft in the event of a false discharge.

Fixed foam systems are used to protect petroleum piers and wharves where products and petroleum crude are handled. Foam monitors of 1000 gpm (3800 Lpm) and greater capacity are mounted on towers and remotely operated to cover both the pier and the tanker deck in the pipe manifold area. Below deck, foam spray systems or oscillating monitors are installed to keep the pier tenable in the event of a spill fire floating on the water surface under the pier.

Fixed systems consisting of automatically operated combinations of foam spray systems and foam monitors are often installed to protect chemical processing plants. Alcohol-resistant foams are usually required. In these designs, where there may be a high risk, process vessels, pumps, and piping often are all included within the foam distribution pattern for overall protection. The system can be automatically activated by heat or fire detectors. See NFPA 11 for design of foam spray systems.

Foam-Water Sprinkler Systems. In areas where flammable and combustible liquids are processed, stored, or handled, water discharge may have limited effectiveness for controlling or extinguishing large spill fires. The effectiveness of water in these applications is a function of many variables, including fuel type, storage container, fuel configuration and geometry, height of the facility, and the level of acceptable risk. NFPA 30 recognizes both water and AFFF protection for indoor storage of liquids.

Sprinklers or nozzles used to protect liquid hazards may be air-aspirating or non-air-aspirating devices. Figures 17.4.31 and 17.4.32 show examples of both types of sprinklers. Air-aspirating sprinklers, such as that shown in Figure 17.4.31, were developed for use with protein-based foam in deluge sprinkler applications. Foam solution is discharged through the device, aerated, and applied through the open sprinkler or nozzle to the hazard. Detection systems are often provided to actuate the system automatically. The design area is the entire area of the deluge system.

Although AFFF can be effectively applied using air aspirating deluge sprinklers, it can also be discharged through traditional water sprinklers. Research was performed by the Factory Mutual Research Corporation related to aircraft hangar fire protection.[2] This research demonstrated that AFFF discharged through non-air-aspirating standard sprinklers was at least as

effective in extinguishing large spill fires as AFFF discharge from air-aspirating sprinklers. The effectiveness of the standard sprinklers was attributed to more effective plume penetration by higher-density foam particles. Figure 17.4.32 shows an example of a non-air-aspirated sprinkler.

Standard sprinklers used with AFFF may be open for use in a deluge system, or closed where the use is similar to a standard closed sprinkler system. For example, NFPA 409 recognizes the use of open standard sprinkler AFFF systems installed at the ceiling of aircraft hangars. NFPA 30 requires the use of closed sprinklers where AFFF is used. The sprinkler temperature rating, response characteristics, and application rate are specified based on test data for a specific hazard.

Air-aspirating foam sprinklers and standard sprinklers used to discharge AFFF are tested in accordance with UL 162.[3] Systems are listed for use by the combination of foam concentrate, proportioning system, and discharge device. For example, a vendor's foam sprinkler design may consist of 3 percent AFFF concentrate using a balanced pressure proportioner discharging through a standard sprinkler. Additionally, foam sprinkler or spray nozzles must have essentially the same discharge pattern when water is discharged. This dual capability affords the system Class A and B extinguishing capability.

Fundamental design requirements can be found in NFPA 16. Listing of system components is required in accordance with UL 162. Listing requirements vary as a function of discharge device (air-aspirating and non-air-aspirating sprinkler), type of fuel (miscible and nonmiscible hydrocarbons), extinguishment time, and burnback resistance. Only AFFF and FFFP can be used through standard orifice sprinkler and spray systems. These agents must extinguish test fires at an application rate of 0.10 gpm/ft^2 (4.1 Lpm/m^2). Standard orifice (½ in. [12.7 mm]) and large orifice ($^{17}/_{32}$ in. [13.5 mm]) sprinklers are recognized. Air-aspirated foam-water sprinklers using protein or flouroprotein foam are tested at 0.16 gpm/ft^2 (6.6 Lpm/m^2). It should be recognized that NFPA 16 requires a minimum design application rate of 0.16 gpm/ft^2 (6.6 Lpm/m^2) for all foam agents. Other standards, such as NFPA 409 and NFPA 30, provide specific requirements for the particular hazards.

Application rates required to protect polar solvents using alcohol-type foams are generally greater than those required for nonmiscible hydrocarbons. The sprinkler design must meet the minimum application rate in the UL listing for the polar solvent being protected. Where polar solvents in containers are protected in warehouses, other factors may impact minimum design application rates. For example, the lowest design application rate currently permitted in NFPA 30 for indoor storage is 0.30 gpm/ft^2 (12.3 Lpm/m^2).

Fixed systems using foam-water or standard sprinklers require associated foam concentrate tanks, proportioners, and suitable pumps to supply the system with foam solution. NFPA 16 is the installation standard that provides fundamental design requirements. Other standards may require specific additional features. For example, NFPA 30 requires that foam solution be discharged when four closed AFFF sprinklers have operated. This requires a system that can proportion at the low end of the flow range, such as the positive pressure ILBP system discussed earlier.

DELIVERING FOAM FROM VEHICLES

The majority of the mobile fire protection vehicles using foam consist of airport crash-rescue trucks and industrial foam trucks used at oil refineries and petrochemical plants. Many of these vehicles are also equipped to discharge dry chemical in combination with foam. These have combined, or "twinned," agent equipment and are described later in this chapter.

Crash-Rescue Trucks

Mobile foam trucks, developed by military and municipal authorities in the United States and other countries, are large, custom-designed vehicles with oversize running gear that allows them to travel over all types of terrain. The trucks carry their own water supply as well as foam concentrate. Automatic balanced pressure proportioning is usually provided, although in some designs an around-the-pump proportioning system is used. The trucks are equipped with separate engine-driven water pumps and foam concentrate pumps so that the turret monitor nozzles and roadway foam nozzles can be discharged while the truck is in motion. Recent designs accomplish this using one or two engines for all necessary power requirements. Crash-rescue trucks are equipped with large-capacity, adjustable foam monitors of 500- to 1500-gpm (1900- to 5700-Lpm) discharge, depending on truck size. The foam monitors are usually installed on top of the cab with remotely operated controls. The trucks are also equipped with portable handlines. Although limited, their supply of foam concentrate and water is sufficient for fire fighters to form a passageway for access to a burning aircraft for rescue. Their primary purpose is rescue of people and not necessarily a total extinguishment of fire. Aircraft crash-rescue foam vehicles are specially designed and require special attention to detail in their fabrication and performance requirements. NFPA 414, *Standard for Aircraft Rescue and Fire-Fighting Vehicles,* provides standards for such vehicles.

Industrial Foam Truck Design

Foam trucks are manufactured by vendors who make a specialty of this design and by some vendors of fire department pumpers. Generally, using NFPA 1901, *Standard for Automotive Fire Apparatus,* as a design basis, these trucks are fabricated on a suitable commercial or custom truck chassis. In the United States, they are available with water pumps in sizes from 750 to 2000 gpm (2839 to 7570 Lpm), using gasoline or diesel engine drives.

Balanced pressure proportioning is provided for maximum flexibility and simplification. A positive-displacement-type foam concentrate pump takes suction from a 500- to 1000-gal (1900- to 3800-L) foam concentrate storage tank. The foam concentrate pump is driven by a power takeoff or hydraulic motor. The water pump is driven by a transfer gear from the main drive shaft behind the transmission. A metering valve at each truck outlet can vary foam proportioning from 3 to 6 percent.

In addition to the foam concentrate, each foam truck usually is equipped with a 500- to 1000-gpm (1900- to 3800-Lpm) monitor and carries fire hose, foam nozzles and adjustable water spray nozzles, hose adapters, and other accessories. The maxi-

mum truck height is limited to permit passage beneath overhead obstructions. When the truck is equipped with a large-capacity nozzle on a telescopic or articulated boom, a second power take-off is used to power the boom hydraulic system.

Foam trucks for special hazard application, instead of fixed foam systems, are popular for refinery and petrochemical plant use. Their advantages are as follows:

1. Capability of discharging their maximum capacity at any hazard in the plant rather than only to the limited areas covered by a fixed system.
2. Improved reliability because their equipment is easily maintained; thus, operating procedures can be simplified and fire fighters can be trained more easily to use the equipment.

Industrial foam trucks are used to extinguish spill fires in process areas, piping runs, and tank diked areas, as well as in fighting tank fires. Their 500- to 1000-gpm (1900- to 3800-Lpm) foam-water monitors and 1½ in. (38 mm) and 2½ in. (64 mm) handlines are used for fighting major spill fires. Designs that are equipped with monitor nozzles on articulated or telescopic booms enable the operator to discharge foam at various elevations in and around process equipment. In some cases, a tank fire can be extinguished with this equipment. Figure 17.4.33 illustrates a typical industrial foam truck. Figure 17.4.34 illustrates a typical foam truck with a telescopic boom, ladder, and basket. The foam trucks with booms may or may not be equipped with a ladder and/or basket.

COMBINED AGENT OR "TWINNED" EQUIPMENT

The capability of dry chemical agent (especially potassium-salt-types) for very fast flame control and three-dimensional flowing fuel extinguishment is well documented. However, dry chemicals have no cooling or vapor-suppressing capability, and reflash can occur. With dry-chemical-compatible foam concentrates, it is possible to apply a coating of vapor-securing foam to a burning fuel surface that has been freshly extinguished by the chemical action of dry chemical discharges.

FIGURE 17.4.33 A Typical Industrial Foam Truck (Source: Motiva Enterprises LLC)

FIGURE 17.4.34 Foam Truck with Telescopic Boom and Nozzle with Ladder and Basket (Source: Kidde Fire Fighting)

The logical extension of these developments has been incorporated into portable and mobile devices with dual-trigger valve nozzles and monitor nozzles discharging AFFF and dry chemical. Figure 17.4.35 illustrates a type of twinned agent nozzle where dry chemical is entrained in the foam stream. Figure 17.4.36 shows a twin agent unit consisting of a dry chemical agent tank and an AFFF solution tank for dual agent application. The use of this combined agent attack allows three-dimensional as well as spill fire extinguishment of flammable liquid with both speed and freedom from reignition. The fire-fighting vehicle shown in Figure 17.4.37 is for aircraft crash-rescue purposes and for extinguishment on freeways or in plants, using combined agents.

In use, the twinned hose from the hose reel supplies dry chemical and AFFF to a dual nozzle for one-person operation. Similarly, the turret nozzles at the front of the vehicle discharge dry chemical from the upper nozzle and AFFF from the lower. With a sweeping motion, the flames are controlled with the dry chemical, quickly followed by a vapor-securing, cooling layer of foam to prevent reflash. This rapid action halts

FIGURE 17.4.36 Twin Agent Unit Consisting of One Dry Chemical Agent Tank and One AFFF Solution Tank for Dual Agent Application (Source: Ansul Incorporated)

FIGURE 17.4.37 A Combined-Agent Vehicle (Source: Emergency One, Inc., and Kidde Fire Fighting)

flame radiation and makes advancement over the fire area safe and cool.

A design especially for petroleum refinery plant protection involves the combined agent concept in a triple-use arrangement consisting of a 2000 lb (908 kg) dry chemical tank, a 200 gal (757 L) AFFF premixed solution tank, nitrogen bottles for pressurization of both tanks, a 500 gal (1900 L) foam concentrate tank, a 1500 gpm (5700 Lpm) water pump, and balanced pressure proportioning up to 2000 gpm (7600 Lpm). Two monitors mounted behind the truck cab are twinned for operation as a unit and consist of a 50 lb/sec (23 kg/sec) dry chemical turret nozzle and a 500 gpm (1900 Lpm) AFFF or foam nozzle as shown in Figure 17.4.38. A different configuration uses three monitors mounted behind the truck cab—twinned 50 lb/sec (23 kg/sec)

FIGURE 17.4.38 Triple-Agent Truck (Source: Kidde Fire Fighting)

dry chemical and 180 gpm (680 Lpm) AFFF nozzles, and one adjacent 1000 gpm (3800 Lpm) adjustable foam monitor. In addition, the truck carries two hose reels, each with 100 ft (30.5 m) of twinned hose, and hose nozzles for dry chemical and AFFF arranged for twinned operation. The hose reels are equipped with an electric motor rewind. Foam nozzles, adjustable water fog nozzles, fire hose, and other accessories are carried on the truck.

The dry chemical turret nozzle will extinguish three-dimensional or pressure fires at a distance of 100 ft (30.5 m) and spill fires at a distance of approximately 150 ft (46 m). In addition, for long-range operation with lengthy duration, the 1000 gpm (3800 Lpm) foam-water monitor has a range of more than 200 ft (61 m). The truck is capable of fighting fires in fixed-roof oil storage tanks with a maximum diameter of 160 ft (49 m). The proportioning system is designed to permit an external tank, such as a tank truck or trailer, to be used for foam concentrate supply without interrupting foam solution proportioning.

Twinned agent hose reels are often used on offshore oil platforms for equipment protection and in naval shipboard engine rooms. These systems have suitably sized potassium bicarbonate (Purple K) dry chemical containers that are pressurized by nitrogen when put into operation and AFFF central pumped systems using balanced pressure proportioning. Similar twinned agent skid-mounted systems are used in refineries and petrochemical plants.

MEDIUM- AND HIGH-EXPANSION FOAM-GENERATING EQUIPMENT AND SYSTEMS

Medium- or high-expansion foam is an aggregation of bubbles resulting from the mechanical expansion of a foam solution by air or by other gases, with expansion ratios in the range of from 20:1 to approximately 1000:1. There are three types of systems: (1) total flooding, (2) local application, and (3) portable.

The foam generators for these systems are of two types: (1) aspirator and (2) blower. The portable or fixed aspirator-type device utilizes jet streams of water-foam solution, entraining suitable amounts of air to produce foam. With the blower-type device, foam solution is discharged onto a screen through which an air stream, developed by a fan or blower, is passing. As the

air passes through the screens wetted with the foam solution, large masses of bubbles or foam are formed. The blower may be powered by a hydraulic or water motor, compressed air or gas, an electric motor, or an internal combustion engine.

System Design and Use

Detailed design information on medium- and high-expansion foam systems can be found in NFPA 11.

Basically, medium- and high-expansion foam systems are used to control or extinguish fires involving surface fires in flammable and combustible liquids and solids, and deep-seated fires involving solid materials subject to smoldering. Three-dimensional fires in flammable liquids (falling or flowing under pressure) with flashpoints below 100°F (38°C) generally cannot be extinguished with this technique, although they may be kept under control. The following are key factors to consider in determining the design adequacy of medium- and high-expansion foam systems:

1. The quality and adequacy of water supply, the adequacy of supply of foam liquid concentrate, and the source of the air supply
2. Suitability of the generator and foam delivery system (piping, fittings, valves, ducts)
3. Needed submergence volume and time as influenced by the space being protected, the nature of the hazards involved, leakage of the foam, and similar factors
4. If outdoors, the effect of wind, because some of the foam may be dissipated by air currents

High-expansion foam may be useful in controlling LNG fires and unignited spills by forming an ice layer on the liquid and by helping disperse the vapor cloud.

Total Flooding Systems

A total flooding system may be used where there is an enclosure surrounding the hazard being protected that will permit the required amount of medium- or high-expansion foam to be built up to extinguish or control the fire. Examples of such enclosures are rooms, vaults, pits, and basement areas. Even an entire building may be so protected where the foam generators are of sufficient capacity and steps are taken to ensure effective distribution and retention of the foam. Since the efficiency of the system depends on the development and maintenance of a suitable quantity of foam within the particular enclosure, leakage of the foam from the enclosure must be avoided. Thus, it is important that doorways or windows be designed to close automatically, with consideration being given to the evacuation of personnel. High-level venting is required for the air that is displaced by the foam.

For adequate protection, sufficient high-expansion foam must be discharged at a rate to fill the space to an effective depth above the hazard before an unacceptable degree of damage occurs. The depth of the foam above the hazard will vary, depending on the type of materials creating the hazard. Generally, the minimum depth above the hazard should be 2 ft (0.6 m). The time allowed to cover the hazard will likewise vary depending on the type of material involved, construction features, and whether the enclosure also has an automatic sprinkler system or similar protection. Consideration has to be given to the disintegration of the foam by the heat of the fire, by normal foam shrinkage, by leakage around doors and windows and through unclosable openings, and by the effects of sprinkler discharge where sprinkler protection is provided.

Local Application Systems

Local application systems can be used where total flooding systems may be impractical or unnecessary. Such hazards may be indoors or outdoors, where air currents are not likely to be severe. These systems are best adapted to the protection of flammable or combustible liquids in dip tanks and associated drainboards, and for pits and trenches. Medium- or high-expansion foam may be used for extinguishing spill fires where it is feasible to apply the foam from fixed or portable nozzles at adequate rates of discharge to develop a foam blanket to achieve complete extinguishment.

Compressed Air Foam Systems

Unlike traditional foam systems in which air aspiration occurs at or near the discharge device, compressed-air foam (CAF) systems inject air prior to the discharge device. Foam is generated by injecting air under pressure into a foam solution stream. As solution moves through a hose or piping system, foam is produced by the combined momentum of the foam solution and the injected-air stream in the hose or pipe.

CAFs for mobile fire fighting have been used primarily as Class A fire-fighting agents. There are mobile systems that are designed for use on Class B fire hazards; sometimes these Class B CAFs are combined with a secondary agent such as Purple K. AFFF foam concentrate is generally used in these systems.

CAF in fixed-pipe systems is a recent development. As with the mobile systems, AFFF is used as the foam concentrate. In one listed/approved system, the AFFF is proportioned at 2 percent compared to 3 percent for traditional foam sprinkler systems. Also, the effective application rate (foam solution, gpm/ft^2 [Lpm/m^2]) is lower than similarly listed low-expansion foam sprinkler systems. NFPA 11 recognizes this system and provides design and installation requirements. The primary advantage of CAF systems is for situations in which there is an extremely limited water supply.

Precautions to Be Observed with Medium- or High-Expansion Foam

Medium- or high-expansion foam is normally nontoxic to persons who may be trapped in a space filled with it, since the air entrained in the foam is generally not contaminated. However, because of the foam bubbles, some difficulty may be experienced in breathing, and breathing discomfort will increase with reduction of foam expansion. Air is usually taken from a clean source, but where products of combustion are introduced, the foam quality may be substandard because of the contaminants present and the temperature of the heated air. Entering a foam-filled space should be avoided unless adequate precautions are taken because loss of vision and disorientation introduce life

and injury hazards. A coarse water spray may be used to "cut" a path in the foam. Personnel should wear self-contained breathing apparatus and employ a lifeline when entering an area filled with high-expansion foam.

FOAM EQUIPMENT TESTING AND SURVEILLANCE

The continued effective emergency performance of foam equipment depends entirely on fully adequate maintenance procedures, with periodic testing where possible. The many variations in system design and equipment applications for hazards requiring foam make it impossible to establish anything other than general procedures for periodic inspection. Because air-foam concentrates, foam equipment, and fire protection systems are subject to change, variation, and even malfunction over long unattended spans of time, they must be kept adequate for the purpose for which they are designed.

Foam Concentrate Surveillance

Because all air-foam concentrates are water solutions of organic and inorganic chemicals of one sort or another, they must be carefully observed for changes in constitution and characteristics. They must be stored in shipping containers and in storage tanks according to the manufacturer's recommendations. Exposure to extreme heat, cold, or contamination, or mixing with other materials must be avoided. Sedimentation or precipitate formation in containers or tanks of concentrate should be carefully checked periodically. The manufacturer or the manufacturer's representative is best qualified to test and determine the extent of reliability of foam concentrates under questionable conditions of deterioration. Foam concentrates should be tested at least annually.

Equipment Testing

The performance of all foam equipment under emergency conditions is best guaranteed by the initial acceptance test and periodic inspection of the equipment. Original design specifications of fixed installations should include provision for periodic testing of proportioners, pumps, and other ancillary equipment, without the trial distribution of foam to the hazard being protected.

Problems of corrosion, clogged orifices, sticky valves, and electric circuitry malfunction may be detected by suitable means without full system activation.

In the absence of an actual fire, and without full system activation, the complete testing of foam equipment performance for fire protection adequacy may be accomplished by various means. In the absence of an actual fire, complete testing may be accomplished by several physical test methods. However, because these tests are similar in nature to "fingerprint" tests, their results can only be interpreted by comparison with similar tests conducted at the installation acceptance of the equipment or as provided for under the performance guarantee of the manufacturer.

Foam equipment performance can be tested for the following physical characteristics of foam:

1. The dimensions of the discharge pattern or patterns of the device or system
2. The percent concentration of foam concentrate in the finished foam solution
3. The degree of expansion of the finished foam
4. The rate at which water drains from the foam, for example, 25 percent drainage time. This correlates with its viscosity or rate of spreading over fuel surfaces
5. Film-forming capacity of the foam concentrate

The preceding tests require specially designed test equipment and standardized techniques. They require qualified operators and may or may not be carried out easily in the field. Detailed information concerning the equipment required, methods used, and some interpretations of the test results can be found in the Appendices of NFPA 11 and NFPA 412, *Standard for Evaluating Aircraft Rescue and Fire-Fighting Foam Equipment,* which includes tests for foam discharge patterns, AFFF-type foams, and protein-based foams.

The test for the concentration of the foam concentrate is very important because it indicates the efficiency of operation of the concentrate proportioning device in the system. It is performed easily in the field with a hand refractometer and volume-measuring device or portable electrical conductivity meter.

ENVIRONMENTAL ISSUES

The use of fire-fighting foams is essential for the control of flammable liquid fire threats. The ability of foam to rapidly extinguish flammable liquid fires has contributed to life safety and property conservation. However, with the increasing global environmental awareness, fire-fighting foams are being scrutinized for their potential environmental impact. The primary concerns are toxicity, biodegradability, persistence, treatability in wastewater treatment plants, and nutrient loading.

Discharge Scenarios

In order to assess the impact of foam on the environment, likely discharge scenarios should be considered. These scenarios include the following:

1. Uncontrolled fire situations
2. Potential hazardous situations (e.g., unignited fuel spills)
3. Fire-fighting training evolutions
4. Fixed or mobile vehicle suppression system discharge
   - Intentional system test
   - Inadvertent discharge

Under many fire-fighting situations, control of foam and water/fuel effluent will be difficult. Control and extinguishment are usually of paramount importance, and rapid control by foam can substantially reduce the potential total effluent from an incident. Where possible, blocking of sewer drains, along with the use of portable dikes or booms, can be used to implement mitigation strategies.

Training scenarios provide greater opportunities to control foam flow, particularly by means of collection. New training

techniques, using simulated pool fires and simulated foams, are available.

System tests can also be performed, to a certain extent, with the use of simulants. Alternatively, small amounts of foam can be flowed and contained for proper disposal in accordance with local regulations and manufacturer's recommendations. Inadvertent system discharges may be handled by preplanned, engineered containment strategies or by portable containment devices, where containment is deemed appropriate.

Environmental Properties and Concerns

Fluorochemical surfactants in film-forming foams can exhibit characteristics having undesirable environmental impact. Of particular concern to the U.S. Environmental Protection Agency (EPA) are chemicals that are persistent, bioaccumulative, and potentially toxic (PBT). A major producer of AFFF, which was produced using the electrochemical fluorination process, has an agreement with the EPA to no longer manufacture a range of products that uses perfluoroctanyl sulfonate (PFOS) chemistry. This decision was based on data that suggest that these chemicals can exhibit a degree of toxicity and bioaccumulation not previously identified in addition to their known persistence to resist biodegradation. Other manufacturers of AFFF use a different process (e.g., telemerization) to produce fluorosurfactants used in their AFFF. Environmental characteristics of these agents have been under study by the industry and the EPA. Telmer-based agents have been found to be persistent but are not generally considered to be significant environmental toxins. Although there was concern that telemer-based AFFF could break down in the environment to perfluoroctanoic acid (PFOA) and would eventually be regulated by the EPA, the EPA decided that AFFF is not likely to be a source of PFOA. There are currently no restrictions on the production or sale of telemer-based AFFF in the United States. Users of AFFF should monitor these regulatory activities to determine the potential impact of regulations that may restrict the future use of AFFF and FFFP.

Foam solutions generally have a high biological oxygen demand (BOD); that is, they extract high levels of oxygen to break down. This is an issue both in the natural environment and where foam is discharged to wastewater treatment plants.

Foaming can occur in natural waterways and in treatment plants. In wastewater plants, foaming can cause bubbles to trap activated sludge, upsetting the normal operation of the plant. Before discharge of foam to a wastewater treatment plant, the plant operator should be contacted to discuss the type of foam, estimated BOD, total volume, and time over which the foam may be discharged to the plant. This should be done, where possible, as part of the emergency planning process.

In sufficient concentrations, foam may affect aquatic life. Where sufficiently diluted, foam solutions may not have an impact on aquatic life; however, localized concentrations in streams or ponds may create levels that are toxic to fish. Under emergency conditions, attempts should be made to prevent discharge to waterways (recognizing the primary concern of controlling the fire). Under controlled discharge conditions, prevention of foam discharge to natural waterways is appropriate.

The U.S. EPA requires reporting of certain releases of chemicals in broadly defined categories. The glycol ether category of chemicals was placed on the list of hazardous air pollutants under the 1990 Clean Air Act Amendments. These chemicals are used as solvents in certain fire-fighting foams. Although the EPA had originally assigned no reportable quantity for any glycol ethers, these chemicals still were designated as hazardous substances under the Comprehensive Environmental Response Compensation and Liability Act (CERCLA). In a 1995 clarification, the EPA decided not to assign reportable quantities to several broad categories of glycol ethers, including the commonly used butyl carbitol. As a result, fire-fighting foams containing solvents within the glycol ethers category no longer require reporting under CERCLA when discharged. Several manufacturers have replaced glycol ether solvents with alternative solvents that have less environmental impact. Manufacturers should be consulted regarding environmental aspects in general and for responsible use guidance.

Disposal Alternatives

The uncontrolled release of foam solutions to the environment should be avoided. Alternative disposal options include the following:

1. Discharge to a wastewater treatment plant with or without pretreatment
2. Discharge to the environment after pretreatment
3. Solar evaporation
4. Transportation to a wastewater treatment plant or hazardous waste facility

When foam is collected, any fuel from a fire should be separated. Dilution with water may be required before discharging foam to a wastewater treatment plant. Defoamers or other pretreatments may also be required. Any discharge to a wastewater treatment plant should be coordinated in advance with the treatment facility personnel. Foam manufacturers can advise on proper disposal techniques for specific circumstances.

SUMMARY

Fire-fighting foam is an effective agent for combating flammable and combustible liquid fuel fires. Various types of foam are applied in different manners, but all act to suppress flammable vapors and cool fuel surfaces to extinguish fires. Foam may have low- or high-expansion ratios. Foam may be proportioned using various methods in both fixed and mobile systems. Foam agents are used to combat fires in various hazards, including tank farms, airfields, aircraft hangars, and flammable liquid hazards. Foam may be discharged through fixed nozzles, sprinklers, hose line nozzles, and monitors.

Chapter 5

Fire Extinguisher Use and Maintenance

Mark T. Conroy

Chapter Contents

Matching Extinguishers to Hazards
Available Personnel—Ease of Use
Physical Environment
Health and Operational Safety Considerations
Operation and Use
Obsolete Extinguishers
Distribution of Fire Extinguishers
Inspection and Maintenance of Fire Extinguishers

Key Terms

AFFF fire extinguisher, carbon dioxide fire extinguisher, Class A fire, Class B fire, Class C fire, Class D fire, Class K fire, Classification of Hazards for Portable Fire Extinguishers, dry chemical fire extinguisher, dry powder fire extinguisher, halogenated agent fire extinguisher, portable fire extinguisher, water-based fire extinguisher

Before choosing an extinguisher, it is important to know the nature of the fuels present, who will use the extinguisher, the physical environment in which the extinguisher will be placed, and whether any chemicals present in the area will react adversely with an extinguishing agent. When choosing from among various extinguishers, one should consider whether it is effective on the specific hazards present, whether it is easy to operate, and what maintenance and upkeep it requires.

Related information can be found in the following chapters in this section: Section 17, Chapter 1, "Carbon Dioxide and Application Systems"; Section 17, Chapter 2, "Chemical Extinguishing Agents and Application Systems"; Section 17, Chapter 3, "Characteristics and Hazards of Water and Water Additives for Fire Suppression"; and Section 17, Chapter 4, "Foam Extinguishing Agents and Systems." See also Section 6, Chapter 9, "Metals."

MATCHING EXTINGUISHERS TO HAZARDS

By far the most important consideration when selecting extinguishers is the nature of the area to be protected. NFPA 10, *Standard for Portable Fire Extinguishers,* classifies fires as either Class A, Class B, Class C, Class D, or Class K, according to the fuel involved:

- Class A fires are fires in ordinary combustible mateirals, such as wood, cloth, paper, rubber, and many plastics.
- Class B fires are fires in flammable liquids, combustible liquids, petroleum greases, tars, oils, oil-based paints, solvents, lacquers, alcohols, and flammable gases.
- Class C fires are fires that involve energized electrical equipment.
- Class D fires are fires in combustible metals, such as magnesium, titanium, zirconium, sodium, lithium, and potassium.
- Class K fires are fires in cooking applicances that involve combustible cooking media (vegetable or animal oils and fats).

Extinguishers are classified for use on one or more of these types of fires.

In addition, the relative hazard in a building varies according to its fire load, or the amount of combustibles it contains. NFPA 10 establishes three types of hazards. A light, or low, hazard exists when there are few combustibles. Light-hazard occupancies include offices, churches, schoolrooms, assembly halls, and so on. An ordinary, or moderate, hazard exists when the combustibles present are substantial but ordinary in nature or where there are small quantities of combustibles capable of rapid fire growth. Examples of ordinary-hazard occupancies are mercantile storage and display areas, auto showrooms, and parking garages. Some offices, schools, and so on can contain a sufficient amount of combustible materials to be classified as ordinary hazard. An extra, or high, hazard exists in areas where there are substantial quantities of on-site combustibles whose nature or configuration could readily support rapid fire growth and large fire size, such as woodworking areas, aircraft servicing areas, and warehouses with high-piled combustibles.

Mark T. Conroy is a senior fire protection engineer for Brooks Equipment Company of Charlotte, North Carolina.

Hazard type is an important factor when selecting extinguishers. For example, a 2½ gal (9.5 L) water extinguisher with a 2-A rating is only suitable in low- and moderate-hazard areas. In a high-hazard area, an extinguisher with a minimum rating of 4-A is needed.

Class-A-rated extinguishers are used most often for ordinary building protection. Among the agents classified for Class A use are water, loaded stream, aqueous film-forming foam (AFFF), film-forming fluoroprotein foam (FFFP), multipurpose (ammonium-phosphate-base) dry chemical, and halogenated agent types. Due to the environmental problems associated with halons, however, they are no longer being produced and their use is being discouraged except in specific circumstances. Extinguishers containing halogenated agents called halocarbons have been introduced to replace halon extinguishers.

Class-A-rated extinguishers are sometimes not the only type needed for building protection. In most areas of a restaurant, for example, the principal combustibles are wood, paper, and fabrics. In the kitchen, however, the hazard of greatest concern is cooking media (vegetable oils and fats), which requires a Class-K-rated extinguisher. In hospitals, there is a general need for Class-A-rated extinguishers in rooms, corridors, and offices, but Class-B:C-rated extinguishers should be placed in laboratories, generator rooms, and areas where anesthetics are stored or used. In short, the extinguishers in any one area should correspond to the hazards of that area.

Class B fires are fires in flammable liquids. Class-B-rated extinguishing agents include carbon dioxide, dry chemicals, AFFF, FFFP, and halogenated agent types. There are three general types of flammable liquids fires: (1) fires in liquids of appreciable depth (deeper than ¼ in. [6.4 mm]), such as those in industrial dip tanks and quench tanks; (2) spill fires or running fires in liquids of a depth of ¼ in. (6.4 mm) or less; and (3) pressurized flammable liquid or gas fires from damaged vessels or product lines. Portable fire extinguishers should not be relied on when the surface area of an indoor open tank is in excess of 10 ft^2 (1 m^2); fires in such areas can give off so much heat and smoke that it is dangerous for anyone to remain in the area.

Pressurized flammable liquids and pressurized gas fires present special hazards. Only dry chemical type extinguishers have proved to be effective. In addition, special nozzles and higher rates of agent application are often required. Extinguishers for these types of fires should therefore be selected on the basis of manufacturers' recommendations. *No* attempt should be made to extinguish these fires unless there is reasonable certainty that the source of fuel can be shut off promptly.

Class-C-rated extinguishers contain extinguishing agents that are considered electrically nonconductive to the extinguisher operator while being discharged and are therefore preferred for fires in charged electrical equipment. They should be chosen based on the materials used in constructing the electrical equipment, the degree of agent contamination that can be tolerated, and the types of other combustibles in the area. Of these, the first is particularly important. For example, a power panel will contain more Class A insulating materials than an oil-filled transformer will, which will contain mostly Class B material. The agents classified for Class C use include carbon dioxide, dry chemicals, and the halogenated agent types.

Class D fires are fires in combustible metals. These require special extinguishing agents, known as dry powder.

Once an area has been analyzed for hazards, appropriate extinguishers can be chosen. For the Class A fire, three basic types of extinguishers can be used: water-based extinguishers, multipurpose (ammonium-phosphate-base) dry chemical extinguishers, or halogenated agent extinguishers. For Class B fires, there are carbon dioxide, dry chemical, halogenated agent, and AFFF and FFFP extinguishers. (Some small extinguishers are rated less than 5-B and, as indicated by their omission from Table 17.5.1, are not permitted as a required extinguisher.) For Class C fires there are carbon dioxide, dry chemical, or halogenated agent extinguishers. Water mist extinguishers have recently been reconsidered for use in the vicinity of live electrical equipment. The various types of extinguishing agents for Class D combustible metal fires are discussed separately. (See Section 6, Chapter 9, "Metals.")

AVAILABLE PERSONNEL—EASE OF USE

Before extinguishers are selected, consideration should be given to who will use them. Evaluation should include the potential user's physical abilities, reactions under stress, and previous training. Many firms have standardized their extinguishers so that employees need only learn one set of instructions. In companies employing trained fire brigades, there may be more variation.

An individual's emotional reaction to a fire will be greatly influenced by his or her familiarity with the extinguisher, experience in using it or observing its use, and self-confidence. Training is, therefore, very important. Many companies have employees practice with extinguishers when the units are scheduled for recharging. Employees should be adequately trained so they will not jeopardize their own safety and safety of others.

Sometimes, the size or weight of an extinguisher is important. Some extinguisher models have lightweight shells or use agents with more extinguishing capacity per unit of weight. A very common fire extinguisher holds 2½ gal (9.5 L) of water and weighs about 30 lb (13.6 kg). The weight of many extinguishers varies. For example, one manufacturer offers two dry chemical extinguishers with a rating of 40-B:C. The sodium-bicarbonate-based model has a 20 lb (9.1 kg) capacity and weighs 27 lb (12.3 kg), but the potassium-bicarbonate-based model has a 9 lb (4.1 kg) capacity and weighs only 14 lb (6.4 kg).

PHYSICAL ENVIRONMENT

Still another factor that influences extinguisher selection is the area in which the extinguishers will be placed. Is the extinguisher affected by extreme temperatures, for example? ANSI standards require evaluation of water-based extinguishers at temperatures between 40 and 120°F (4 and 49°C) and all other types between –40 and 120°F (–40 and 49°C).

Performance Standards for Fire Extinguishers:[1]

(a) Carbon Dioxide Types. ANSI/UL 154, *Standard for Carbon Dioxide Fire Extinguishers;* CAN/ULC-S503-M90, *Standard for Carbon Dioxide Hand and Wheeled Fire Extinguishers*

(b) Dry Chemical Types. ANSI/UL 299, *Standard for Dry Chemical Fire Extinguishers;* CAN/ULC-S504-M86, *Standard for Dry Chemical and Dry Powder Hand and Wheeled Fire Extinguishers*

If extinguishers are installed in areas subject to higher or lower temperatures, they should be listed for those areas or put in an enclosure where the proper temperature is maintained. Some

stored-pressure extinguishers for Class B fires use nitrogen rather than carbon dioxide as the pressurizing force. For units that must perform in temperatures as low as –65°F (–54°C), nitrogen pressurization is used.

Other conditions that may affect extinguisher performance are direct sunlight, snow, rain, airborne debris, and corrosive fumes. If extinguishers must be placed outdoors, installing them in cabinets and sheltered areas or placing a protective cover over them will help prevent damage or premature deterioration (Figures 17.5.1 and 17.5.2).

Corrosives can cause extinguishers to fail, and extinguishers capable of withstanding corrosive conditions are listed separately. For example, extinguishers that may be used in salt-air atmospheres appear under the heading "Marine Type, USCG." Where corrosive fumes exist at industrial sites, special analysis should be made before extinguishers are chosen.

Extinguishers may also be affected by the vibration found in places such as a drop forge or hammer mill, trains, vehicles, and power boats. In such cases, they should be of rugged design, mounted securely, and inspected at frequent intervals.

FIGURE 17.5.1 Cover Used to Protect Extinguishers That Are Mounted Outside from Substances That Would Interfere with Operation (Source: Ansul Incorporated)

HEALTH AND OPERATIONAL SAFETY CONSIDERATIONS

Potential health hazards should always be considered when selecting extinguishers. Manufacturers normally provide prominent labels of caution on extinguishers that could produce toxic vapors or decomposition vapors. Sometimes, however, the danger resides not in the extinguisher but in the area in which it will be used. Useful safeguards include posting warning signs at the entries to confined areas, providing extinguishers with long-range nozzles, installing special ventilation, or supplying employees in the area with self-contained breathing apparatus.

Most water-based extinguishers are rated only for Class A fires. AFFF and FFFP models are also rated for Class B fires. Class K fire extinguishers have water additives intended for fires

FIGURE 17.5.2 Surface-Mounted Extinguisher Cabinet with a Hinged Door (Source: Larsen's Manufacturing Company)

in commercial fryers. If the nonfoam/water types are used on Class B fires, the fire may flare up, spread, or injure the operator in some way. If water-based extinguishers are used on fires in or near live electrical equipment, the water stream may transmit an electric shock to the operator.

Although carbon dioxide is not itself toxic, it will not support life when used in concentrations high enough to extinguish a fire. (See Section 17, Chapter 1, "Carbon Dioxide and Application Systems.") If a carbon dioxide extinguisher is used in an unventilated area, it dilutes the oxygen supply, and those remaining in the area may become unconscious or even die if they do not receive oxygen. In addition, the thick cloud of condensing water vapor that forms upon discharge may cause persons to become disoriented.

Older carbon dioxide extinguishers may have metal horns that transmit a shock to the user when the horns touch live electrical equipment. These metal horns should be replaced with nonmetallic horns. Occasionally, the operator may receive a shock even when no contact has been made; these result from built-up static electricity and are generally more annoying than hazardous.

Dry chemical extinguishers are not considered toxic, but their discharge can be irritating if breathed for a long time. Monoammonium phosphate is the most irritating, followed by potassium-based agents. Sodium bicarbonate is the least irritating. If dry chemicals are discharged in a confined area, they may reduce visibility and cause disorientation. Because dry chemical agents are nonconductors, deposits left on electrical contacts can reduce or negate the ability of the contacts to conduct. They may also clog air conditioning and air cleaning filters if discharged nearby.

Multipurpose dry chemical (ammonium-phosphate-base) is acidic and, if mixed with even a small amount of water, will corrode some metals unless all agent residues are removed promptly and thoroughly. Finally, the initial discharge of agent from an extinguisher has considerable force. If it is aimed at close range at a small flammable liquid or grease fire, it can cause the fire to spread extensively before it can be brought under control.

Extinguishers containing halogenated agents such as halons (Halon 1301 or Halon 1211 or a mixture of these) or halocarbons (halocarbon agents include hydrochlorofluorocarbon [HCFC], hydrofluorocarbon [HFC], perfluorocarbon [PFC], and fluoroiodocarbon [FIC]) present some degree of toxicity under normal operating conditions. However, the decomposition products of these agents can be hazardous. When using these extinguishers in unventilated places, such as small rooms, closets, motor vehicles, or other confined spaces, it is best to avoid breathing the vapors or the gases produced by thermal decomposition.

Class D fires involving burning metal chips can be scattered if the full force of a dry powder extinguisher is used at close range. To avoid spreading the fire, the discharge lever should be squeezed slowly, beginning at a safe distance.

Virtually every fire produces toxic products of combustion, and some burning materials create highly toxic gases. Until the fire has been extinguished and the area well ventilated, it is important either to stay out of the area or to wear protective breathing apparatus.

OPERATION AND USE

Whether an extinguisher is effective often depends on who is using it. One person may be able to extinguish a fire that someone else, using the same equipment, may not. Many extinguishers discharge their entire contents in 8 to 15 seconds, leaving little time for experimentation. Occasionally, improper use of an extinguisher injures the operator and delays extinguishment.

There are several kinds of extinguishers. Because differences exist among extinguishers, it is imperative that people be trained to use them properly. Ideally, this includes the general public. In any case, fire fighters and others responsible for fire protection, such as industrial fire brigades, should be trained thoroughly in the operation and use of extinguishers.

Currently, listed fire extinguishers are classified into six major groups, based on the extinguishing medium each contains. They are (1) water-type, (2) carbon dioxide, (3) halogenated agent, (4) dry chemical, (5) foam, and (6) wet chemical. Dry powder for Class D fires receives special testing and listing based on specific combustible metals. Additionally, special extinguishers containing wet chemical are tested and listed for cooking oil fires that could occur in commercial fryers. Information about each of these can be found in the following subsections and in Table 17.5.1.

In addition, extinguishers that are no longer manufactured may still be found in some areas. Some information on them is provided under the heading "Obsolete Extinguishers."

Water-Based Extinguishers

Water-based extinguishing agents include water, antifreeze, loaded stream, wetting agent, wet chemical, and foam. All except AFFF, FFFP, and wet chemical are for use on Class A fires only. Antifreeze, loaded stream, AFFF, wetting agent, and wet chemical all use water as a base to which chemicals are added to improve the extinguisher's performance. Both antifreeze and loaded stream models are specially treated to withstand low temperatures; the additive in loaded stream extinguishers is an alkali metal-salt solution. In wetting agents, a material is added to reduce the surface tension of the water so that it will spread and penetrate better. Wet chemicals include, but are not limited to, aqueous solutions of potassium acetate, potassium carbonate, potassium citrate, or combinations of these materials.

Originally, water-based extinguishers were of three basic designs: (1) stored-pressure, (2) pump tank, and (3) inverting. In 1969, however, the manufacture of all inverting extinguishers was discontinued. Consequently, the soda-acid and foam agents used exclusively in inverting extinguishers also became obsolete. The two designs that remain, stored-pressure and pump tank, are discussed later.

If ordinary, or nonfoam, water-based extinguishers are used on flammable liquids or electrical fires, they can spread the fire, injure the operator, or both. After activating an extinguisher, the operator should point the stream at the base of the flames and work from side to side or around the fire. When flames are high, the range of the stream (about 30 ft [9 m]) should be used to best advantage. As the flames diminish, it is possible to move closer and change the solid stream to a spray by holding a fingertip over the end of the nozzle. A spray stream is more effective on burning embers. Deep-seated smoldering or glowing areas should be wetted thoroughly. If necessary, a hand tool should be used to poke apart burning materials to do this.

Stored Pressure. For the capacities, ratings, discharge times, stream range, and temperature requirements of the various stored-pressure water-based extinguishers available, see Table 17.5.1. The most common stored-pressure water-based extinguisher contains 2½ gal (9.5 L) and weighs about 30 lb (13.6 kg). It can be operated intermittently, is rechargeable, and has a comparatively long stream range and discharge time. It consists of a single chamber that contains both the agent and expellant gas. The head assembly includes a siphon tube, a combination carrying handle/operating lever, a discharge valve, an air valve and pressure gauge, a discharge hose, and a nozzle (Figure 17.5.3). The extinguisher is pressurized with air or inert gas by means of an automobile-tire-type valve. Charging pressures range from 90 to 125 psi (620 to 862 kPa). A "fill mark" is stamped on many older stored-pressure water-based extinguishers about 6 in. (152.4 mm) from the top; when refilling, this level should never be exceeded. Some models use a special tube device to prevent overfilling.

In most models, the operating lever is locked by a ring pin that prevents accidental discharge. To activate the extinguisher, set it on the ground. Hold the combination handle loosely in one hand and pull out the ring pin or release a small latch with the other hand. Then grab the hose in one hand and squeeze the discharge lever with the other.

Pump Tanks. Two different types of pump tanks are available: one is cylindrical, and the other is made to be used as a backpack. The sizes, ratings, discharge times, stream ranges, and weather requirements of the various pump tanks are given in Table 17.5.1. The cylindrical model has carrying handles either attached to the container or built into the pump handle, and the water is discharged by a built-in, hand-operated vertical piston pump with an attached short rubber hose. The pump is double-acting and discharges water on both the up and the down strokes (Figure 17.5.4). The cylindrical models are available with copper, steel, or plastic shells.

To operate a cylindrical pump tank, place it on the ground and put one foot on the extension bracket at the base to steady the unit. To force water through the hose, pump the handle up and down. Cylindrical pump tanks have two characteristics that may be slight disadvantages: (1) to move the extinguisher, the operator must stop pumping, and (2) the force, range, and duration of the stream are dependent, in part, on the operator.

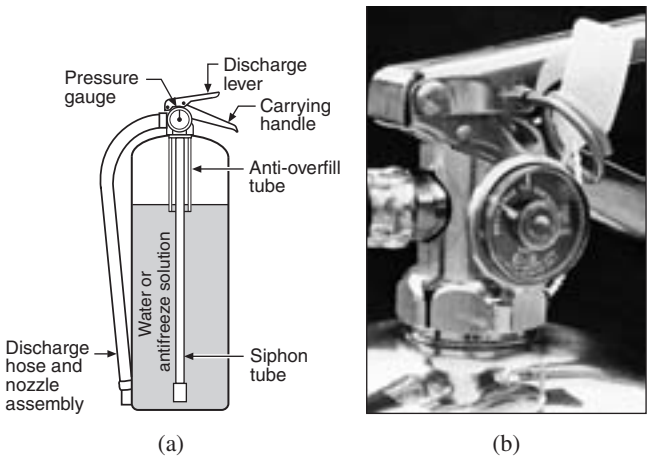

FIGURE 17.5.3 (a) Stored-Pressure Water Fire Extinguisher; (b) Close-Up of Head Assembly (Photo courtesy of Badger Fire Protection)

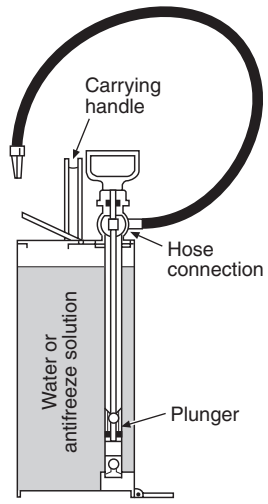

FIGURE 17.5.4 Cylindrical Pump Tank Fire Extinguisher

Cylindrical pump tanks can be filled with either plain water or antifreeze charges recommended by the manufacturer. Common salt or other freezing depressants might corrode the extinguisher or damage the pump assembly. Copper- or plastic-shell models do not corrode as easily as steel and are recommended for use with antifreeze.

Backpack pump tanks are used chiefly for fighting outdoor brush and wildland fires. As the name implies, they are carried on the operator's back. The most common backpack pump tank holds 5 gal (19 L) and weighs about 50 lb (23 kg) when full (Figures 17.5.5 and 17.5.6). Although listed, backpack pump tanks do not have a designated rating. Generally, the tank is filled with plain water, though antifreeze agents, wetting agents, and other special water-based agents may be used. The tank may be made of fiberglass, stainless steel, galvanized steel, or brass, or it may be a flexible water bag. Some models have a large opening with a tight-fitting filter that allows speedy refilling and prevents foreign matter from entering and clogging the pump.

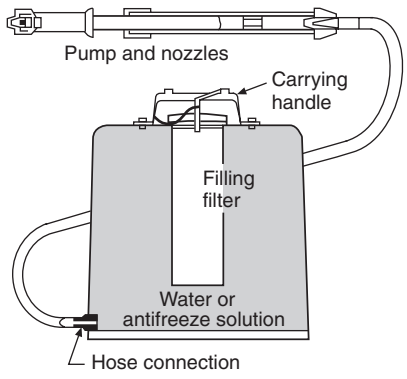

FIGURE 17.5.5 Backpack Pump Tank Fire Extinguisher

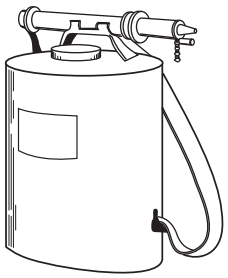

FIGURE 17.5.6 Backpack Pump Tank Fire Extinguisher with 5 gal (19 L) Tank Made of Fiberglass and with Trombone-Type Pump Action at Nozzle

This design also permits refilling from sources such as ponds, lakes, and streams.

The most common backpack pump tank has a trombone-type, double-acting piston pump connected to the tank by a short length of rubber hose. To discharge the device, the operator holds the pump in both hands and moves the piston back and forth. Other models have compression pumps mounted on the right side of the tank. In these, the expellant pressure is built up with about ten strokes of the handle and then maintained by slow, easy pumping. The left-hand controls discharge by means of a lever-operated shutoff nozzle at the end of the hose.

Water Mist. The water mist extinguisher is a fairly recent development. Currently it is available in the 2½ gal (9.5 L) size, and it is similar to the stored-pressure water extinguisher, but has a wand with a special nozzle, which disperses the water into a fine spray. The wand allows the operator to stand at a safe distance from the fire and deliver the low velocity water mist to the burning materials. The mist does not conduct electricity, but operators need to be cautious if pooling of the water occurs near energized electrical equipment, since pooled water will conduct electricity. Besides the advantage of being nonconductive while in a mist, the water can cool and soak the burning materials, helping to extinguish the fire and prevent reflash.

Carbon Dioxide Extinguishers

Carbon dioxide is a compressed gas agent and is commonly referred to as CO_2. Although rated for use on Class B and C fires, it is often effectively used on small Class A fires.

Carbon dioxide prevents combustion by displacing the oxygen in the air surrounding a fire and by cooling the fuel. Its principal advantage is that it does not leave a residue, a consideration that may be important in laboratories and in areas in which food is prepared or electronic equipment is present. The rapid expansion and pressure reduction of the pressurized liquid carbon dioxide in the cylinder results in the cooling and refrigeration effect. However, carbon dioxide extinguishers have a relatively short range because the agent is expelled in the form of a gas/snow cloud; they are also affected by wind or drafts. If a carbon dioxide extinguisher is used in a confined or unventilated area, precautions should be taken so that people are not overcome from lack of oxygen. For the various sizes, stream ranges, discharge times, temperature requirements, and ratings of carbon dioxide extinguishers available, see Table 17.5.1.

In all carbon dioxide extinguishers, the agent is retained as a liquid at 800 to 900 psi (5516 to 6205 kPa) at temperatures below 88°F (31°C), and is self-expelling. The extinguisher design consists of a pressure cylinder, or shell; a siphon tube and valve for releasing the agent; and a discharge horn or horn-hose combination. The siphon tube extends from the valve almost to the bottom of the shell, so that normally only liquid carbon dioxide reaches the discharge horn until about 80 percent of the content has been released. The remaining 20 percent enters the siphon tube as a gas. The rapid expansion from liquid to gas when most of the carbon dioxide is discharged converts about 30 percent of the liquid into a very cold "snow" or "dry ice," which then sublimes into a gas.

To operate a carbon dioxide extinguisher, hold it upright by its carrying handle, remove the locking pin, and squeeze the operating lever (Figure 17.5.7). In smaller portable models, the discharge horn often is connected to the valve assembly by a metal tube/swing joint connector, and the models may be operated with one hand. Larger portable models require two hands, and their discharge horns are attached to a length of hose. Wheeled extinguishers have a cylinder valve with a locking ring pin, a long hose of 15 to 40 ft (4 to 12 m), and a projector that consists of a horn, a long handle, and a control valve. Once the cylinder valve has been opened, the operator controls the discharge with the valve on the projector handle.

Care should be taken not to touch the discharge horn during operation, because it can become extremely cold. If carbon dioxide extinguishers are used in subzero temperatures, the valve must remain open at all times or the discharge may become blocked unless a special low-temperature charge has been added.

Because carbon dioxide extinguishers have a limited range and are affected by draft or wind, they should be applied as close to the base of a fire as possible. Agent should be applied even after the flames have been extinguished to allow time for cooling and to prevent reflash. Due to the relatively short discharge range, carbon dioxide extinguishers are of limited effectiveness on large Class B fires. For flammable liquid fires, the usual method is to begin at the near edge and sweep from side to side toward the back of the fire. However, there is another method called "overhead application." In this method, the discharge horn is pointed downward at an angle of about 45 degrees toward the center of the burning area. Usually, the horn is not moved, and the agent spreads out in all directions. The side-to-side sweeping method may give better results on spill fires, while the overhead method may be best for confined fires.

For fires involving electrical equipment, the discharge should be directed at the source of the flames. It is important to deenergize the equipment as soon as possible to prevent possible reignition.

Halogenated Agent Extinguishers

Halogenated agents fall into two categories. These categories are (1) halons, which include bromochlorodifluoromethane (Halon 1211), bromotrifluoromethane (Halon 1301), and mixtures of

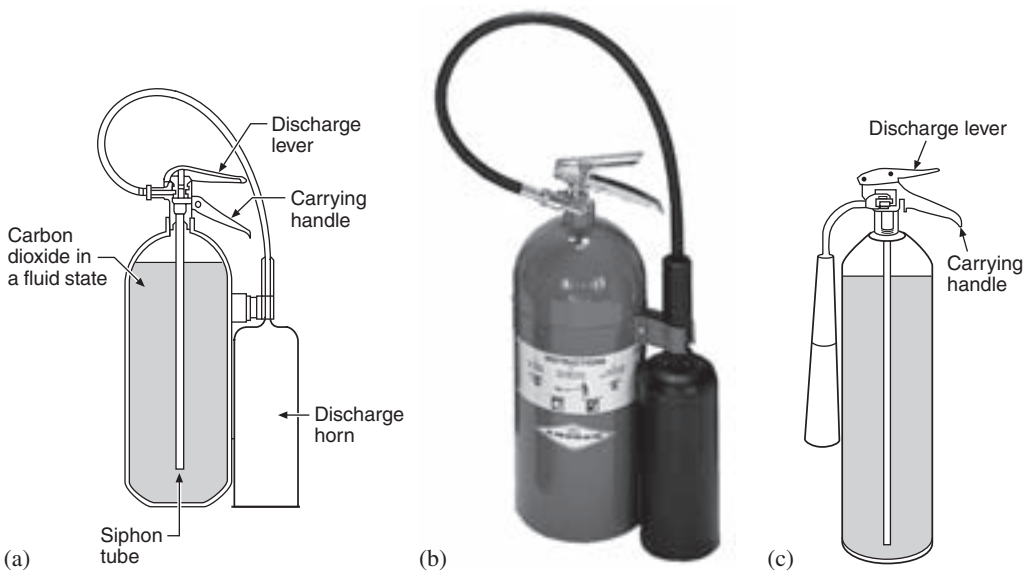

FIGURE 17.5.7 Carbon Dioxide Fire Extinguisher (Photo courtesy of Amerex)

Halon 1211 and Halon 1301; and (2) halocarbons, which include hydrochlorofluorocarbon (HCFC), hydrofluorocarbon (HFC), perfluorocarbon (PFC), and fluoroiodocarbon (FIC) (Figure 17.5.8). These extinguishing agents are often called "clean agents" because they leave no residue.

Halogenated agents not only leave no residue, but are virtually noncorrosive and nonabrasive, and are effective on Class A and B fires. With the exception of Halon 1301, these extinguishing agents are streaming agents because they discharge as a liquid stream from the extinguisher. Because of their physical properties, they need no cold weather protection. When halogenated agents are used on a fire, the decomposition products are a concern to the user and people in the area as the products are toxic. Normally, only small quantities of these chemicals are formed, and, as a warning of their presence, they give off an acrid odor. Using a halogenated agent extinguisher on a large intense fire such as a large flammable liquid spill fire will produce large quantities of decomposition products. Although halogenated agents are retained under pressure in a liquid, a booster charge of nitrogen or inert gas is added to ensure proper operation.

The most common application for halogenated agent extinguishers is for the protection of delicate electronic equipment such as in computer rooms. Since there are production restrictions on the chemical Halon 1211 due to environmental concerns, the halocarbon agent extinguishers have been installed where Halon 1211 was previously the preferred extinguishing agent. Due to these concerns, Halon 1211 use is being discouraged except in specific circumstances. Halon 1211 should never be inadvertently discharged into the atmosphere or used for training purposes.

Dry Chemical Extinguishers

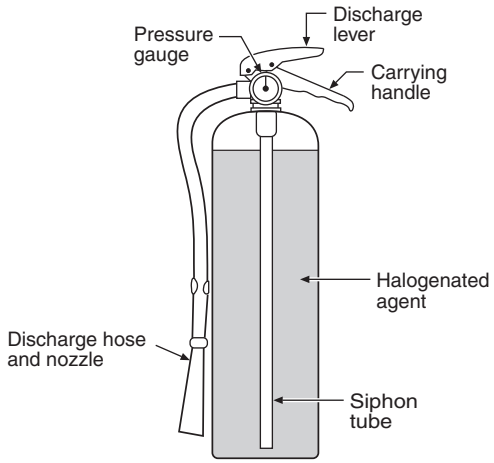
There are two basic kinds of dry chemical agents: (1) ordinary dry chemicals, which are rated B:C and include sodium bicarbonate, potassium bicarbonate (Purple K), urea-potassium-bicarbonate (Monnex®), and potassium-chloride-based agents; and (2) multipurpose dry chemical, ammonium-phosphate-based agent, which achieves the A:B:C rating. There are also two basic designs of dry chemical extinguishers: one uses a separate pressurized cartridge or cylinder of gas to expel the agent *(cartridge- or cylinder-operated extinguisher),* and the other pressurizes the agent chamber for the same purpose (stored pressure extinguisher). The stored-pressure is the most widely used. It is best suited to areas where infrequent use is anticipated and where skilled personnel with professional recharge equipment are available. By contrast, the cartridge-operated type can be refilled quickly in remote locations without special equipment.

The size, rating, and method of operation of any particular extinguisher depends both on its design and on the agent. Table 17.5.1 gives specific information on the capacities, ratings, discharge times, and stream ranges of the dry chemical extinguishers now available.

In areas where Class A:B:C protection is needed, water-based extinguishers may be omitted if multipurpose dry chemical extinguishers are installed. However, they are not replacements for water-based extinguishers under all conditions.

When choosing a dry chemical extinguisher for Class C protection, it is important to remember that potassium chloride and ammonium phosphate are more corrosive than the other dry chemicals.

The various dry chemical extinguishers possess certain common characteristics. Dry chemical extinguishers can be discharged while being carried, and all can be stopped from discharging momentarily to conserve the agent. Dry chemicals also can be used simultaneously with water, either straight stream or spray. Special long-range nozzles may be necessary for some very hazardous areas, such as those with pressurized gases and flammable liquids. Dry chemicals are dispersed less easily by wind than carbon dioxide, though dry chemicals can be more



(a)

(b)

FIGURE 17.5.8 Halogenated Agent Stored-Pressure Fire Extinguisher (Source: *NFPA Guide to Portable Fire Extinguishers,* NFPA, 2003, Figure 1-29. Reproduced courtesy of Jones and Bartlett Publishers.)

effective during windy conditions if the wind is at the operator's back.

If dry chemicals are used on wet, energized electrical equipment, such as rain-soaked utility poles, high-voltage switch gear, and transformers, electrical leakage problems may be aggravated. The combination of dry chemical with moisture provides an electrical path that can keep insulation from being effective. In such cases, all traces of dry chemical should be removed after the fire has been extinguished.

Although all dry chemicals are treated for water repellancy, they may harden if exposed to water. It is therefore important to avoid exposing them to any moisture during storage, handling, and recharging. Manufacturers' specifications must be followed carefully.

Ordinary dry chemicals are rated for use on Class B:C fires, but they may be used on Class A fires to knock down flames rapidly until something more suitable can be obtained. When used on flammable liquid fires, the stream should be directed at the base of the flame. Attack the fire near the edge, and move the discharge toward the back of the fire while sweeping the nozzle from side to side. Do not direct the initial discharge directly at the burning surface at close range (less than 5 to 8 ft [1.5 to 2.4 m]), because the high velocity of the stream may splash and spread the burning material.

Multipurpose dry chemical extinguishers should be used in exactly the same manner as ordinary dry chemical agents on Class B fires. On Class A fires, the multipurpose agent softens and sticks to hot surfaces. In this way, it forms a coating that smothers and isolates the fuel from the fire. The agent itself has little cooling effect and cannot penetrate below the burning surface. For this reason, it may be hard to extinguish deep-seated fires unless the agent is discharged below the surface or the material is broken apart and spread out.

Dry chemicals extinguish fires by interfering with the propagation of the combustion chain reaction, which reduces the concentration of "free" radicals present within the flames. The dry chemical thermally decomposes and prevents the flaming process from continuing. In other words, discharge of dry chemical into the flames prevents reactive particles from coming together and continuing the combustion chain reaction.

Cartridge-Operated Extinguishers. Cartridge-type dry chemical extinguishers have a chamber in which the agent is kept at atmospheric pressure; the chamber has a large opening at the top through which the extinguisher may be filled. Attached to the side of the extinguisher, on most models, is a small cartridge of propellant gas, either carbon dioxide or nitrogen, threaded into a puncture valve and gas tube assembly. The agent is discharged through a hose attached to the bottom edge of the shell, and the discharge is controlled by a squeeze-grip nozzle at the end of the hose (Figure 17.5.9). Cartridge-operated extinguishers should be recharged once they have been pressurized. Even if no agent has been released, the propellant gas can leak away in several hours.

To activate a cartridge-operated extinguisher, hold it upright or place it on the ground. Remove the nozzle from its holder, and hold it in one hand while first pushing down the puncture lever before squeezing the nozzle. Pushing the puncture lever releases the propellant from the cartridge and pressurizes the agent cylinder. On some models, it may be necessary to remove a locking pin before pushing the puncture lever. This operation requires two hands, one to hold the device and the other to release and direct the discharge. Do not stand directly over the extinguisher when pressurizing it.

Stored-Pressure Extinguishers. Dry chemical extinguishers with this expellant method are available in both rechargeable and disposable shell models. Most disposable models have a

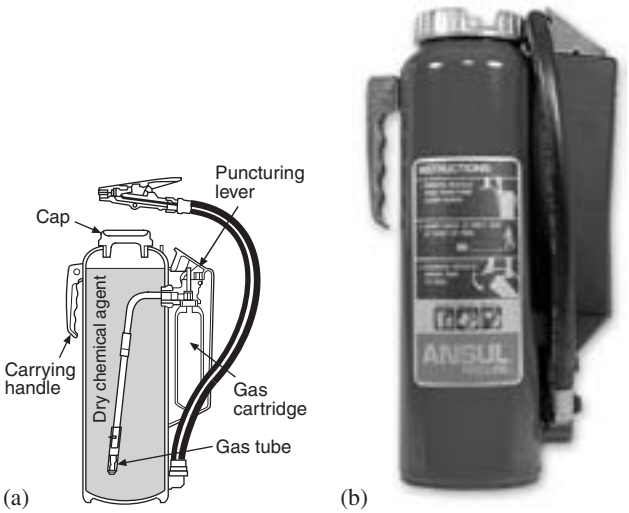


FIGURE 17.5.9 Cartridge-Operated Dry Chemical Fire Extinguisher (Photo courtesy of Ansul Incorporated)

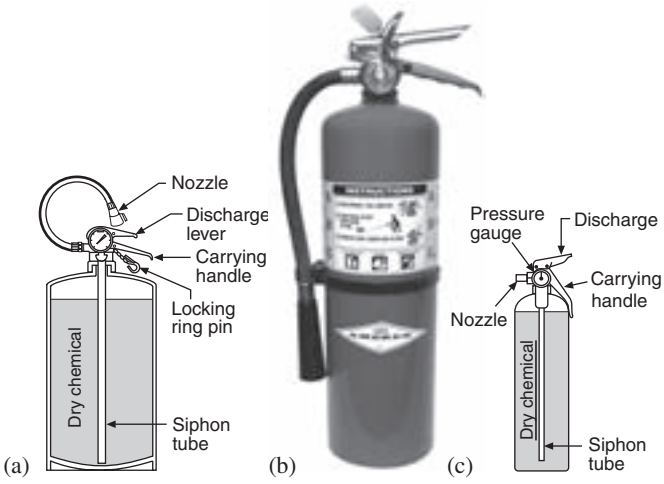

FIGURE 17.5.10 Stored-Pressure Dry Chemical Fire Extinguisher (Photo courtesy of Amerex)

disposable, factory-sealed cylinder containing agent and propellant gas that is threaded into the valve and nozzle assembly. Some small models are designed so that the entire device can be discarded after use. Once this type of device has been used, it should be replaced, even if only a small amount of agent has been discharged, because the propellant gas will leak, leaving no pressure to discharge to agent.

Rechargeable stored-pressure extinguishers come in two types. In both, the agent and the propellant gas are in the extinguisher shell. When the extinguisher is activated, the agent is forced up the siphon tube, where its release is controlled by the operator. One type of extinguisher has a threaded valve assembly and combination carrying handle/operating lever that screws into an opening on the top of the shell. To activate it, release the locking device and squeeze the operating lever (Figure 17.5.10). On smaller sizes of this extinguisher, only one hand is needed to operate the device because the nozzle is part of the valve assembly. Larger sizes require two hands for operation, one to squeeze the lever and carry the device, and the other to direct the agent discharge from the hose.

The other rechargeable stored-pressure dry chemical extinguisher (pre-1975) has a release lever and a hose attached to the cap assembly that covers the fill opening. The hose has a squeeze-grip nozzle for controlling the discharge. To activate it, pull the ring pin and push down the release lever. The agent will travel down the hose to the nozzle, where its discharge can be controlled by squeezing the nozzle. Two hands are needed to operate this extinguisher, one to carry the extinguisher, and the other to release and aim the discharge stream.

Dry Powder Extinguishers

Dry powder extinguishers are intended for use on Class D fires, which involve combustible metals. The agent and method of application should be chosen according to manufacturers' recommendations. The agent may be applied to the fire from an extinguisher or with a scoop and shovel, depending on the type of both agent and metal. In any case, the agent should be applied so that it covers the fire and provides a smothering blanket. More agent may be necessary on hot spots. Care should be taken not to scatter the burning material, which should be left undisturbed until it has cooled.

If there is a fire in finely divided combustible metal or combustible metal alloy scrap that is wet, or if such a fire is wetted with water or water-soluble machine lubricants, the metal may burn rapidly and violently. Such fires may become so hot that it is impossible to get close enough to apply extinguishing agent. If burning metal is on a combustible surface, it should be covered with dry powder. Then a 1- or 2-in. (25- or 50-mm) layer of powder should be spread out nearby, and the burning metal shoveled into it.

One cartridge-operated portable (30 lb [13.6 kg]) dry powder extinguisher currently is available (Figure 17.5.11). Wheeled models are available in 150- and 350-lb (68- and 159-kg) sizes. The extinguishing agent is sodium chloride with additives that render it freeflowing. Thermoplastic material also is added to bind the sodium chloride particles into a solid crust when applied to a fire. With the nozzle fully open, the portable model has a range of 6 to 8 ft (1.8 to 2.4 m).

The method of agent application depends on the type, quantity, and physical form of the burning metal. If the fire is very hot, discharge should begin at the maximum range with the nozzle fully open. Once control is established, the nozzle should be partly closed to produce a soft, heavy flow so that complete coverage can be accomplished at close range. More complete details should be obtained from the manufacturer.

In bulk form, dry powder agents are available in 40- or 50-lb (18- or 23-kg) pails and 350 lb (159 kg) drums. The two most common agents are sodium chloride and G-1 powder. The latter consists of graded, granular graphite to which compounds containing phosphorous have been added. The sodium chloride can be used in an extinguisher or applied by hand. The G-1 agent must be applied by hand. When G-1 is applied to a metal fire, the heat of the fire causes the phosphorous compounds to generate vapors that blanket the fire and prevent air from reaching the

burning metal. The graphite, being a good conductor of heat, cools the metal.

Aqueous Film-Forming Foam (AFFF) and Film-Forming Fluoroprotein Foam (FFFP) Extinguishers

AFFF and FFFP are extinguishing agents that contain an aqueous film-forming surfactant. When added to water, AFFF and FFFP form solutions that create a foam when discharged through an aspirating nozzle. On Class A fires, these agents both cool and penetrate to reduce temperatures below the ignition level. On Class B fires, they act as a barrier to exclude oxygen from the surface of the fuel.

AFFF and FFFP currently are available in 2½ gal (9.5 L) stored-pressure models rated at 3-A:20-B. They discharge their contents in approximately 50 seconds and have a range of 20 to 25 ft (6 to 8 m). They should be installed only in areas not subject to temperatures below 40°F (4°C). There is also a 33 gal (125.4 L) unit with 20-A:160-B ratings.

These types of extinguishers closely resemble the stored-pressure water extinguisher, except for their special aspirating nozzles (Figure 17.5.12). On flammable liquid fires of appreciable depth, the best results are obtained when the discharge is played against the inside of the back wall of the vat or tank just above the burning surface, which should permit the natural spread of the foam back over the burning liquid. If this is not possible, the operator should stand far enough away from the fire to allow the foam to fall lightly on the burning surface instead of splashing it into the burning liquid. Where possible, the operator should walk around the fire while directing the stream to get maximum coverage during discharge. For flammable liquid spill fires, the foam may be flowed over a burning surface by bouncing it off the floor just in front of the burning area. The operator should never turn his or her back on the fire, as unburned fuel may reignite. For fires in ordinary combustibles, the foam may be used to coat the burning surface directly. Foam is not effective on flammable liquids and gases escaping under pressure, nor is it suitable for fires involving ethers, alcohols, esters, acetone, lacquer thinners, carbon disulfide, and other flammable liquids that either break down or penetrate the foam blanket.

OBSOLETE EXTINGUISHERS

In 1969, the manufacture and testing of all inverting-type extinguishers—soda acid, chemical foam, and cartridge-operated water and loaded stream—was halted in the United States. It was not only the difficult and unorthodox "upside-down" method of actuation that brought about the discontinuance of these extinguishers. Of greater importance was the fact that, after 10 to 15 years, many inverting types tended to fail the minimum test pressure requirements of NFPA 10 (original factory test pressure). When pressurized, the failure record, including hydrostatic test failures, was alarmingly high. Since the inverting types are not normally pressurized, potential failures generally are not evident until the time of operation or hydrostatic testing.

When inverted, normal operating pressures are about 100 psi (690 kPa). Should the discharge elbow or hose become blocked, however, pressures in excess of 300 psi (2069 kPa) may occur. Container failures can injure the operator seriously.

NFPA 10 was revised in 1978, and stated that extinguishers with copper or brass shells joined by soft solder or rivets could no longer be hydrostatically tested, which would result in their removal from use within five years of the latest hydrostatic test date. Reliability and safety of this type of construction could not be determined by standard hydrostatic test procedures.

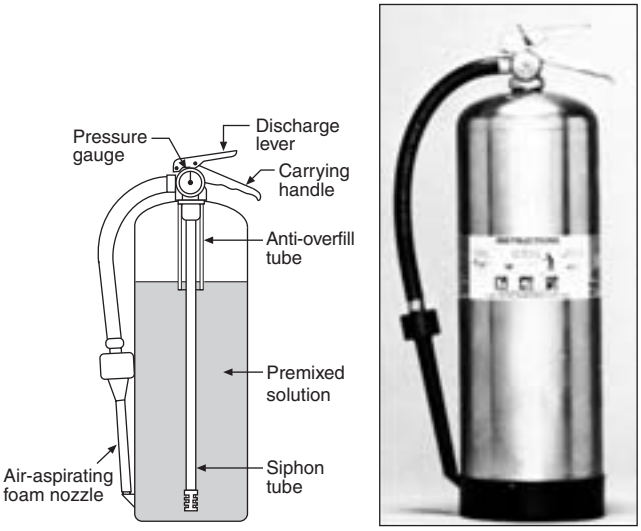

FIGURE 17.5.12 Aqueous Film-Forming Foam (AFFF) Extinguisher (Photo courtesy of Amerex)

In 1978, NFPA 10 called for the removal from service, by or before 1983, of all riveted and soft-solder copper and brass shell extinguishers of the inverting type. The one exception is stainless-steel shells and brass shells that are brazed, as opposed to soft-soldered. Also in 1978, stored-pressure water and/or antifreeze fiberglass shell types were required to be removed from service immediately because they had been recalled by the manufacturer. The following types of fire extinguishers are considered obsolete and should be removed from service:

- Soda acid
- Chemical foam (excluding film-forming agents)
- Vaporizing liquid (e.g., carbon tetrachloride)
- Cartridge-operated water
- Cartridge-operated loaded stream
- Copper or brass shell (excluding pump tanks) joined by soft solder or rivets
- Carbon dioxide extinguishers with metal horns
- Solid charge–type AFFF extinguishers (paper cartridge)
- Pressurized water fire extinguishers manufactured prior to 1971
- Any extinguisher that must be inverted to operate
- Any dry chemical extinguisher with a stainless steel shell
- Any stored pressure extinguisher manufactured prior to 1955
- Any extinguisher with a 4B, 6B, 8B, 12B, or 16B fire rating
- Stored-pressure water extinguishers with fiberglass shells (pre-1976)
- Any extinguisher that can no longer be serviced in accordance with the manufacturer's maintenance manual

Vaporizing liquid extinguishers with CCl_4 (carbon tetrachloride) and CBM (chlorobromomethane) became obsolete in the late 1960s. The toxic properties of these agents expose the operator to unwarranted health hazards, and their use was supplanted by safer, more effective extinguishers. In 2007, NFPA 10 called for the removal from service, at the next six-year maintenance interval or the next hydrostatic test interval, all dry chemical stored pressure extinguishers that were manufactured prior to October 1984.

DISTRIBUTION OF FIRE EXTINGUISHERS

No matter how carefully extinguishers are chosen to match the hazards of an area and the ability of the people who will use them, they will not be effective unless they are readily available. Sometimes extinguishers are kept at hand, as in welding operations, but, more often, one has to travel from the fire to the extinguisher and back before beginning to put out the fire. In such cases, travel distance to the nearest extinguisher is very important. Travel distance is the actual distance around partitions, through doorways and aisles, and so on that someone must walk to reach the extinguisher.

When placing extinguishers, select locations that provide uniform distribution, easily accessible and relatively free from temporary blockage, near normal paths of travel, near exits and entrances, free from the potential of physical damage, and readily available.

Mounting Extinguishers

If an extinguisher falls, it may injure someone or be so damaged that it must be replaced. Extinguishers should be mounted on walls or columns by securely fastened hangers so that they are supported adequately. Some extinguishers are mounted in cabinets or wall recesses. The operating instructions should always face outward, and the extinguisher should be placed so that it can be removed easily. Cabinets should be kept clean, dry, and ventilated if installed in outdoor locations.

Where extinguishers may become dislodged, brackets specifically designed to cope with this problem are available. In areas where they are subject to physical damage, such as warehouse aisles, protection from impact is important. In large open areas, such as aircraft hangars, extinguishers may be mounted on moveable pedestals or wheeled carts. To maintain some pattern of distribution and specify intended placement, locations should be marked on the floor.

NFPA 10 specifies floor clearance and mounting heights, based on extinguisher weight, as follows:

1. Extinguishers with a gross weight not exceeding 40 lb (18 kg) should be installed so that the top of the extinguisher is not more than 5 ft (1.5 m) above the floor.
2. Extinguishers with a gross weight greater than 40 lb (18 kg), except wheeled types, should be installed so that the top of the extinguisher is not more than 3½ ft (1 m) above the floor.
3. In no case can the clearance between the bottom of the extinguisher and the floor be less than 4 in. (100 mm).

When extinguishers are mounted on industrial trucks, vehicles, boats, aircraft, trains, and so on, special mounting brackets, available from the manufacturer, should be used. It is also important that the extinguisher be located at a safe distance from the hazard so that it will not become involved in the fire.

Extinguisher Distribution for Class A Combustibles

Table 17.5.2 is a guide to determining the minimum number and rating of extinguishers for Class A fires needed in any particular area. Sometimes extinguishers with ratings higher than those indicated in Table 17.5.2 may be necessary because of process hazards, building configuration, and so on, but in no case should the recommended maximum travel distance be exceeded.

The first step when calculating how many Class A extinguishers are needed is to determine whether an occupancy is light-, ordinary-, or extra-hazard, according to NFPA 10. Next, the extinguisher rating should be matched with occupancy hazard to determine the maximum area that an extinguisher can protect. The maximum travel distance, or actual walking distance, allowed for Class A extinguishers is 75 ft (23 m).

The figure of 11,250 ft^2 (1044 m^2) in Table 17.5.2 is used instead of 12,000 ft^2 (1115 m^2), which would appear to be a normal progressive increment. This is because the largest square inside a circle with a 75 ft (23 m) radius would be 106 ft × 106 ft (32 m × 32 m), or 11,250 ft^2 (1044 m^2). Because buildings are usually rectangular, this is the largest open area one can have and still comply with the 75-ft (23-m) travel distance rule (Figure 17.5.13).

The area that can be protected by one fire extinguisher with a given A rating is shown in Table 17.5.3. These values are determined by multiplying the maximum floor area per unit of A shown in Table 17.5.3 by the various A ratings until a value of 11,250 ft^2 (1044 m^2) is exceeded.

NFPA 10 also provides that up to half of the complement of extinguishers for Class A fires, as specified in Table 17.5.2, may be replaced by uniformly spaced small-hose (1½ in. [38 mm]) stations. However, the hose stations and extinguishers should be located so that the hose stations do not replace more than every other extinguisher.

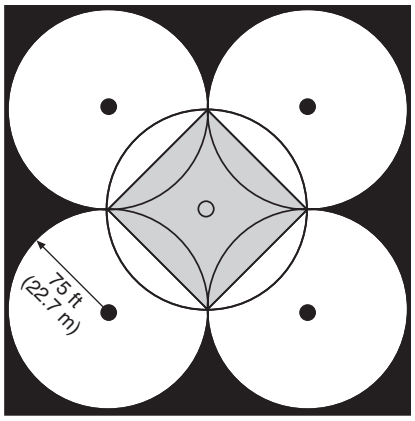

FIGURE 17.5.13 Maximum Extinguisher-Protected Area. The shaded square shows the maximum area (11,250 ft^2 [1044 m^2]) that an extinguisher can protect within the limits of a 75 ft (23 m) radius.

The following examples illustrate the number and placement of extinguishers according to occupancy hazard and extinguisher rating. The sample building is 150 ft by 450 ft (46 m by 137 m), which gives a floor area of 67,500 ft^2 (6270 m^2). Although several different ways of placing extinguishers are given, a number of other locations could have been used with similar results.

The first example demonstrates placement at the maximum protection area limits (11,250 ft^2 [1044 m^2]) allowed per extinguisher in NFPA 10 for each class of occupancy. Installing extinguishers with higher ratings will not affect distribution or placement.

TABLE 17.5.2 Fire Extinguisher Size and Placement for Class A Hazards

	Light (Low) Hazard Occupancy	*Ordinary (Moderate) Hazard Occupancy*	*Extra (High) Hazard Occupancy*
Minimum rated single extinguisher	2-A[a]	2-A[a]	4-A[b]
Maximum floor area per unit of A	3,000 ft^2	1,500 ft^2	1,000 ft^2
Maximum floor area for extinguisher	11,250 ft^2	11,250 ft^2	11,250 ft^2
Maximum travel distance to extinguisher	75 ft	75 ft	75 ft

[a]Up to two water-type extinguishers, each with 1-A rating, can be used to fulfill the requirements of one 2-A rated extinguisher.
[b]Two 2½ gal (9.46 L) water-type extinguishers can be used to fulfill the requirements of one 4-A rated extinguisher.
For SI units: 1 ft = 0.305 m; 1 ft^2 = 0.0929 m^2.

TABLE 17.5.3 Maximum Area in Square Feet to Be Protected per Extinguisher

Class A Rating Shown on Extinguisher	*Light (Low) Hazard Occupancy*	*Ordinary (Moderate) Hazard Occupancy*	*Extra (High) Hazard Occupancy*
1-A	—	—	—
2-A	6,000	3,000	—
3-A	9,000	4,500	—
4-A	11,250	6,000	4,000
6-A	11,250	9,000	6,000
10-A	11,250	11,250	10,000
20-A	11,250	11,250	11,250
30-A	11,250	11,250	11,250
40-A	11,250	11,250	11,250

Note: 11,250 ft^2 is considered a practical limit.
For SI units: 1 ft^2 = 0.0929 m^2.

Source: NFPA 10, *Standard for Portable Fire Extinguishers,* Table E.3.4, 2007, p. 10-43.

EXAMPLE 1:

$\frac{67{,}500}{11{,}250} = 6$

4-A Extinguishers for light-hazard occupancy

10-A Extinguishers for ordinary-hazard occupancy

20-A Extinguishers for extra-hazard occupancy

This placement along outside walls would not be acceptable because it clearly violates the travel distance rule (Figure 17.5.14). Instead, relocation and/or additional extinguishers are needed.

Example 2 is for fire extinguishers having ratings that correspond to protection areas of 6000 ft^2 (557 m^2). Example 3 is for extinguishers having the minimum ratings permitted by Table 17.5.2 with corresponding minimum protection areas. As the number of lower-rated extinguishers increases, meeting the travel distance requirement generally becomes less of a problem.

EXAMPLE 2:

$\frac{67{,}500}{6{,}000} = 12$

2-A Extinguishers for light-hazard occupancy

4-A Extinguishers for ordinary-hazard occupancy

6-A Extinguishers for extra-hazard occupancy

EXAMPLE 3:

$\frac{67{,}500}{6{,}000} = 12$ 2-A Extinguishers for light-hazard occupancy

$\frac{67{,}500}{3{,}000} = 23$ 2-A Extinguishers for ordinary-hazard occupancy

$\frac{67{,}500}{4{,}000} = 17$ 4-A Extinguishers for extra-hazard occupancy

Extinguishers could be mounted on exterior walls or, as shown in Figure 17.5.15, on building columns or interior walls, and conform to both distribution and travel distance rules.

The arrangement illustrated in Figure 17.5.16 shows extinguishers grouped together on building columns or interior walls in a manner that still conforms to distribution and travel distance rules.

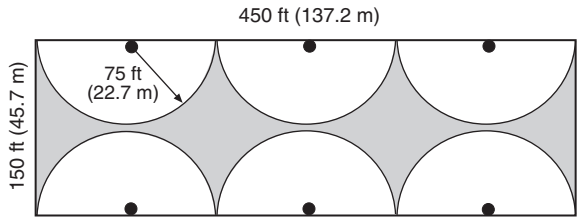

FIGURE 17.5.14 Diagrammatic Representation of Extinguishers Located Along Outside Walls of a 150 ft × 450 ft (46 m × 137 m) Building. The large dots represent extinguishers. The shaded areas indicate "voids" that are farther than 75 ft (23 m) from the nearest extinguisher.

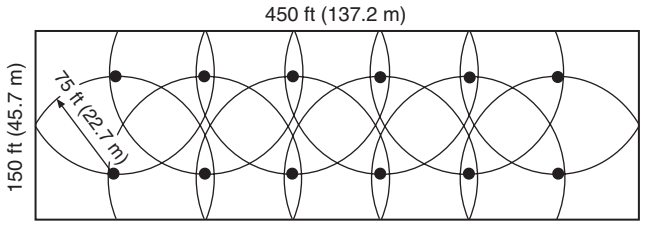

FIGURE 17.5.15 Configuration of 12 Extinguishers Mounted on Building Columns or Interior Walls, Meeting Requirements for Travel Distance and Extinguisher Distribution

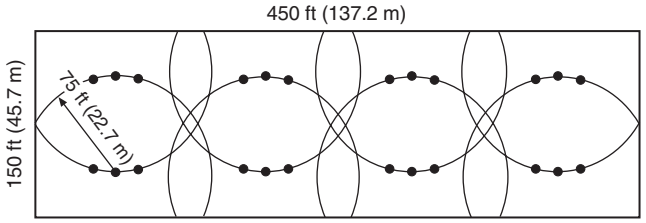

FIGURE 17.5.16 Extinguishers Grouped Together

Extinguisher Distribution for Class B Combustibles

Class B fire hazards fall into two distinct categories. The first includes liquids ¼ in. (6.4 mm) deep or less, and the other includes liquids deeper than ¼ in. (6.4 mm).

In areas where liquids do not reach an appreciable depth, extinguishers should be provided according to Table 17.5.4. The reason the basic maximum travel distance to Class B extinguishers is 50 ft (15 m), as opposed to 75 ft (23 m) for Class A extinguishers, is that flammable liquid fires reach their maximum intensity almost immediately, and thus the extinguisher must be nearer to hand. With lower-rated extinguishers, the travel distance is reduced to 30 ft (9 m).

Even though Table 17.5.4 specifies maximum travel distances to extinguishers for Class B fires, judgment should be used when actually placing the devices. The closer the extinguisher to the hazard, the better—up to the point at which a fire might damage or obstruct access to the device.

When flammable liquids reach an appreciable depth, the extinguisher's rating number, except for foam types, should be at least twice the number of square feet (m^2) of surface area of the largest tank in the area, assuming that other requirements are met. The travel distances specified by Table 17.5.4 should also be used to locate extinguishers for protection of spot hazards. Sometimes, one extinguisher can be installed to provide protection against several different hazards, provided that travel distances are not exceeded.

Where there are open process tanks of flammable liquids with surface areas greater than 10 ft^2 (1 m^2), complete dependence should not be placed on fire extinguishers. It is often advisable to consider installing fixed fire protection systems for

TABLE 17.5.4 Fire Extinguisher Size and Placement for Class B Hazard Excluding Protection of Deep-Layer Flammable Liquid Tanks

Type of Hazard	*Basic Minimum Extinguisher Rating*	Maximum Travel Distance to Extinguishers	
		ft	*m*
Low	5-B	30	9
	10-B	50	15
Moderate	10-B	30	9
	20-B	50	15
High	40-B	30	9
	80-B	50	15

these tanks because of the potential size and intensity of the fire which could occur. If a fixed protection system suitable for Class B fires is installed, then the extinguisher requirement may be waived for the hazard, or hazards, it protects, though not for the complete structure or any other special hazards in the area. Portable extinguishers can be useful even when fixed protection systems have been installed, in case a burning tank spills liquid outside the range of the fixed equipment or a fire begins adjacent to a tank rather than in it.

Pressurized flammable liquids and gases are not stored in open containers, and it is not possible to select extinguishers for them according to the square foot (m^2) requirements. Instead, extinguishers with special nozzles and rates of agent application should be chosen. The manufacturers of these specialized extinguishers usually recommend what equipment they are suited for. In general, however, no attempt to extinguish pressurized fuel fires should be made unless the source of fuel can be shut off promptly. As before, the travel distances to portable extinguishers should not exceed those specified by Table 17.5.4.

Because Class B fires can become so intense so quickly, the flow rate and the duration of discharge of an agent are very important. For these reasons, NFPA 10 does not permit substituting two or more extinguishers of lower rating for the minimum ratings given in Table 17.5.4, except for certain foam extinguishers. The exception permits the substitution because foam progressively "secures" a fire, and the foam from one extinguisher is effective during the time it takes to bring other units into operation. With carbon dioxide and dry chemical extinguishers, however, four extinguishers rated 5-B are not equal to one extinguisher rated 20-B; the larger extinguisher has a higher flow rate in pounds per second (kg/sec) and a longer continuous discharge time than the smaller models.

Wheeled extinguishers with ratings from 20-B to 480-B are available. They are designed chiefly for outdoor fire fighting and should be used only by trained employees. They should be distributed according to the 50 ft (15 m) travel distance rules of Table 17.5.4, though longer travel distances may be authorized by the authority having jurisdiction.

A sample problem from NFPA 10 for protection by portable extinguishers follows.

Sample Problem. A light-occupancy office building is to be protected by portable fire extinguishers. The floor area is 11,100 ft^2 (1031 m^2) and of unusual design (Figure 17.5.17).

The most common fire extinguisher selections would be 2½ gal (9.5 L) stored-pressure water models rated 2-A. According to Table 17.5.2 (Table E-3.4 from NFPA 10), two fire extinguishers are needed (11,100/6000 = 2). Travel distance requirements are 75 ft (23 m) maximum.

The two units are placed at points 1 and 2, and a check is make on the travel distance requirement. Because of the area's unusual shape, it is found that the shaded areas exceed the 75 ft (23 m) distance. Two additional fire extinguishers (at points 3 and 4) are needed. The additional fire extinguishers afford more flexibility in placement, and alternative locations are indicated. It is important to consider any partitions, walls, or other obstructions in determining the travel distance.

As an additional item, consider that Area A contains a small printing and duplicating department that uses flammable liquids. This area is judged to be an ordinary Class B hazard. A 10-B:C or 20-B:C fire extinguisher should be specified to protect this area.

There are now two alternatives to be considered. First, a fifth fire extinguisher, either carbon dioxide or ordinary dry chemical, with a rating of 10-B:C or 20-B:C could be specified. Second, the water fire extinguisher at point 2 could be replaced with a multipurpose dry chemical fire extinguisher that has a rating of at least 2-A:10-B:C. It should be located near point 2, keeping in mind the 75 ft (23 m) travel distance for the 2-A protection and the 30 ft or 50 ft (9.1 m or 15.25 m) travel distance required for the Class B protection that this fire extinguisher provides.

Extinguisher Distribution for Class C Fires

Extinguishers for Class C fires are required wherever there is live electrical equipment. This sort of extinguisher contains a nonconducting agent, usually carbon dioxide, dry chemical, or a halogenated agent.

Once the power to live electrical equipment is cut off, the fire becomes a Class A or Class B fire, depending on the nature of the burning electrical equipment and the burning material in

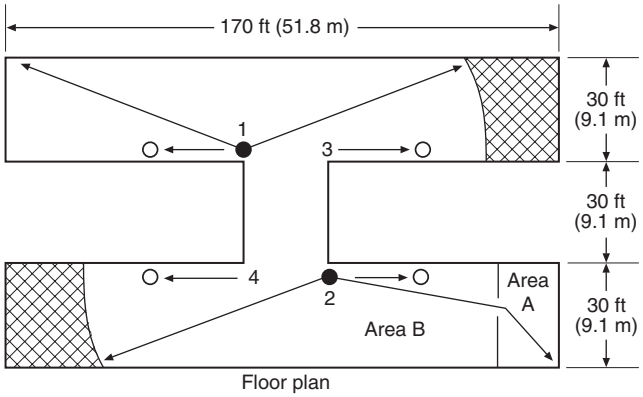

FIGURE 17.5.17 Floor Plan

the vicinity. Extinguishers for Class C fires should be selected according to the size of the electrical equipment; the configuration of the electrical equipment, particularly the enclosures of units, which influence agent distribution; and the range of the extinguisher's stream. At large installations of electrical equipment where continuity of power is critical, fixed fire protection is desirable. But even when fixed fire protection is present, it is recommended that some Class C extinguishers be provided to handle incipient fires.

Class D Extinguisher Distribution

It is particularly important that the proper extinguishers be available for Class D fires. Because the properties of combustible metals differ, even an agent for Class D fires may be hazardous if used on the wrong metal. Agents should be chosen carefully according to the manufacturers' recommendations. The amount of agent needed is normally figured according to the surface area of the metal, plus the shape and form of the metal, which could contribute to the severity of the fire and cause "bake-off" of the agent. For example, fires in magnesium filings are more difficult to put out than fires in magnesium scrap, and more agent is needed for magnesium filings. The maximum travel distance to all extinguishers for Class D fires is 75 ft (23 m).

INSPECTION AND MAINTENANCE OF FIRE EXTINGUISHERS

Once a fire extinguisher has been purchased, it becomes the responsibility of the purchaser or an assigned agent to maintain the device. Adequate maintenance consists of periodically inspecting each extinguisher, recharging each extinguisher following discharge, and performing periodic hydrostatic tests or as needed.

A fire equipment servicing agency is considered the most reliable way for the general public to maintain extinguishers, but large industries often train employees to handle this maintenance themselves. Many jurisdictions require service technicians to be licensed. Carson[2] provides checklists for periodic inspection and maintenance of fire extinguishers.

Inspection Considerations

An inspection is a quick check that visually determines whether the fire extinguisher is properly placed and will operate. The purpose of an inspection is to give reasonable assurance that the extinguisher is fully charged and will function effectively if needed. An inspection should determine that the extinguisher is in its designated place, is conspicuous, is not blocked in any way, has not been activated and partially or completely emptied, has not been tampered with, and has not sustained any obvious physical damage or been subjected to an environment that could interfere with its operation, such as corrosive fumes. If the extinguisher is equipped with a pressure gauge and/or tamper indicators, the inspection should show conditions to be satisfactory. In addition, the maintenance tag can be checked to determine the date of the last thorough maintenance check.

In order to be effective, inspections must be frequent, regular, and thorough. In a small building with few extinguishers, the manager, property owner, or some designated person could check extinguishers at the beginning of each workday. If a building is large enough to employ security guards or a surveillance service, extinguishers should be inspected at least once during each 8 hour shift. In industrial plants, the plant fire brigade or fire inspector often inspects extinguishers either daily, weekly, or monthly. The maximum time period between inspections is 30 days.

An individual evaluation must be made of each property to determine how frequently inspections should be made. If a particular operation is fire prone or is crucial to the use of the property, more frequent inspections should be made. For example, if all the products manufactured in a particular industrial plant had to be painted, a fire in the painting room could be disastrous, so inspections should be very frequent.

It is important to consider the nature of the hazards present that influence the potential use of the extinguisher: the exposure of the extinguisher to tampering, vandalism, and malicious mischief; extraordinary weather conditions; the likelihood of accidental damage to the extinguisher; and the possibility of visual or physical obstructions to the accessibility of extinguishers.

Manual Inspection Alternative

An alternative to a manual inspection of extinguishers is to have them electronically monitored. These extinguisher monitoring systems have gained acceptance and are now routinely used to check the condition of extinguishers. Typically, extinguishers are connected to a fire alarm system and are electronically monitored to ensure that they are in their designated places. Such electronic monitoring can also verify that there are no obstructions to accessing the extinguishers and that the pressure gauge is in its operable range. This alternative is desirable for locations where the extinguishers were previously neglected or where there is a problem of theft.

Maintenance Considerations

Maintenance, as distinguished from inspection, means a complete and thorough examination of each extinguisher. A maintenance check involves examining parts, cleaning and replacing any defective parts, and reassembling, recharging, and, where appropriate, pressurizing the extinguisher.

Maintenance checks sometimes reveal the need for special testing of extinguisher shells or other components. For example, they may reveal that the extinguisher container should be hydrostatically tested or even replaced.

Frequency. Maintenance should be performed periodically, but at least once every 12 months, after each use, or when an inspection shows that the need is obvious. If an inspection reveals evidence of serious damage by corrosion, for example, the extinguisher should be subjected to a thorough maintenance check, even though it may have undergone one recently. Similarly, if an inspection shows evidence of tampering, agent leakage, or physical damage, a complete maintenance check

should be initiated. NFPA 10 contains specific details related to maintenance.

Tags and Tamper Seals. For many years, extinguisher tags have been used as a convenient means for recording maintenance checks. For routine maintenance, a tied-on tag or pressure-sensitive label is used to record the date and the inspector's initials. Newer technology using bar code readers also can be used. Tamper seals also should be used. Lead and wire seals were used commonly until plastic seals were introduced in 1972. As long as the seal remains intact, one can be reasonably sure that the extinguisher has not been used. However, it is important to note that a stored-pressure extinguisher can develop a leak and lose its pressure even though the tamper indicator remains intact or the pressure gauge reads normal. During annual maintenance, the tamper seal is removed by operating the pull pin or locking device. This is done to ensure that they operate freely. A new tamper seal is then installed.

A neck ring collar is installed on an extinguisher following servicing, which necessitates the removal of the extinguisher valve assembly. This is used to verify if the extinguisher was depressurized and the valve was removed. The collar design also necessitates the removal of the valve before the collar can be attached to the extinguisher. The collar design permits the date to be recorded. The collar provides the authorities having jurisdiction with convenient visual proof that the extinguisher was disassembled. Figure 17.5.18 provides a guide to the design of a "Verification of Service" collar.

Maintenance Operations

In any operational test of a portable fire extinguisher, there are three basic items that need to be checked: (1) the mechanical parts of the device—that is, the extinguisher shell and other component parts; (2) the amount and condition of the extinguishing agent; and (3) the condition of the means for expelling the agent.

A record of the date of purchase, as well as maintenance dates, should be kept for each extinguisher. A separate record is also desirable and should include the maintenance date and the name of the person or agency performing the maintenance; the date last recharged and the name of the person or agency performing the recharge; the hydrostatic retest date and the name of the person or agency performing the hydrostatic test; description of dents remaining after passing a hydrostatic test; and the date of the six-year maintenance for certain stored-pressure dry chemical and halogenated agent extinguishers.

Individuals who own extinguishers might neglect them if there is no planned periodic follow-up program. It is recommended that owners become familiar with their extinguishers so that they can detect telltale signs which suggest the need for maintenance. An alternative is to have the dealer from whom the extinguisher was purchased establish an annual follow-up maintenance program.

On properties where extinguishers are maintained by the occupant, a supply of recharging materials should be kept on hand. When recharging extinguishers other than those with plain water, use only those recharging materials specified on the extinguisher's nameplate. Other recharging materials may impair the efficiency of the extinguisher or cause it to malfunction and injure the operator. Special precautions are necessary for certain types of extinguishers, and they are discussed elsewhere in this chapter.

NFPA 10 has an appendix with a checklist of items that require maintenance. The checklist is divided into two sections. One section of the checklist is arranged to pinpoint the mechanical parts common to most extinguishers. The other section addresses agent and expelling means.

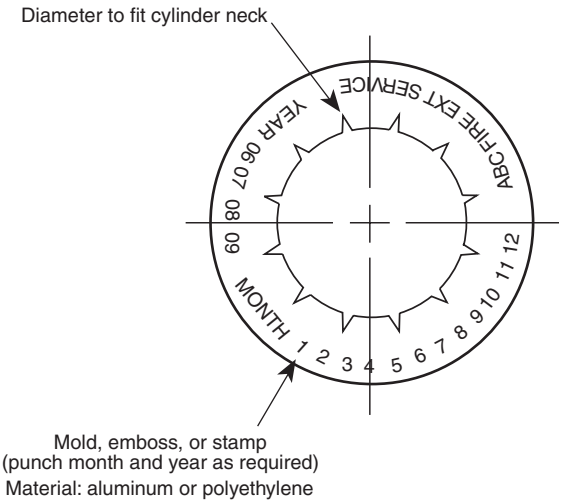

FIGURE 17.5.18 Design of a "Verification of Service" Collar

Inspection and Maintenance of Water-Type Extinguishers

Inspection and maintenance for stored-pressure models is too often thought of as quite simple. Unless the extinguisher has been used or a routine inspection reveals a defect, maintenance is sometimes left until the five-year hydrostatic test is performed. This practice can result in failures and malfunctions. The principal items that need to be checked during an inspection are a loose, worn, or damaged hose; a plugged nozzle; a dented shell; a damaged indicator gauge; and a damaged or jammed ring pin. Normal maintenance service, as specified in NFPA 10, should be performed annually.

Mechanical pump extinguishers, such as pump tanks and backpacks, are easy to inspect and maintain. The tanks containing the water or antifreeze solution must be checked to ensure they are in good condition, have not been weakened by corrosive action, and do not contain sediment that might block the stream during the pumping operation. If the device has not been used in the last 12 months, the liquid should be removed from the tank and the tank should be flushed and filled with new liquid. Pumps require lubrication from time to time. They should be checked annually to ensure that the plungers are in proper condition, that seals and washers have not deteriorated, and that

hoses are not clogged. Antifreeze solutions need to be checked to ensure that they are not contaminated and can withstand the temperatures in the area.

Inspection and Maintenance of Dry Chemical Extinguishers

Dry chemical extinguishers should be inspected monthly, and they should also undergo normal annual maintenance. The quantity of agent for a cartridge-operated model can be checked by weighing or by removing the fill cap and checking it visually. The gas cartridge also can be checked by weighing. On stored-pressure models, the pressure gauge will indicate if adequate pressure is maintained, and the agent quantity can be checked by weighing.

Dry chemical extinguishers should be refilled promptly after use, even if they have been discharged only partially. When refilling, extreme caution must be taken to ensure that no water, moisture, or foreign material enters the cylinder. Even though dry chemical agents are treated for moisture repellency, they can eventually harden if moisture is present. When these extinguishers are hydrostatically tested, they must be dried thoroughly so that no trace of water or moisture remains. Before new agent is added, all of the unused agent should be removed by dumping or vacuuming, and any residue should be removed from the hose.

An extinguisher containing a Class B:C dry chemical (bicarbonate-base or potassium chloride) should not be refilled with a Class A:B:C agent (monoammonium-phosphate-base). Mixing different dry chemical agents can result in malfunction, damage to the extinguisher, or both. The bicarbonate-based agent is chemically alkaline and will react with the acidic ammonium phosphate. This reaction is aggravated by exposure to heat or the presence of moisture in amounts as small as 0.1 percent. One result is caking of the agent; another possible result is the internal corrosion of the extinguisher. Under certain conditions, the reaction will cause excess pressure to build up within the shell, which may damage or rupture the extinguisher.

Substituting another manufacturer's dry chemical of the same type is not recommended unless it has the same chemical and physical characteristics, or has been tested and found to give equivalent performance. The problems involved in substitution include the following:

1. An altered flow rate of the dry chemical, which could influence extinguishing efficiency
2. The amount of agent that could be placed in the extinguisher, which could influence discharge time
3. Incompatibility of one dry chemical to another, including chemical reactions, caking, and jamming of hose or nozzles. The flow rate can change with the particle size and density of the agent. A discharge nozzle designed to dispense one dry chemical efficiently might well be less efficient for another. An extinguisher designed to hold a given weight of one formula may not hold the same amount of another. Dip tubes, hoses, or valves could become plugged.

Recharge operations for the cartridge-operated models are relatively easy. The rubber sleeves on the gas tube should be checked for cracking or overstretching, and the gasket and gasket seats on the shell and cap should be wiped clean. The cap should be screwed on handtight. When replacing the cartridge, care should be taken that the threads are not dirty, cross-threaded, or otherwise damaged. For stored-pressure models, the entire valve body, stem, and "O" ring should be carefully wiped clean and blown out with dry nitrogen to get rid of all traces of agent residue which might cause a pressure leak.

Nitrogen gas used for pressurizing should be of the standard industrial grade, with a dew point of –60°F (–51.1°C) or lower so that it is free of moisture. Once the extinguisher has been pressurized, it should be given a leak test or allowed to stand for about 12 hours and then checked for leaks before it is returned to service.

Some stored-pressure extinguishers are factory-sealed and are not rechargeable. No effort should be made to recharge these units in the field. Normally, the shell of the extinguisher is discarded following use; only the valve and nozzle assembly are retained. Refill units should be obtained from the manufacturer, and detailed instructions for replacement are included on the extinguisher nameplate.

The general inspection and maintenance procedures for dry powder (Class D) extinguishers are the same as for cartridge-operated dry chemical extinguishers.

Inspection and Maintenance of Carbon Dioxide Extinguishers

Weighing is the only way to determine whether carbon dioxide extinguishers are fully charged. They should be weighed at least semiannually for loss of weight and inspected for deterioration and/or physical damage. The full and empty weights are stamped on the valve assembly. Any carbon dioxide extinguisher that has a weight loss of 10 percent or more should be recharged and tested for leaks. Recharging is generally done by an extinguisher servicing company. Should on-site recharging be desirable, however, the manufacturer should be contacted for assistance in setting up a recharging station.

Recharging extinguishers with carbon dioxide from dry-ice converters is no longer permitted due to the high potential for moisture in the carbon dioxide. The vapor phase of carbon dioxide must not be less than 99.5 percent carbon dioxide. The water content of the liquid phase must not be more than 0.01 percent by weight (–30°F [–34.4°C] dew point). The oil content of the carbon dioxide must not exceed 10 ppm by weight.

Specific recommendations are given for such recharging in NFPA 10. The required source of carbon dioxide is a low-pressure carbon dioxide supply (300 psi at 0°F [206.8 kPa at –17.8°C]), either directly from the source or through dry cylinders used as intermediaries. It cannot be emphasized too strongly that internal moisture can seriously corrode an extinguisher, and that moisture is most easily introduced into a cylinder either during recharging or following a hydrostatic test.

Inspection and Maintenance of Halogenated Agent Extinguishers

The general inspection and maintenance procedures for halogenated agent extinguishers are similar to the requirements

for other extinguishers. They are physically similar to stored-pressure dry chemical extinguishers. The specific requirements of each manufacturer should be followed.

Hydrostatic Testing of Extinguishers

The purpose of hydrostatic testing of portable fire extinguishers that are subject to internal pressures is to protect against unexpected, in-service failure. Such a failure may be due to undetected internal corrosion caused by moisture in the extinguisher; external corrosion caused by atmospheric humidity or corrosive vapors; damage caused by rough handling, which may or may not be obvious by external inspection; repeated pressurizations; manufacturing flaws in the construction of the extinguisher; improper assembly of valves or safety relief discs; or exposure of the extinguisher to abnormal heat, as during a fire.

NFPA 10 requires that hydrostatic pressure tests be performed on extinguishers according to Table 17.5.5. The first hydrostatic retest may be conducted between the fifth and sixth year for those with a designated test interval of five years. However, carbon dioxide types require a strict five-year interval according to federal law. Hydrostatic tests also should be conducted immediately upon discovery of any mechanical injury or corrosion to the extinguisher shell.

In the United States, various U.S. Department of Transportation (DOT) rules apply to specific types of cylinders used for fire extinguishers. Title 49 of the *Code of Federal Regulations* calls, with some exceptions, for the hydrostatic retesting every five years of compressed-gas cylinders offered for interstate transportation in a charged condition. Paragraph 173.34(e) calls for periodic retesting of DOT compressed-gas cylinders whether or not the cylinders are shipped interstate.

Many different DOT specification cylinders are used for dry chemical extinguishers, including Types DOT-4B and DOT-4BA. The requirements for these types are peculiar to them.

The preferred method of hydrostatic testing of compressed-gas cylinders is the water-jacketed, volumetric expansion method recommended in NFPA 10. The guide to follow in conducting this type of test is Pamphlet C-1, "Methods for Hydrostatic Testing of Compressed Gas Cylinders," published by the Compressed Gas Association, Inc. (CGA).[3] For visually evaluating the condition of cylinders made to DOT specifications, CGA's Pamphlet C-6, "Standards for Visual Inspection of Steel Compressed Gas Cylinders,"[4] is helpful.

Procedures for testing extinguishers other than compressed-gas extinguishers or affixed compressed-gas cylinders are detailed in NFPA 10. Table 17.5.6 gives the basic data on the hydrostatic test pressure requirements. Figures 17.5.19 and 17.5.20 illustrate equipment used in hydrostatic testing work.

It is not necessary to hydrostatically test certain extinguishers, such as pump tanks, backpacks, and similar devices. Factory-sealed, nonrefillable, disposable fire extinguishers cannot be hydrostatically tested. When such extinguishers are damaged, they must be replaced.

Proper hydrostatic testing requires competent personnel and suitable testing equipment and facilities. The preparation for testing and the removal of all traces of water and moisture with special drying equipment after testing are very important and reinforce the recommendation that only those experienced in this type of work should undertake such servicing. The DOT requires that agencies testing carbon dioxide extinguishers hydrostatically be certified by the DOT.

Extinguisher hoses of certain types also need to be hydrostatically tested, and the details of these tests can be found in NFPA 10.

Because hydrostatic test results are of major importance, they must be recorded on the extinguisher. For high-pressure cylinders and cartridges passing a hydrostatic test, the month and year is stamped into the cylinder, in accordance with CGA Pamphlet C-1, or the Canadian Transport Commission regula-

TABLE 17.5.5 Hydrostatic Test Interval for Extinguishers

Extinguisher Type	*Test Interval (Years)*
Stored-pressure water loaded stream and/or antifreeze	5
Wetting agent	5
AFFF (aqueous film-forming foam)	5
FFFP (film-forming fluoroprotein foam)	5
Dry chemical with stainless-steel shells	5
Carbon dioxide	5
Wet chemical	5
Dry chemical, stored-pressure, with mild steel shells, brazed brass shells, or aluminum shells	12
Dry chemical, cartridge or cylinder operated, with mild steel shells	12
Halogenated agents	12
Dry powder, stored pressure, cartridge- or cylinder-operated, with mild steel shells	12

TABLE 17.5.6 Hydrostatic Test Pressure Requirements

Carbon dioxide extinguishers Carbon dioxide and nitrogen cylinders (used with wheeled extinguishers)	5/3 service pressure stamped on cylinder
Carbon dioxide extinguishers with cylinder specification ICC3	3000 psi (20,685 kPa)
All stored-pressure	Factory test pressure not to exceed 3 times the service pressure
Carbon dioxide hose assemblies	1250 psi (8619 kPa)
Dry chemical and dry powder, water, foam, halogenated agent hose assemblies	300 psi (2068 kPa) or at service pressure, whichever is higher

Note: The factory test pressure is the pressure at which the shell was tested at time of manufacture. This pressure is shown on the nameplate.
The service pressure is the normal operating pressure as indicated on the gauge and nameplate.

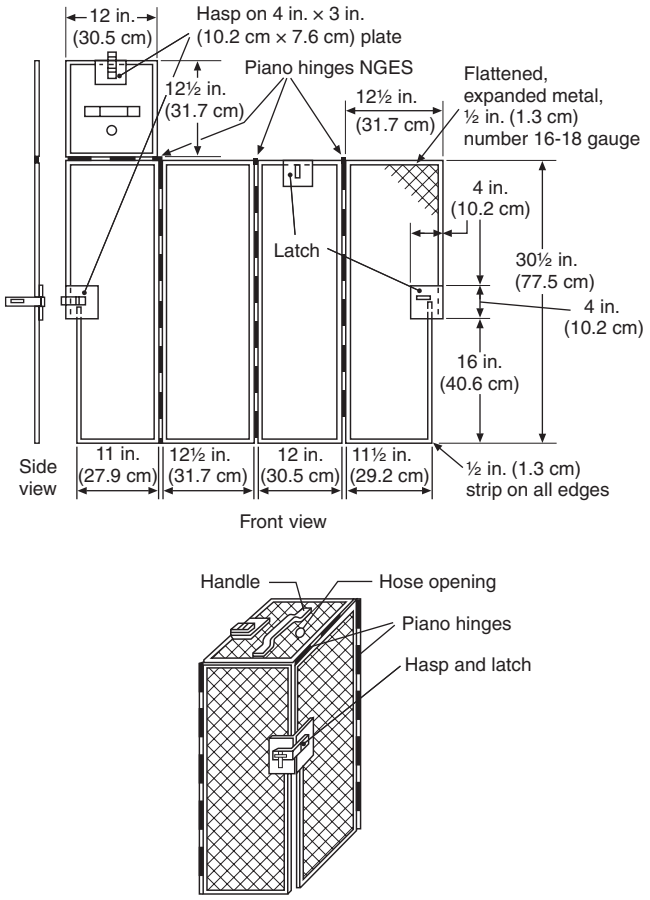

FIGURE 17.5.19 Low-Pressure Portable Hydrostatic Test Cage Used for Hydrostatic Tests of Low-Pressure Cylinders. Cage is not used for hydrostatic testing of high-pressure cylinders. Cage should not be anchored to floor during testing. Such cages can be made by any metal fabricator. For SI units: 1 in. = 25.4 mm.

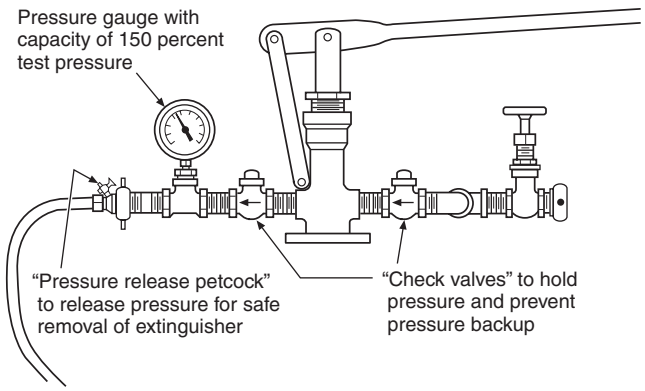

FIGURE 17.5.20 Hydrostatic Hand Pump

tions. It is important that the recording, or stamping, be placed only on the shoulder, top head, neck, or footing (when so provided) of the cylinder. For low-pressure cylinder extinguishers, the test information should be recorded on metal or some equally durable material. The label should be affixed by a heatless process to the shell and should be self-destructive if removal is attempted (Figure 17.5.21.) The label must include the following information:

1. The month and year the test was performed, indicated by a perforation, such as by a hand punch
2. The test pressure used
3. The name or initials of the person performing the test, and the name of the agency performing the test

Above all, remember the following: Allow only competent personnel with proper equipment and facilities to do the testing. Do not use air or gas for pressure testing because a violent rupture may occur in cases of failure. Place any extinguisher undergoing a test in a protective cage before applying the test pressures. Remove all traces of moisture from dry chemical, carbon dioxide, halogenated agent, and dry powder extinguishers before refilling after each test; a heated air stream not exceeding 150°F (65°C) is recommended for such drying. Destroy any extinguisher shell that fails a hydrostatic test—do not attempt to repair it.

Do not hydrostatically test any cylinder or shell if it has one or more of the following conditions:

1. Repairs by soldering, welding, brazing, or use of patching compounds; for welding or brazing on mild steel shells, consult the manufacturer of the extinguisher
2. Damaged cylinder or shell threads
3. Pitting caused by corrosion, even under the removable nameplate band assemblies
4. Burns from a fire
5. Calcium chloride agent in a stainless steel extinguisher

Destroy any such cylinder or shell.

Extinguisher Maintenance Services

Fire extinguisher maintenance, particularly hydrostatic testing, is a specialized activity and should be performed by competent, dependable people. Fire extinguishers are provided to protect life and property; this means that there should be no doubt as to

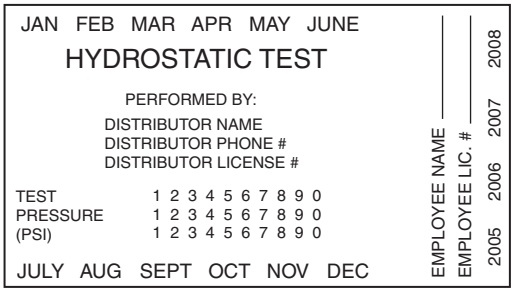

FIGURE 17.5.21 Typical Hydrostatic Test Label

their reliability or safe use in an emergency. Extinguisher owners are thus urged to seek out the services of reliable fire extinguisher maintenance firms. Such firms should be able to show proof that they are competent, that their facilities are adequate, and that they are licensed or registered in accordance with any local or federal law.

SUMMARY

Extinguishers are available in a number of different forms and use a variety of extinguishing agents, including water, carbon dioxide, halogenated agents, dry chemicals, dry powders, and foam. Extinguishers are classified for use on one or more types of fire, known as Class A, Class B, Class C, Class D, and Class K fires. In addition to the class of fire, the selection of the extinguisher should take into account the hazard level of the area being protected, the physical environment, the ease of operation and maintenance, and safety considerations. In order to provide effective fire protection, extinguishers must be distributed, mounted, maintained, and tested properly.

Clean Agent System Design

Key Terms

application fire extinguishing systems, carbon dioxide, clean fire extinguishing agents, clean fire suppression agents, explosion suppression, halogenated extinguishing agents, halon, safety factors, total flooding fire extinguishing systems

Clean fire-extinguishing agents include halogenated and inert gas fire suppressants. Halon and halon replacement clean agents including inert gases are used to provide total flooding fire-extinguishing systems that do not result in lethal conditions for any occupants of a protected space inadequately exposed when properly designed and installed. Although some clean agents cannot be used in occupied areas due to toxicity concerns, the primary distinction today between clean agents and carbon dioxide is the toxicity of the gases. Whereas carbon dioxide is used in fire-extinguishing concentrations far in excess of fatal limits, clean agents are generally used in occupied areas in fire-extinguishing concentrations below toxic thresholds.

Halogenated extinguishing agents are hydrocarbons in which one or more hydrogen atoms have been replaced by atoms from the halogen series: fluorine, chlorine, bromine, or iodine. This substitution confers not only nonflammability but also flame extinguishment properties to many of the resulting compounds. Halogenated agents are used both in portable fire extinguishers and in extinguishing systems. Streaming agents, such as Halon 1211 and 2402, have most often been used in manually applied fire equipment and local application-type fixed systems. Halon 1301 has most often been used in total flooding-type fixed systems.

Halons have been identified as stratospheric ozone-depleting substances. In fact, halons have been identified as the most potent of all ozone-depleting substances. The Montreal Protocol on Substances That Deplete Stratospheric Ozone is an international agreement to control the production and trade of ozone-depleting substances. The agreement has been signed by over 140 countries and is administered by the United Nations Environment Programme.

Production of Halons 1301, 1211, and 2402 ceased in developed countries on January 1, 1994, and is currently being phased out in the last developing country that produces halons. Many halon systems remain in use worldwide and, consequently, this chapter discusses Halons 1211, 1301, and 2402. The transition to other forms of fire protection for applications that historically used halons is well underway.

Recycled halons, recovered from less critical applications, now serve as a source of supply for those specialized applications such as mobile military equipment, aviation applications, and explosion prevention applications that remain dependent on halons.

See also Section 2, Chapter 7, "Theory of Fire Extinguishment"; Section 17, Chapter 1, "Carbon Dioxide and Application Systems"; Section 17, Chapter 7, "Application of Gaseous Agents to Special Hazards Fire Protection"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

Philip J. DiNenno, P.E., is president of Hughes Associates, Inc., chair of the NFPA Standards Council, and has been heavily involved in the testing and development of halon replacement chemical and alternative fire suppression technologies.

Gary M. Taylor is a professor in fire protection engineering technology at Seneca College, Toronto; past chair of the NFPA Standards Council; and former chair of the NFPA Technical Committee on Halogenated Extinguishing Agent Systems.

BACKGROUND AND DEFINITIONS

Background

The use and development of halogenated fire-extinguishing agents have evolved over many years. The first member of this family of chemicals was carbon tetrachloride (Halon 104). Use as a fire extinguishant probably occurred before 1900, and by 1910 portable fire extinguishers, tested by independent agencies, had appeared. The growing popularity of the automobile and other uses of internal combustion engines signaled an increasing need for fire extinguishants suitable for use on flammable liquids fires.

By 1917, there were discussions regarding the possible effects that carbon tetrachloride could have on the human system. In 1919 the first known deaths due to carbon tetrachloride use occurred. Two men working on the construction of a submarine were killed. One man's clothing caught fire, and the other man extinguished the fire with a carbon tetrachloride agent fire extinguisher. Both were overcome by the fumes and later died. During the 1920s, the discussions regarding the toxicity of carbon tetrachloride continued with particular attention to the possibility that freezing point depressants and impurities were contributing factors.

Methyl bromide (Halon 1001) gained popularity after it was discovered in the late 1920s. Due to its high toxicity, it was never popular for use in portable extinguishers, although it was used in British and German aircraft and ships during World War II. During World War II, Germany developed bromochloro-methane (Halon 1011) to replace methyl bromide. In 1947 a report by Underwriters Laboratories Inc. (UL) showed that the toxicities of carbon tetrachloride (Halon 104) and bromochloro-methane (Halon 1011) were comparable, but bromochloro-methane was a more efficient fire-extinguishing agent.

In the post–World War II era, the addition of stearate to sodium bicarbonate–based dry chemicals provided improved flow and moisture repellency characteristics to sodium bicarbonate–based dry chemicals. This, in turn, encouraged the use of portable dry chemical fire extinguishers as an alternative to vaporizing liquid extinguishers that used early halons as extinguishants.

By the 1950s the era of the early halons (Halons 104, 1001, and 1011) was ending. Increased popularity of dry chemicals had decreased the need for widespread use of these early halons, and growing concerns with their toxic effects resulted in their "official" death by the 1960s.

In 1947, the Purdue Research Foundation conducted a systematic evaluation of more than 60 new candidate extinguishing agents. Simultaneously, the U.S. Army Corps of Engineers undertook toxicological studies of these same compounds. As a result, four halons were selected for further study: dibromodifluoromethane (Halon 1202), bromochlorodifluoromethane (Halon 1211), bromotrifluoromethane (Halon 1301), and dibromotetrafluoroethane (Halon 2402). Testing showed that Halon 1202 was the most effective fire extinguishant, but it was also the most toxic. Halon 1301 ranked second in fire-extinguishing effectiveness and least toxic. As a direct result of this program, a portable fire extinguisher employing Halon 1301 was developed by the U.S. Army, primarily for use inside armored personnel carriers and tanks. The U.S. Air Force selected Halon 1202 for military aircraft engine protection, and the U.S. Federal Aviation Administration approved the use of Halon 1301 for commercial aircraft engine fire protection.

In the 1960s attention began to focus on the use of Halon 1301 as a total flooding extinguishant for the protection of computer rooms. For the next 25 years, Halon 1301 grew in popularity as an agent for use in fixed fire protection systems, primarily for the protection of vital electronics facilities, such as computer rooms and communications equipment rooms. Other significant applications for Halon 1301 systems include protection for museums, shipboard machinery spaces, and pipeline pumping stations.

In 1966, NFPA organized a Technical Committee on Halogenated Fire Extinguishing Agent Systems to develop standards covering installation, maintenance, and use of such systems. NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems,* and NFPA 12B, *Standard on Halon 1211 Fire Extinguishing Systems* (discontinued), were approved in the early 1970s. NFPA 12CT was a tentative standard for Halon 2402; however, the standard was never adopted as a full standard due to lack of acceptance of this agent by users of NFPA standards. Halon 2402 has been employed extensively within the Russian federation as both a total flooding system agent and a streaming agent for use in portable fire equipment. There is limited experience with Halon 2402 in the United States; therefore, it cannot be treated as extensively as the other agents in this handbook.

In 1972, following extensive testing by several major companies on the effects of Halon 1301 decomposition products on electronic equipment, the NFPA Committee on Electronic Computer/Data Processing Equipment recognized Halon 1301 total flooding systems as suitable for protection of electronic computer/data processing equipment. With suitable precautions, such as time delays, Halon 1211 total flooding systems have been used in Europe.

The regulation of Halon 1301 under the Montreal Protocol on Substances That Deplete Stratospheric Ozone and its amendments culminated in the phaseout of production of halons in the developed countries on December 31, 1993. This regulation engendered tremendous research and development efforts across the world in a search for replacements and alternatives. There are currently over 12 commercialized total flooding, clean agent alternatives to Halon 1301, and development continues on others. In addition to clean agent total flooding gaseous alternatives, new technologies, for example, water mist and fine solid particulate, are being introduced. This chapter focuses on total flooding clean agent halon replacements.

The primary design and installation standard used in North America is NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems.* The first edition of the standard was published in 1994. The third and current edition was issued in February 2000. The first International Standards Organization (ISO) standard, ISO Standard 14520—Parts 1 through 15—was issued in 2000.[1]

Clean Agents Defined

Clean fire suppression agents are defined as fire extinguishants that vaporize readily and leave no residue.[1] Clean agent halon replacements fall into two broad categories: (1) compounds

and (2) inert gases and mixtures. Halogenated agents include compounds containing carbon, hydrogen, bromine, chlorine, fluorine, and iodine. They are grouped into seven categories, as displayed in Table 17.6.1.

Table 17.6.2 summarizes currently available clean fire suppression agents included in NFPA 2001.

Although the characteristics of halocarbon clean agents vary widely, they share several common attributes:

- All are electrically nonconductive.
- All are clean agents; they vaporize readily and leave no residue.
- All are liquefied gases or display analogous behavior (e.g., compressible liquid).
- All can be stored and discharged from typical Halon 1301 hardware (with the possible exception of HFC-23, which more closely resembles 600 psig [40 bar] superpressurized halon systems).
- All (except HFC-23) use nitrogen superpressurization in most applications for discharge purposes.
- All are less efficient fire extinguishants than Halon 1301 in terms of storage volume and agent weight; the use of most of these agents requires increased storage capacity.
- All are total flooding gases after discharge; many require additional care relative to nozzle design and operating pressure to ensure mixing.
- All produce more decomposition products than Halon 1301, given similar fire type, fire size, and discharge time.

TABLE 17.6.1 Categories of Clean Agent Fire Suppression Agents

Category	*Compounds*
Halon	Chlorine, bromine, or fluorine and hydrogen and carbon
Hydrofluorocarbons (HFC)	Fluorine, hydrogen, and carbon
Hydrochlorofluorocarbon (HCFC)	Fluorine, chlorine, carbon, and hydrogen
Perfluorocarbons	Carbon and fluorine
Fluoroiodocarbon (FIC)	Carbon, fluorine, and iodine
Fluoroketones (FK)	Carbon, fluorine, and oxygen
Hydrobromofluorocarbon (HBFC)	Bromine, fluorine, and carbon

Inert gas alternatives include nitrogen and argon, and blends of these. One inert gas replacement has a small fraction of carbon dioxide. Carbon dioxide is not an inert gas because it is physiologically active and fatal at low concentrations (approximately 9 percent). Inert gas clean agents are stored as pressurized gases and, hence, require substantially greater storage volume. They are electrically nonconductive, form stable mixtures in air, and leave no residue.

EXTINGUISHING MECHANISMS

Halocarbon clean agents extinguish fires by a combination of chemical and physical mechanisms, depending on the compound. Chemical suppression mechanisms of HBFC and HFIC compounds are similar to Halon 1301; that is, the Br and I species scavenge flame radicals, thereby interrupting the chemical

TABLE 17.6.2 Clean Fire Extinguishing Agents in NFPA 2001

FC-2-1-8	Perfluoropropane	C_3F_8
FC-3-1-10	Perfluorobutane	C_4F_{10}
FIC-13I1	Trifluoroiodide	CF_3I
FK-5-12mmy2	Dodecafluoro-2-methylpentan-3-one	$CF_3CF_2C(O)(CF(CF_3)_2)$
HCFC Blend A	Dichlorotrifluoroethane HCFC-123 (4.75%) Chlorodifluoromethane HCFC-122 (82%) Chlorotetrafluoroethane HCFC-124 (9.75%) Isopropeny-1-methylcyclohexene (3.75%)	$CHC_{12}CF_3$ $CHCIF_2$ $CHCIFCF_3$
HCFC-124	Chlorotetrafluoroethane	$CHCIFCF_3$
HFC-125	Pentafluoroethane	CHF_2CF_3
HFC-227ea	Heptafluoropropane	CF_3CHFCF_3
HFC-23	Trifluoromethane	CF_3CHFCF_3
HFC-236fa	Hexafluoropropane	$CF_3CH_2CF_3$
IG-01	Argon	Ar
IG-100	Nitrogen	N_2
IG-541	Nitrogen (52%) Argon (40%) Carbon dioxide (8%)	N_2 Ar CO_2
IG-55	Nitrogen (50%) Argon (50%)	N_2 Ar

chain reaction. Other replacement compounds suppress fires primarily by extracting heat from the flame reaction zone, reducing the flame temperature below that which is necessary to maintain sufficiently high reaction rates by a combination of heat of vaporization, heat capacity, and the energy absorbed by the decomposition of the agent.

Burgess et al.[2] performed kinetic simulations on a range of fluorinated compounds (CF_4, CF_3H, CF_2H_2, CF_3-CF_3, CF_3-CF_2H, and CF_3-CFH_2) for chemical kinetic fire suppression effects of fluorine compounds. Of the agents examined, only CF_3H was seen to have any chemical effect on flame suppression. They concluded that the differences in flame suppression properties can be explained by differences in heat capacity and relative amounts of heat release during agent combustion. Battin-LeClerc et al.[3] indicate that, while clearly some noncatalytic flame inhibition may occur with FC and HFC compounds, this effect is expected to be limited. Richter et al.[4] draw similar conclusions, owing to the inability of fluorine atoms to be continuously recycled in the flame, as occurs with bromine.

Oxygen depletion also plays an important role in reducing flame temperature. The energy absorbed in decomposing the agent by breaking fluorine and chlorine bonds is quite important, particularly with respect to decomposition production formation. There is undoubtedly some degree of "chemical" suppression action in flame radical combustion with halogens, but it is considered to be of minor importance because it is not catalytic.

The lack of significant chemical reaction inhibition in the flame zone by HCFC, HFC, and FC compounds results in higher extinguishing concentrations relative to Halon 1301. The importance of the energy sink, represented by breaking halogen species bonds, results in higher levels of agent decomposition relative to Halon 1301.

Inert gas agents suppress flames by reducing the flame temperature below the threshold necessary to maintain combustion reactions. This flame supression is done by reducing the oxygen concentration and by raising the heat capacity of the atmosphere supporting the flame. For example, the addition of a sufficient quantity of nitrogen to reduce the oxygen concentration below 12 percent (in air) will extinguish flaming fires. The agent concentration required (and, hence, the minimum oxygen level) is a function of the heat capacity of the inert gas added. Hence, there are differences in minimum extinguishing concentrations between inert gases.

The differences between argon and nitrogen are clearly shown in Table 17.6.2, with nitrogen extinguishing concentrations in the range of 30 percent (14.6 percent O_2) and argon extinguishing concentrations of 41 percent (12.3 percent O_2). Inert gas blends with more nitrogen than argon will have lower minimum extinguishing concentrations. When one considers nitrogen as the primary inert gas in examining oxygen concentrations at extinction in fire experiments, the minimum oxygen concentration at extinction can be as low as 12 percent, or a 42.5 percent "agent" concentration.[5,6]

FLAME SUPPRESSION EFFECTIVENESS

Flame suppression effectiveness of total flooding halon replacement agents has been evaluated in a number of ways. The predominant small-scale test method for establishing flame extinguishing concentrations for liquid and gaseous fuels is the cup burner.

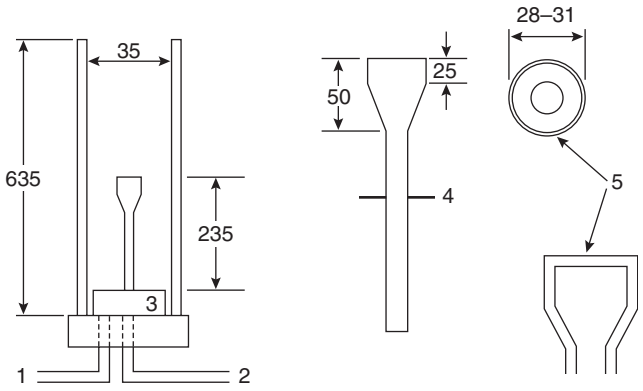

FIGURE 17.6.1 ISO Standard Cup Burner Apparatus (Source: ISO 14520-1, "Gaseous Fire Extinguishing Systems—Physical Properties and System Design, Part 1: General Requirements," International Organization for Standardization, Geneva, Switzerland, 2005. Copyright International Organization for Standardization.)

Figure 17.6.1 is a schematic of the standardized ISO cup burner.[1] A small laminar flame is established above a "cup" of fuel surrounded by a cylindrical chimney. An air/agent mixture flows up the chimney surrounding the flame. The minimum concentration of agent (in air) at which the flame is extinguished is the minimum extinguishing concentration (MEC). There are many variations of the basic device as used by different laboratories; these variations include cup and chimney diameter, different mixing and measuring methods, chimney height, and agent/air mixture velocity past the flame.[7]

Table 17.6.3 gives the most recent heptane cup burner values vetted on a consensus basis and contained in the ISO series of documents. These data are the best available consensus values for the MEC for heptane. There have been substantial differences between MEC values published in the past. These differences are largely due to the use of more standardized test devices, different test procedures, and operator error.

TABLE 17.6.3 Minimum Class B Extinguishing Concentration

Agent	*ISO Class B Extinguishing Concentration (%)*
HFC-227ea	6.9
HFC-125	9.3
HFC-23	12.6
FK-5-1-12	4.5
IG 541	31.7
IG 55	36.5
IG 01	39.5
IG 100	33.6

Minimum extinguishing concentrations for Class A fuels are determined as part of the third-party approval process. They are based on standardized tests of plastic sheet array. There are substantial differences between Class A extinguishing concentrations developed for use in NFPA 2001 versus those required in ISO 14520. The differences are largely based on the details of the test, such as ignition pan size and preburn, but are also substantially affected by the allowable extinguishment time. Both UL and FM and, therefore, NFPA 2001 allow a much longer extinguishment time (600 seconds) than the 180 seconds presented by ISO. This partially explains the substantially higher Class A extinguishing concentrations obtained under ISO 14520, as seen in Table 17.6.4.

Wickham[8] has provided comparative values for cost and footprint of halon and halon replacement systems for use in marine applications. These comparisons are given for weight, footprint, and cost in Tables 17.6.5, 17.6.6, and 17.6.7, respectively.

Note that all clean agent alternatives require at least 50 percent more agent by weight as a consequence of the elimination of bromine in the compounds and subsequent level of catalytic recombination of flame radicals. These data should be taken as representative values, as there are variations among hardware manufacturers. The storage volume equivalent does not translate directly to a required area or volume for storage cylinders. The relative "footprint" of these storage volume equivalents will vary with the volume of the space protected and the maximum storage cylinder size offered by a manufacturer for a particular gas.

EXPLOSION INERTING

One of the most important application areas of total flooding fire suppressants is explosion inertion. The inerting concentration of an agent is the concentration required to prevent unacceptable pressure increases in a premixed fuel/air/agent mixture subjected to an ignition source. Inertion concentrations are typically measured in small laboratory-scale spheres with an electric spark initiator.

The measured inerting concentration of an agent is dependent on the details of the test apparatus used, particularly the ignition source strength and "allowable" pressure rise. The "allowable" pressure rise is a surrogate measurement of the distance the flame front travels inside the constant volume sphere prior to suppression. Inerting concentrations are not appropriate for use in deflagration or detonation (explosion) suppression.

Small-scale sphere data are used to develop flammability diagrams for various fuel/oxidizer/agent concentrations. The chapter on flammability limits by Beyler in the *SFPE Handbook of Fire Protection Engineering* gives an excellent introduction to the subject.[9] A wealth of data on flammability limits for inert gases, such as nitrogen and argon, and for a variety of fuels is available in the combustion literature.

Table 17.6.8 provides inerting concentration data for several agents and fuels taken from small-scale inertion spheres. There are some substantial differences in results. Ignition source type and strength as important variables with differences of approximately 40 percent for Halon 1301 inerting concentrations are reported. Figure 17.6.2 shows flammability diagrams[10] derived from small-scale inertion data along with points taken from a large-scale 795 ft^3 (22.5 m^3) explosion vessel. Although the small- to large-scale agreement is reasonable, there are scale effects.

Explosion suppression systems employ rapid delivery of agent following very early detection of an ignition. Such systems employ significantly higher agent quantities (than flame suppression or inertion) delivered at higher rates. The total agent delivery time is on the order of 100 millisecond.

Explosion suppression systems must be specifically designed for a particular application. There are no generic design requirements or standards currently available for such systems.

Senecal et al.[11,12] report on explosion suppression testing for occupied armored fighting vehicles and aerosol filling rooms. Results were obtained on premixed fuel droplet sprays. In contrast to flame suppression or inerting, suppression or deflagration requires significantly more agent. The aerosol filling room tests employed 44.1 lb (20 kg) of HFC-227ea, FC-3-1-10, HFC-236fa, and 22 lb (10 kg) of water in a 2827 ft^3 (80 m^3) test room to suppress a 3.2 oz. (90 g) propane release in a simulated aerosol fill station. Suppression of the propane-air deflagration was achieved, and the maximum flame front extension was approximately 4 ft (1.22 m). Suppression tests of heated diesel fuel droplet cloud deflagrations were conducted in simulated armored fighting vehicle crew compartments.

Table 17.6.9 summarizes typical data for flame suppression, inertion, and deflagration suppression concentrations. Note that these values are for comparison purposes only. They should not be used in any way for design purposes.

Suppression of detonations requires substantially higher agent concentrations. An excellent discussion is given in "Review of the Use of Carbon Dioxide Total Flooding Fire Extinguishing Systems." [8]

TOXICITY[13]

Background

Toxicology tests are performed based on (1) the duration and frequency of the exposure and (2) determination of specific biological effects.[14] The studies examining duration and frequency are divided into four categories:[15]

1. Acute: less than 24 hour exposure
2. Subacute: 1 month or less of exposure
3. Subchronic: 1- to 3-month exposure
4. Chronic: more than 3 months of exposure

The specific biological effects examined are many, but for the purposes of halocarbon fire-fighting agents, the following are the most common:

1. Inhalation toxicity
2. Developmental toxicity
3. Reproductive toxicity
4. Genetic toxicity
5. Cardiotoxicity
6. Central nervous system (CNS) effects

The separation into categories is based on experience that acute exposure toxicity and chronic exposure toxicity can be significantly different. For example, the acute (single) exposure toxicity for organic solvents is typically central nervous system disturbances that are reversible once the exposure ends. Chronic (repeated, long-term exposure) toxicity for organic solvents can include liver damage and cancer, which are not considered reversible. Each chemical may cause different specific acute

A., "Large-Scale Inertion Evaluation of NFPA 2001 Agents," *Proceedings* of the 1993 International CFC and Halon Alternatives Conference, Washington, DC, October 20–22, 1993)

and chronic toxicity problems that need to be addressed. These include cancer, birth defects, liver toxicity, heart toxicity, and so on.[15] Different chemicals within the same family may cause different effects or similar effects over a wide range of concentrations. Lastly, the route of exposure is examined. For gaseous fire-fighting agents, inhalation studies are required.

A series of tests is required, beginning with the acute studies. This is done to build on the results from previous shorter-term studies. One important reason is to establish the correct exposure concentrations for testing. An improper dosage could cause the invalidation of a long-term test halfway or more through the study; that is, too many test specimens may die from an excessive test dosage. An equally important reason is to preclude running expensive, longer-term chronic studies when the shorter-term studies do not suggest any need. The shorter-term studies can be used as screens to give indications, but not direct results, for the type of toxicity problems that longer-term tests may need to address. The toxicology series is not a "cookbook" process. Professional toxicologists must evaluate the results through each step of the process and make educated decisions on the next phase of testing.

A minimum set of tests required by the U.S. Environmental Protection Agency (EPA) under the Significant New Alternatives Policy (SNAP) program would likely include:[16]

1. Acute toxicity "range finder," for example, limit or LC_{50} test
2. Cardiac sensitization test

3. Developmental and reproductive toxicity
4. 4- or 13-week subchronic test
5. Genetic toxicity screening test (such as Ames test)
6. Thermal decomposition product test

As noted, acute toxicity studies are usually the first to be done. These tests provide information on acute lethality. For inhalation toxicity this is called the LC_{50} and is the concentration at which 50 percent of the animals die within 14 days of the exposure. This study is usually a single 4 hour exposure and generally performed with mice and rats.

Subacute studies are the lowest tier of the repeated exposure tests. They are used to (1) discover specific toxicity problems above the acute effects and (2) refine the proper doses for follow-up tests. Subacute studies generally run 14 days.

Subchronic studies are used to (1) establish final dosage data to be used in chronic studies and (2) identify further the specific toxicity concerns of long-term exposures. These studies are usually performed for 90 days on one or two species.

Chronic studies are generally performed in the same way as subchronic tests, except that the exposure is increased beyond 3 months and up to 2½ years. Often chronic studies incorporate carcinogenicity (cancer) tests to preclude running separate tests.

Developmental and reproductive toxicity studies are designed to look at the adverse effects on the reproductive system and on offspring. Developmental tests examine the effects on a developing organism any time during its life span as the result of repeated exposure by either parent before conception or during pregnancy and postnatally until puberty. Reproductive toxicology is a multigenerational study concerned with the adverse effects to the reproductive system that may be passed on to the first-generation and second-generation offspring by either parent. The specific study of defects caused between conception and birth is called teratology.

Genetic toxicity studies examine mutangenic potential, that is, the capability of a chemical to cause changes in the genes of a cell. These studies are also effective as screens and tests for the potential to cause cancer. Two of the most common tests used for halocarbon agents are (1) the Ames test and (2) the micronucleus test. The Ames test examines the ability of the chemical to cause changes or mutations in the genes of a cell. The micronucleus test studies look at chromosome aberrations. Both screens are used as indicators of the potential to cause cancer. Results of these screens are used to decide whether longer-term cancer studies, other genetic toxicity studies, or developmental and reproductive studies are required.

Beyond the preceding tests, specific toxicology concerns may warrant requiring other, less standard, toxicity studies. Such is the case for halocarbons where they have been found to depress the heart rate. In the presence of adrenaline, the heart can experience mild conditions of an irregular heartbeat to severe conditions of a full heart attack. This effect was first seen with chloroform when it was widely used as an anesthetic. The test developed to assess this type of cardiotoxicity is called "cardiac sensitization."

The data gathered from these tests on nonhuman species are only an indication of the toxicity for humans. Toxicologists use these studies to do risk assessments to predict the toxicity of a chemical or specific mixture of chemicals in a particular exposure scenario. The acute tests are used to establish limits for single or very infrequent exposures. For example, acute toxicity is used in determining the effects that can be expected when a fire suppression system is discharged. Subchronic and chronic studies are used to establish limits for repeated exposures for workers who are subjected to the halocarbon on a more frequent basis, such as production plant workers and maintenance personnel who fill/refill cylinders.

The EPA requires, as a minimum for halocarbon fire suppression agents, cardiac sensitization and developmental toxicology studies to set acute exposure limits. To set worker/manufacturer exposure limits, the EPA uses, as a minimum, genetic toxicology, 90-day subchronic and developmental toxicology studies.[16]

Although all halocarbon agents are tested for long-term health hazards, the primary end point is acute, or short-term, exposure. The primary acute toxicity effects of the halocarbon agents described in this chapter are anesthesia and cardiac sensitization. For inert gases, the primary physiological concern is reduced oxygen concentration.

Halocarbon Agents

Cardiac sensitization is the primary short-term "acute" toxicity problem for fire suppression applications. *Cardiac sensitization* is a term describing the sudden onset of cardiac arrhythmias in the presence of a concentration of an agent caused by sensitization of the heart to epinephrine. The presence of epinephrine is critical to the onset of arrhythmias. This is important in fire protection applications due to the increased production of epinephrine by the body under stress.

The toxicity end points used to describe cardiotoxicity and allowable exposure levels are no observed adverse effect level (NOAEL) and the lowest observed adverse effect level (LOAEL). The NOAEL is the highest concentration of an agent at which no "marked" or adverse effect occurred. The LOAEL is the lowest concentration at which an adverse effect was measured.

The procedures used to evaluate cardiac sensitization vary somewhat. The procedure involves intravenous dosing of male beagles with epinephrine for 5 minutes. Continuous inhalation exposure to the agent follows for 5 minutes. Following this inhalation exposure, the dog is dosed again with epinephrine and monitored for 5 minutes to determine the effect of the agent and epinephrine. The protocol is performed at higher doses until an effect occurs.

Effects are monitored by electrocardiograph (ECG) measurements. An adverse effect is generally considered to be the appearance of five or more arrhythmias or ventricular fibrillation. The data from these tests are evaluated by medical experts, and the appropriate NOAEL and LOAEL values are reported by the EPA under the SNAP program.

There is no direct correlation between the experimental results from dogs to humans. It is generally accepted due to the combination of the high doses of epinephrine in the tests and the similarity in cardiovascular function between dogs and humans that the results can be applied to humans. It is believed that the results of these tests are conservative with respect to direct

application of the results to humans in typical fire suppression applications.

In addition to the short-term chronic exposure limits of interest in fire suppression system design, the EPA evaluates longer-term inhalation data for these compounds. Table 17.6.10 summarizes NOAEL, LOAEL, and LC_{50} values. Note that the LC_{50} values greatly exceed the NOAEL.

The use of halocarbon agents in occupied areas is generally subject to the constraint that the design concentration must be less than the NOAEL. In the 1996 edition of NFPA 2001, an exception allows the use of total flooding gases up to LOAEL for Class B hazards where a predischarge alarm and time delay are provided and where acceptable to the authority having jurisdiction. The rationale for the exception is based on (1) the conservative nature of NOAEL/LOAEL, (2) consistency with EPA guidelines, and (3) positive benefit of higher agent concentrations in certain flammable/combustible liquid hazards. Although it is recommended that all systems employ predischarge alarms and that personnel evacuate prior to system actuation, it is understood that inadvertent discharges and short-term exposures will occur, hence the limitation. It is expected that emergency exposures for up to several minutes at or below the NOAEL and possibly the LOAEL are reasonably safe. In no case should systems be designed or installed where intentional exposure of any duration is anticipated.

In the 2000 edition of NFPA 2001, the exposure limits for halocarbon agents have been modified. Physiologically based pharmacokinetic modeling (PBPK) for evaluation of acute exposure to halocarbon agents has been used to establish alternative exposure limits for halogenated agents. PBPK modeling attempts to account for the time-dependent uptake rate of halocarbons in the body and establishes exposure limits based on the rate of uptake.[17–22] The limits are based on the concentration of agent and the time at which the concentration of agent in the blood equals that of the LOAEL. Typical PBPK results for safe exposure times for HFC-227ea and HFC-125 are given in Table 17.6.11. Note exposure above the NOAEL limits and up to the LOAEL is permitted.

These limits were derived and supported by the EPA, which has the primary regulatory authority for health and toxicity associated with halon replacements. The use of the PBPK approach partially accounts for the differences between laboratory animal tests and humans. The laboratory results form the basis of the end points (LOAEL) and are still conservative due to the nature of epinephrine dosage used during the animal tests.

TABLE 17.6.10 Toxicity Data for Halocarbon Clean Agent Fire Suppression

Designation	*Formula*	*NOAEL Percentage V/V$_a$*	*LOAEL Percentage V/V$_a$*	*LC_{50} or $ALC_{b,c}$ Percentage*

			13.5	135,000	0.49

Inert Gas Agents

Inert gas agents are effectively physiologically inert. The primary physiological problem with these agents is the reduced oxygen concentration caused by the high agent design concentrations. One inert gas blend employs a low concentration of CO_2 (which is not physiologically inert) in order to counter the effects of the reduced oxygen concentration. The mechanism of this effect is discussed in "Research Basis for Improvement of Human Tolerance to Hypoxic Atmospheres in Fire Prevention and Extinguishment." [23]

The EPA had previously determined that inert gases can be used in concentrations up to 43 percent in normally occupied areas subject to similar limits placed on halocarbon agents when used at the NOAEL. This usage results in a residual oxygen concentration of 12 percent. The analog to the LOAEL is 52 percent agent concentration with a 10 percent residual oxygen concentration. NFPA 2001 requirements mirror the EPA limitations at 43 percent agent concentration with the exemption permitting use up to 52 percent concentration for Class B hazards. There appears to be a growing consensus among independent toxicologists that inert gases could be safely used up to 52 percent concentration for a 5-minute exposure time.

This consensus was further developed in the 2000 edition of NFPA 2001. The current limitations on exposure limits for inert gases are as follows:

> For gas concentrations up to 43 percent (a residual oxygen concentration of 12 percent), exposure time is limited to 5 min. For agent concentrations between 43 and 52 percent (12 and 10 percent residual oxygen concentration), the exposure time is limited to 3 min. For concentrations between 52 and 62 percent (10 and 8 percent residual oxygen concentration), exposure time is limited to 30 s. For concentrations above 62 percent (above 8 percent residual oxygen concentration) exposure must be avoided.

There is strong indication that small concentrations of CO_2 added to inert gases (such as IG-541) substantially reduce hypoxic effects and improve human performance at low oxygen levels. Regulatory authorities have not yet differentiated between such agents and other inert gases or blends.[23]

ENVIRONMENTAL FACTORS

Two main environmental impacts need to be considered with respect to halocarbon extinguishing agents: (1) ozone depletion and (2) global warming.[24] Another environmental factor, atmospheric lifetime, can be considered in the discussion of each of these environmental impacts. It is also a "stand-alone" environmental concern that needs to be addressed. International, national, state, and local governments currently regulate halocarbon fire-fighting agents based on their effect on ozone depletion. However, the U.S. EPA also takes into account atmospheric lifetimes and global warming potentials in the implementation of its SNAP program under Section 612 of the Clean Air Act, as amended in 1990. Although no specific national environmental regulations cover global warming and atmospheric lifetimes, the consideration of these issues in the EPA's implementation of existing regulations makes these issues of concern.

Ozone Depletion

Ozone (O_3) is a naturally occurring gas that is found in the atmosphere. Most naturally occurring ozone is created by the reaction of O_2 with ultraviolet (UV) light coming from the sun.

$$O_2 + UV \rightarrow O + O$$

$$O + O_2 \rightarrow O_3$$

The UV light causes this reaction to occur. Ozone is also created in nature when the high energy output from lightning initiates a similar reaction.

Ozone is also formed by a number of manufactured sources, mainly as a result of air pollution. When carbon monoxide, methane, and other hydrocarbons meet nitrogen oxide (e.g., from car exhaust) and ordinary sunlight, ozone is produced.[25] It is also produced by laser printers and electrical motors, and is responsible for the pungent odor often associated with the devices. Man-made ozone is often called "smog" and is a considerable health risk.

With respect to the environment, an important difference exists between naturally occurring and man-made sources of ozone. Man-made ozone is produced in the region of our atmosphere called the troposphere. This is the portion that starts at the earth's surface and extends 3.7 to 10.6 mi. (6 to 17 km) above the surface. (The thickness of this region is different at the poles versus the equator.) Naturally occurring ozone is produced primarily in the stratosphere. The stratosphere is the region directly above the troposphere and extends to approximately 31 mi (50 km) above the earth's surface.[26] The ozone produced in the stratosphere by the reaction described earlier is what is known as the "ozone layer" and serves a very important purpose. Ozone absorbs the UV-b portion of the total UV in sunlight and prevents it from entering further into the atmosphere. This absorption has two net effects: (1) it lowers the amount of harmful UV-b that plants and animals are exposed to and (2) it prevents more ozone from being created naturally in the troposphere.

Over about the last decade, the United States has begun to give "ozone alerts," typically as part of daily weather reports. The ozone referred to by these alerts is tropospheric ozone and does not refer in any way to stratospheric ozone or ozone depletion. There are, however, concerns with tropospheric ozone. These concerns will be addressed along with the discussion of global warming.

Halons, HCFCs, and other halocarbons containing chlorine or bromine have been shown to cause the destruction of stratospheric ozone. The characterization of stratosphere ozone destruction is not a measure of the exact amount of ozone destroyed. Instead, it is the relative amount of ozone destroyed as compared with an arbitrary standard. The standard chosen is CFC-11, which has been assigned an ozone depletion potential (ODP) of 1. ODP of all other halocarbons relates to their relative effect on the destruction of ozone as compared with CFC-11. Halon 1301 has an ODP of 13, meaning it will destroy 13 times

as much ozone as CFC-11 on a pound-for-pound (kilogram-for-kilogram) basis. A compound having an ODP of 0.1 would have 10 percent of the relative ozone-depleting effects of CFC-11. All ODP values are based on mass (weight) and not on moles (numbers of molecules).

Atmospheric Lifetimes

When one thinks of a chemical species lifetime, the term *half-life* is often used. This usage is most common in the nuclear field where calculations are made to determine how long it takes a species to decay to half its original concentration. Atmospheric lifetime values used in the determination of ozone depletion and global warming potentials are *not* half-lives. They are $1/e$ lifetimes, sometimes called *e*-folding lifetimes.

It has been determined that greenhouse gases break down in the atmosphere according to the following equation:

$$C = C_0 e^{-kt}$$

where

C = Concentration at time t

C_0 = Initial concentration at time

k = An experimentally determined rate constant (units = 1/time)

A mathematical manipulation can be made to express this equation as a function of more readily quantifiable terms and is accomplished by defining the atmospheric lifetime, *L,* as an *e*-folding lifetime, or the time it takes for the ratio of C:C_0 to be equal to $1/e$ (e is the base of the natural logarithm system and has a numerical value of approximately 2.718). The resulting equation is as follows:

$$C = C_0 e^{-t/L}$$

Although the term *half-life* is most commonly used when describing the decay of a species concentration, the use of the *e*-folding lifetime allows for quantification of concentration in terms of a compound's atmospheric lifetime, as previously shown. A half-life refers to the time it takes for half a given amount of compound to be broken down in the atmosphere; thus, the ratio C:C_0 is equal to $1/2$. Using an *e*-folding lifetime, the ratio is equal to $1/e$ or 0.368. After one lifetime, the concentration will be equal to 0.368 times its original value. After two lifetimes, the concentration will be 0.135 or $(0.368)^2$ its original value. After three lifetimes, the concentration will be 0.0498 or $(0.368)^3$ times its original value, and so on.

An important factor when using the preceding equation to solve for concentration as a function of time is that, no matter what value is used for time, the concentration never equals zero. Some portion will always exist in the atmosphere. When the atmospheric lifetime is small, the concentration over hundreds of years may become negligible. When the atmospheric lifetime is very large, on the order of tens of thousands of years, the concentration in the atmosphere may not be negligible.

The environmental concern is one of "what if" The halocarbons were believed to be "safe" for many years after their release into the atmosphere began. It was not until many years later that they were linked to ozone depletion. There is a concern that these other halocarbons, or other compounds, may cause other environmental impacts that yet are unknown. If the atmosphere is filled with these chemicals and they exist in appreciable amounts for hundreds, thousands, and millions of years, what then? Might the damage we do to our environment be more than humans can cope with? Nature can probably overcome this impact, but it may take tens of millions of years. This is a short time frame for nature but not for man. Current implementation of the EPA SNAP program places restrictions on perfluorocarbons that have very large or "outlying" atmospheric lifetimes as compared with the rest of the halocarbons. This restriction is not based on any known or anticipated environmental problem. It is a response to the "what if" concerns raised previously.

Global Warming Potential

A basic understanding about the earth's climate and atmosphere is needed to understand what global warming potential (GWP) is and how to attempt its measurement.

The atmospheric region closest to Earth, the troposphere, represents approximately 81 percent of the earth's atmosphere. It is made up mainly of nitrogen (N_2) and oxygen (O_2), representing 99 percent of its composition. The remaining 1 percent is made up of mostly argon, with smaller amounts of water, 0.2 percent; and CO_2, 0.03 percent (300 parts per million by volume [ppmv]). The atmosphere also contains several compounds in very small amounts known as "trace gases." These are methane, nitrous oxide, carbon monoxide, hydrogen, ozone, and halocarbons, which are so dilute that they are measured in parts per billion by volume (ppbv).

Weather and climate are not the same. Weather is the short-term, day-to-day conditions of temperature, humidity, rainfall, winds, and so on.[27] Climate is the long-term condition averaged over many years. Based on the climate of a region, particular weather is expected or predicted. Many factors determine a region's climate. These are a complex interaction of both natural and man-made activities. The biggest factor on the overall behavior of the earth's climate is the sun. The sun's energy hits Earth more at the tropics and equator than at the poles. Driven by diffusion principles, Earth distributes heat away from the tropics, which leads to the major wind and ocean currents.

Estimates of the average temperature of Earth's atmosphere have been made, assuming two theoretical conditions. The first assumes no atmosphere at all, and the second assumes an atmosphere made up solely of N_2 and O_2 (normally representing 99 percent of our atmosphere). In both cases, models have predicted that the earth's surface would be some 91°F (33°C) cooler than it is. The temperature difference is believed to be a direct result of the very small amounts of trace gases, water vapor, and CO_2. These act very much like the glass on a greenhouse that lets the sunlight in but helps to prevent the heat from escaping—hence, the terms *greenhouse effect* and *greenhouse gases.* A greenhouse gas is defined as any gas that absorbs infrared (IR) radiation.

It should not be surprising that certain constituents in the air can cause it to stay warmer. For example, it is common knowledge that the temperature on a hot, humid night does not

drop as much as on a less humid night. During the winter, a clear night will have a larger drop in temperature than a cloudy night. In both cases, the difference is due to the water vapor present in the air. In fact, water is the largest contributor to the natural greenhouse effect, followed by CO_2.

Climate change and global warming are not synonymous. Climate change includes cooling and warming of the atmosphere. Global warming only deals with the aspects of climate change that result in warming of the atmosphere.

It is estimated that about one-third of the total solar radiation is reflected off earth's atmosphere. Most of the remaining two-thirds passes through the atmosphere and is absorbed by the earth's surface, causing it to warm.[28] The earth cools itself by releasing heat, or IR. In order for a balance to be maintained, the solar radiation coming in must equal the radiation going out. If more radiation entered the atmosphere than left, the earth would be constantly getting warmer. The opposite would be true if more radiation left earth than came in; that is, the earth would be constantly getting cooler.

O_2 and N_2 are transparent to IR, meaning that these compounds easily let IR radiation or heat pass through. Greenhouse gases are not transparent to IR—they absorb it. Their ability to absorb IR is finite, however, and some of what they absorb is reradiated out of the atmosphere. The IR reradiated is what is important. For a given concentration of greenhouse gases, reradiation depends on two factors: (1) how much IR comes in and (2) the temperature of the gas. Given the premise that the atmosphere wants to establish an equilibrium, the IR from the earth's surface and the amount reradiated from these gases want to be equal. Because the IR coming from the earth's surface does not change, the only remaining variable to affect the equilibrium is temperature. The atmosphere will heat until the IR balance is achieved. As stated previously, this has been predicted as a 91°F (33°C) rise in the temperature of the atmosphere.

On a day-to-day basis, the premise that the solar radiation is equal to the sum of IR radiated from the earth's surface and the IR reradiated from the greenhouse gases is not necessarily true. Daily, weekly, monthly, and yearly changes in weather are always occurring. Nevertheless, over the years, the averages are very close to equal and have resulted in a stable climate. To understand the greenhouse effect, scientists studying the climate have developed the concept of *radiative forcing.* They define radiative forcing as anything that will cause the energy balance at the top of the troposphere to no longer be in balance. Put another way, it is when radiation in and the radiation out of the top of the troposphere are not equal. This unbalanced radiation forces the climate to adapt, hence the term *radiative forcing.* The theory is that the climate will change to equalize the incoming and outgoing radiation. Any condition that results in a positive radiative forcing will cause a rise in the average temperature and, therefore, is responsible for global warming. Any condition that results in a negative radiative forcing will cause a drop in the average temperature and, therefore, is responsible for global cooling.[28]

To estimate the amount of global warming expected from a release of a particular greenhouse gas, a scale was developed by the International Panel on Climate Change (IPCC), based on the idea of radiative forcing. This scale is called the global warming potential (GWP) and relates to positive radiative forcing that will cause the atmosphere to heat up. The GWP is the cumulative amount of radiative forcing between the present and some future time caused by a unit mass (weight) of a compound, as compared with the same unit mass (weight) of an arbitrary standard. CO_2 is the most common reference, and 20 year, 100 year, and 500 year time periods, or horizons, are the most common time references cited in the literature.[28] The choice of time horizons is a policy issue and not a technical one.[29]

Since the GWP is a cumulative effect, summed year by year over a given time horizon, the quantity present in the atmosphere must be known year by year over that horizon. The atmospheric lifetime is used to perform these calculations. GWPs are also affected by the specific IR-absorbing capabilities of the chemical. Analogous to ODPs, GWPs are not exact numbers showing the precise effect on global warming. A 100 year horizon GWP of 6200 for Halon 1301 means that 1 lb (0.454 kg) of Halon 1301 will cause as much global warming as 6200 lb (2812 kg) of CO_2. A 500 year horizon GWP for methylene chloride of 0.3 means that 1 lb (0.454 kg) of methylene chloride will cause the same warming as 0.3 lb (0.14 kg) of CO_2.

GWPs are used to determine the future global warming contribution of a substance *over a given time* by multiplying the weight of the greenhouse gas by a specific time-horizon-GWP. The resultant number can be compared with others to decide which will have the least (or greatest) impact *over that time horizon.* Emitting a large quantity of a small GWP greenhouse gas may cause less global warming than a small release of a very large GWP greenhouse gas over a certain time horizon. Different time horizons may lead to different results.

The choice of which time horizon to use is a policy issue and not a technical one. A standard measure to predict future global warming commitments was developed as a tool to help policy makers and regulators in making decisions of which greenhouse gases would provide the biggest "bang for the buck." Currently, there is no standard in choosing a time horizon. In the future, however, this may change. It is also possible that different time horizons will be used for different greenhouse gases.

Environmental Regulation of Halon Replacements

The evaluation of clean agent fire suppressants includes a consideration of environmental factors. International, national, and local government regulations control the use of any alternatives in this regard. The primary environmental consideration is ODP. This is a measure of a chemical's ability to deplete stratospheric ozone with CFC-11 as a basis with an ODP of 1. All chemicals with a nonzero ODP are subject to phaseout under the Montreal Protocol and its amendments. Table 17.6.12 summarizes environmental impact data for halocarbon alternatives. Note that FC and HFC compounds have zero ozone depletion potential. One relatively recent advance has been the development of the Fluoroketone FK-5-1-12, a halogenated agent with essentially zero GWP.[30] This agent pressures many of the advantages of a halogenated agent but with an environmental impact similar to inert gases.

In the United States, the EPA has the responsibility for regulating the use of halon replacements. Through the SNAP

TABLE 17.6.12 Environmental Factor for Clean Agents

Designation	*ODP*	*GWP (100 years)*	*Atmospheric Lifetime (years)*
Halon 1301	12.000	7,030	LS
HFC-227ea	0.000	2,900	34.2
HFC-23	0.000	14,310	270
HFC-125	0.000	3,450	29
FK-5-1-12	0.000	Extremely low	0.038
Inert gas	0.000	0	NA

program, the EPA may prohibit or restrict the use of halon replacements on the basis of certain environmental factors or toxicity. There are two basic types of restrictions given to date: (1) restrictions on use in occupied versus unoccupied areas and (2) use restrictions (e.g., HCFC-22, HCFC-124, CF_3I) related to high atmospheric lifetime (e.g., C_4F_{10}, C_3F_8). The EPA periodically updates this list as new agents are proposed or as new data become available. It is relatively common to have NOAEL/LOAEL values updated, usually increased, as additional data become available. Such updates may change the acceptability of an agent for use in occupied areas.

HFCs and PFCs are part of the basket of industrial gases (also including methane, sulfurhexafluoride, and nitrous oxide) included in the Kyoto Protocol and may therefore be subject to emission controls in signatory nations. Currently, HFCs and PFCs represent less than 2 percent of greenhouse gas emissions on a carbon equivalency basis. Some PFCs were briefly used as fire extinguishants.

THERMOPHYSICAL PROPERTIES

Tables 17.6.13 and 17.6.14 give thermophysical properties of clean agent replacement update from NFPA 2001, in U.S. custom and SI units, respectively.

Representative isometric diagrams for various clean agents are given in Figures 17.6.3, 17.6.4, and 17.6.5 for HFC-227ea, HFC-23, and IG-541, respectively. The features of a typical isometric diagram for a liquefied halocarbon, superpressurized to 360 psig, can be seen in Figure 17.6.3. The importance of an isometric diagram is that it determines the maximum fill density for an agent in a cylinder with a fixed pressure rating. The basic rule is that the cylinder must not become liquid full at 130°F (54°C) (for U.S. DOT) and/or the pressure developed at 130°F (54°C) must not exceed $^5/_4$ cylinder design pressure. The pressure developed is a function of the agent, the superpressurization level, and the temperature. For 360 psig (at 70°F) cylinders, pressure is limited to $^5/_4$ of the design working pressure of 500 psig at 130°F. For HFC-227ea, as seen in Figure 17.6.5, this yields a maximum fill density of 72 lb/ft^3. The 360 psig pressurization level is not based on characteristics of halon replacement halocarbons but is a vestige of standard Halon 1301 systems.

Figure 17.6.4 is an isometric diagram for HFC-23. HFC-23 is not pressurized with nitrogen. At a maximum fill density of 54 lb/ft^3, it has a vapor pressure of 609 psi at 70°F. Above its critical point of 78.6°F, there is no distinction between liquid

and gas with no liquid/gas separation in the cylinder. Further, compression does not result in formation of a liquid phase. Since it is not possible for the cylinder to be "liquid" full at 130°F, the pressure developed at a maximum fill density of 54 lb/ft^3 must be less than $^5/_4$ of the container design level working pressure of 1800 psi or 2250 psig, as shown in the graph. Below the critical temperature, the agent will exist as a liquid with a vapor or gas phase above it.

Figure 17.6.5 is a typical isometric diagram for inert gases exhibiting ideal gas law behavior at the pressures and temperatures of interest. Because these are compressed gases only, there is no fill density variation, only a linear relationship between temperature and pressure.

APPLICATION SYSTEMS

An application system consists of a supply of agent, a means for releasing or propelling the agent from its container, and one or more discharge nozzles to apply the agent into the hazard or directly onto the burning object. A system may also contain other elements, such as one or more detectors, remote and local alarms, a piping network, mechanical and electrical interlocks to close fire doors and to shut down ventilation, directional control valves, installed reserve agent supplies, and so on. The extent of the auxiliary functions of a system is usually dependent on the nature of the hazard in keeping with the desires and resources of the user.

A system is usually a fixed or stationary apparatus, but some portable or mobile systems have been designed. A portable or mobile system may be moved from one hazard to a similar one, but it is placed in a stationary position while it is in service. In this regard, all systems may be considered to be "fixed" but not necessarily permanently placed.

Halogenated clean agent systems are broadly classified by their method of applying agent to the hazard. The two main types are (1) total flooding and (2) local application systems. Another category, called "specialized systems," includes those systems that are designed to protect special or unique hazards and that have been tested and approved under these specific conditions. There are no NFPA design and installation standards for local application clean agent systems.

Total Flooding Systems

These systems protect enclosed, or at least partially enclosed, hazards. A sufficient quantity of extinguishing agent is discharged into the enclosure to provide a uniform fire-extinguishing concentration of agent throughout the entire enclosure. Examples of total flooding systems using halogenated agents are found in computer rooms, electrical switchgear rooms, magnetic tape storage vaults, and electronic control rooms; storage areas for artwork, books, and stamps; aerosol filling rooms; machinery spaces in ships; cargo areas in large transport aircraft; processing and storage areas for paints, solvents, and other flammable liquids; and so on.

Total flooding systems may be further distinguished by their method of design or installation. An engineered system is custom designed for a particular hazard, using components that are approved or listed only for their broad performance characteristics. Components may be arranged into an almost unlimited variety of configurations.

In preengineered systems, the number of components and configurations are determined in advance and included in the description of the system's approval or listing. Although the degree of preengineering can differ from one system to another, the following limits of components and configurations must be considered:

1. Maximum number of cylinders per manifold
2. Maximum and minimum size and length of piping
3. Maximum and minimum size and number of elbows, tees, and discharge nozzles
4. Container volume, fill density, and level of nitrogen superpressurization

Modular systems consist of single containers connected to discharge nozzles with minimal piping. A group of container-nozzle assemblies may be distributed throughout the protected area and interconnected electrically. Modular systems permit a more attractive and less expensive initial installation but often result in higher maintenance costs.

Central storage systems locate all agent containers in one centralized location. The agent can be stored in multiple tanks

connected by a manifold arrangement or in a single bulk storage tank. A piping network distributes the agent to the various discharge nozzles. Ease of maintenance is the primary advantage of central storage systems.

Local Application Systems

As the name implies, these systems discharge extinguishing agent in such a manner that the burning object is surrounded locally by a high concentration of agent to extinguish the fire. In local application systems, neither the quantity of agent nor the type or arrangement of discharge nozzles is sufficient to achieve total flooding of the enclosure containing the object. Often, too, a local application system is required because the enclosure itself may not be suitable to provide total flooding. Examples of areas protected by local application are printing presses, dip and quench tanks, spray booths, oil-filled electric transformers, vapor vents, and so on. The protected object is not enclosed; therefore, discharge nozzles and rate of application must be capable of enveloping the object. The agent supply must be sufficient to maintain flow for the required time of protection, usually several minutes. Nozzle design is critical and must be determined by extensive testing.

Because of its lower volatility, Halon 1211 is well suited for local application systems. The lower volatility, plus a high liquid density, permits the agent to be sprayed as a liquid and, thus, propelled into the fire zone to a greater extent than is possible with other gaseous agents. Halon 2402 also is well suited for local application systems.

The material relating to local application systems, in NFPA 12B, was largely theoretical and intended for use by equipment manufacturers and testing laboratories in designing and evaluating components for local application systems. The component of overriding importance was the discharge nozzle, and its performance characteristics must be known with a high degree of reliability.

USE CONSIDERATIONS FOR CLEAN AGENT SYSTEMS

Advantages and Disadvantages

The primary advantages of total flooding clean agent systems are (1) the ability to extinguish shielded, obstructed, or three-dimensional fires in complex geometries; (2) the ability, through the use of appropriate detector-based actuation, to extinguish fires at a very early stage, well before direct or indirect fire/smoke damage occurs; and (3) the ability to cause no collateral damage due to agent discharge. These three technical attributes drive much of the usage of these agents in both flammable and combustible liquid hazards (e.g., shipboard engine rooms, pump rooms, etc.) and electronics equipment areas.

There are, however, the following technical disadvantages with respect to the use of clean agents:

1. They require a reasonably intact enclosure with the doors closed and external ventilation secured prior to discharge.
2. These agents provide virtually no cooling. This is an important consideration for situations in which large fires with long preburn times are expected.
3. Electrical power to wire/cable and equipment must be secured, or sufficiently high agent concentrations and hold times must be provided to ensure extinguishment at the expected electrical power density in the cable.
4. All elements of the detection, control, actuation, release, and distribution system must perform as designed. This requirement places increased reliance on both acceptance testing and postinstallation maintenance and test.

Use Recommendations

The decision to use total flooding clean agents is a relatively complex risk management decision. There are several recommendations on the use of these systems in the context of an overall fire protection program. The following are some commonsense recommendations:

1. In general, it does not make sense to protect a hazard area with a total flooding gas system within a building in which all other areas are not protected. Consider the case of a sensitive electronics facility within an office building. The probability of a fire occurring outside the space is at least equal to, and probably greater than, a fire occurring inside the space. Given the cost of protecting the electronics space, the cost/benefit of providing alternative protection (for example, automatic sprinklers) in the remainder of the building is much lower. For a fixed investment, it makes more sense to protect areas outside the electronics area first. As a general rule, never protect an area with a clean agent total flooding system unless the remainder of the building is adequately protected. Notable exceptions to this rule are cases in which the only or predominant fire hazard is in the space to be protected with a clean agent.

2. In facilities where the room or enclosure geometry changes frequently, sufficient administrative control of such modifications is required to ensure a clean agent total flooding system is not rendered inoperable or useless by changes in partitioning, modifications to detection equipment, and so forth. Although the same can be said for other types of fire protection, total flooding gas systems are particularly vulnerable to enclosure volume changes, enclosure integrity, and the integrity of the originally designed and installed detection, actuation, and control system.

3. Wherever possible, individual fire suppression equipment item failures should be anticipated and accounted for in the design. Examples include the use of higher design concentration to account for floodable volume changes or leakage changes, the addition of an extra cylinder to account for valve actuation failure, and provision of very early warning sampling detectors to permit human intervention prior to discharge.

4. Given the cost of halon replacement clean agent systems, it is expected that one significant use area will be in critically important sensitive electronics facilities. Substantial additional risk reduction at very high benefit/cost ratios may be realized by protecting these facilities with *both* clean agent total flooding systems and, at a relatively low incremental cost,

standard wet-pipe automatic sprinklers. Because both systems are designed to perform at different levels, the provision of an additional wet-pipe sprinkler system can be viewed as a backup system to the total flooding gas system. Although one expects higher direct and indirect damage levels in sensitive electronics, due to the difference in actuation time of sprinklers, they are relatively inexpensive and a reliable means of preventing excessively large losses in the event of the primary system (i.e., clean agent system) failure. For a typical 8 ft (2.4 m) high compartment, the additional cost of providing a simple wet-pipe sprinkler system as a secondary system can be as low as 5 percent of the installed clean agent system cost.

Clean agent total flooding systems can offer unequaled performance for the very early extinguishment of fires, which is critical in certain electronics facilities and the suppression of three-dimensional flammable liquid fires. However, the system must function as designed through the life of the facility. In the case of these total flooding gases, the system includes not only the detection, alarm, and suppression system but also the hazard enclosure, doors, dampers, ventilation/fans, and electrical power isolation. A study of existing clean agent system installations undertaken by Taylor/Wagner, Inc., indicated that within 5 years of initial installation, over 50 percent of the systems no longer met design requirements due to changes in the configuration of the protected space. The consequences included inability to achieve design concentration or the possibility of achieving concentrations that would have exceeded human exposure limits. The need to control and maintain this "system" cannot be overstated. See also Section 17, Chapter 7, "Application of Gaseous Agents to Special Hazards Fire Protection."

CLEAN AGENT SYSTEM DESIGN

The basic process of designing a total flooding gaseous extinguishing system involves the following:

1. Determine the design concentration
2. Determine the total agent quantity
3. Establish the maximum discharge time
4. Select piping material and thickness consistent with pressure rating requirements
5. Design piping network and select nozzles to deliver required concentration at required discharge time to ensure mixing
6. Evaluate compartment over/underpressurization and provide venting if required
7. Establish minimum agent hold requirements and evaluate compartments for leakage

These attributes apply only to the mechanical design of the system.

The detection and actuation system is a critical and integral part of a clean agent system design. The detection system should be designed to actuate the system, with appropriate predischarge alarms, before unacceptable thermal or nonthermal damage occurs. This is particularly important relative to the thermal decomposition in which products of halocarbon clean agents are a concern. Section 14, Chapter 2, "Automatic Fire Detectors," provides engineering methods and calculation procedures for this purpose.

In addition to the detection, actuation, and alarm system, the enclosure itself is critical in the design of any total flooding gaseous suppression system. The most important considerations are that the enclosure's integrity is sufficient to prevent (1) preferential agent loss during discharge and (2) excessive agent/air mixture loss after discharge to ensure adequate hold time.

As a general rule, all openings, notably doors and ventilation fans and/or openings, must be secured prior to discharge in conjunction with the detection and alarm system. System installation in rooms with unenclosable openings should not be attempted with these agents unless sufficient test data are available to ensure adequate concentrations. Some enclosures, such as very tightly sealed low electromagnetic field (EMF) emission electronics spaces, require additional care to avoid compartment damage due to overpressurization or underpressurization during agent discharge.

Design Concentrations

Design concentrations for various agents and fuel combinations are generally determined by a combination of small-scale testing, large-scale testing, independent laboratory approval of hardware, and addition of design safety factors.

Historically, minimum design concentrations for Halon 1301 were set by the cup burner extinguishing concentration plus a 20 percent safety factor. A minimum Halon 1301 design concentration of 5 percent was also established for all applications. For *n*-heptane, the cup burner value was approximately 3 percent; with a 20 percent safety factor, a design concentration of 3.6 percent is obtained. At the minimum design concentration set by NFPA 12A of 5 percent, a 66 percent safety factor was achieved. For fuels with cup burner extinguishing concentrations greater than 4.2 percent, the safety factor remained at 20 percent.

The basic requirement for determining the design concentration of clean agents in NFPA 2001 is twofold. First, the minimum extinguishing concentration as determined by the cup burner must be established. After this minimum is established by the *system* manufacturer, full-scale third-party approval testing is conducted using the manufacturer's hardware on *n*-heptane, wood crib, and selected flammable liquids. These tests are performed at the cup burner minimum extinguishing concentration, not the design concentration. Further, they are conducted with flooding factors lower than utilized in design. Hence, the minimum set by the cup burner or equipment manufacturer, whichever is higher, is tested in full scale as part of the approval/listing process for the agent/system combination. Often hardware manufacturers will establish a minimum concentration greater than the cup burner value to account for nozzle efficiency.

Reliance on the cup burner to set a minimum value is supported by the observation that no full-scale test known to the author conducted at the cup burner concentration plus 80 percent safety factor has failed to extinguish a flammable liquid fire in an enclosure. It is critical to recognize that, in real system design, the agent and the hardware delivering it, particularly the nozzle, are not independent. They must be taken as a system

and designed and installed per the listing/approval guidelines and limitations.

There has been some full-scale test work that indicates that the 20 percent safety factor may be insufficient for certain applications, depending on the performance required of the system. Sheinson noted significant improvement in extinguishing time performance with a safety factor of 40 percent.[31] Brockway noted similar results with no performance improvement beyond a safety factor of 40 percent.[32]

It has also been noted by several investigators that higher safety factors result in lower thermal decomposition products.[31–33] None of the previously referenced investigations utilized listed or approved hardware for the specific agents tested; as in most cases, the tests were performed before such hardware was available.

There was an exception in the first edition of NFPA 2001 to the general rule that a minimum extinguishing concentration be established by the cup burner method. It was alleged that reliable cup burner data were not available for HCFC Blend A due to two facts: (1) the agent was a blend and (2) one of the blend components heats at a low vapor pressure. In the case of this agent, a minimum extinguishing concentration of 7.2 percent and, hence, a design concentration of 8.4 percent was established through limited full-scale testing. Since at the time insufficient data were available to evaluate the claim, the exception that requires full-scale testing at minimum extinguishing concentration consistent with UL 1058, *Halogenated Agent Extinguishing Systems Units,* was invoked. Since that time, reliable cup burner data were obtained for the blend from several laboratories. The data are consistent with MEC values for the blend components, primarily HCFC-22. Furthermore, some full-scale testing has indicated that the design concentration of 8.6 percent may be inadequate.[34] This exception was removed in the second edition of NFPA 2001. The current requirement for Class B fires is that the cup burner concentration for the worst-case fuel in the protected enclosure forms the MEC basis for that hazard.

It is important to recognize that the use of *n*-heptane cup burner values as a minimum for design concentration has no technical basis. With Halon 1301, *n*-heptane was a reasonable "worst case" fuel, but such is not the case with the replacements. It is important, therefore, that the design concentration be based on the "worst case" or fuel requiring the highest design concentration when designing systems for flammable or combustible liquid risks.

Extinguishing concentrations for Class A fuels were traditionally developed using wood cribs as part of the equipment listing/approval process. Further, the minimum Class A extinguishing concentration used for design purposes was required to be greater than or equal to the minimum extinguishing concentration for heptane. Recently, additional tests utilizing plastic sheet arrays of polymethylmethacrylate (PMMA), acrylonitrile-butadiene-sytrene (ABS), and polypropylene (PP) have been required.[35,36]

The test consists of an array of four sheets of polymer, 200 mm × 4000 mm × 10 mm thick, oriented vertically, forming three vertical channels. The array is enclosed on two sides and the top and surrounded by an additional baffle arrangement as shown in Figure 17.6.6. The array is tested in a minimum 100 m^3 compartment. The fuel is ignited by a small heptane pan, and the entire array is subjected to a 210-second preburn time.

Clean agent systems are widely used in electronic equipment areas where fires involving electrically energized cables and equipment are often encountered. Extinguishment tests involving PMMA heated externally with nichrome wire indicated

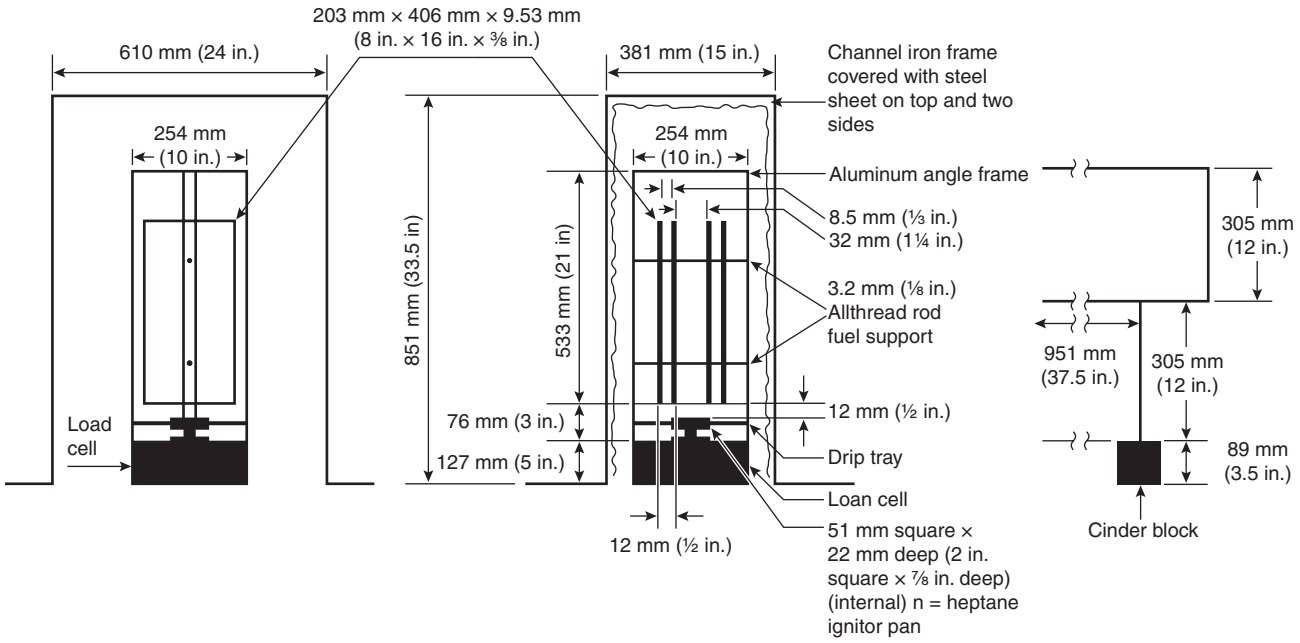

FIGURE 17.6.6 Four-Piece Modified Plastic Setup

that agent concentrations substantially higher than those typical for plastic fuels were required. For example, extinguishing concentrations of 9.5 percent, 9.0 percent, and 20 percent were required for FC-3-1-10, HFC-227ea, and HFC 23, respectively.

Extinguishment tests on actual wire and cable materials were reported by McKenna et al.[37] Three types of tests were conducted: ohmic heating, conductive heating, and printed wiring board arcing. The ohmic heating tests involved deliberate electrical overheating of the conductor. Under severe overcurrent conditions, all cable assemblies were extinguished at 5.8 percent, a typical Class A extinguishing concentration. The one exception was the 18 AWG polyethylene coaxial cable, which is generally not used in power applications. The striking difference between these results and those discussed earlier for PMMA probably lies in the fire-retardant nature of real electrical wire and cable assemblies. Results for cable assemblies heated at the ends by conduction, a situation simulating an overheated connection, showed results similar to the ohmic heating tests for Hypalon and PVC cables. There has, however, been no systematic evaluation of grouped electrical cables or high-voltage cables. Cable arrays with long preburn times have been demonstrated to require substantially higher agent concentration than for surface fires in the case of Halon 1301 and carbon dioxide.

Given the widespread use of clean agents in areas involving continuously energized equipment and recognizing the significant gaps in knowledge of required extinguishing concentration, the ISO standard[2] has required an extinguishing concentration no less than 95 percent of the heptane extinguishing concentration when any of the following conditions apply:

1. Cable bundles greater than 100 mm in diameter
2. Cable trays with a fill density greater than 20 percent of the tray cross section
3. Horizontal or vertical stacks of cable trays (closer than 250 mm)
4. Equipment energized during the extinguishment period in which the collective power consumption exceeds 5 kW

The issue of inadequate design concentration is exacerbated by the relatively recent decline in extinguishing concentration achieved in the Class A polymeric sheet tests. Additional uncertainty in the Class A extinguishing concentration was seen in Table 17.6.3, in which minimum required concentration is a function of system hardware. The extinguishing concentration for total flooding systems should be system and scale independent.

There has been no systematic evaluation of these agents under so-called "deep-seated" fire scenarios. However, the Underwriters Laboratories Inc. (UL) and FM Global Research listing procedures require testing on wood cribs subsequent to long preburn times (approximately 5 minutes). Under these tests, surface oxidation and char reactions do occur.

Design concentrations for fire scenarios involving long preburn times in thick arrays of cellulosic fuels may require additional testing. For most applications in which incidental quantities of cellulosic materials may be involved and preburn times have relatively short (5 minute) time frames (i.e., automatic actuation), the flame extinguishing concentrations for Class A fuels that are less than, or equal to, that of *n*-heptane can be used.

IG-541 is used at 37.5 percent minimum design concentration where Class A materials are involved. IG-55 may have slightly higher minimum design concentrations; IG-01 (argon) should have substantially higher MEC.

The minimum design concentration is a function of the fuel, the agent, and the delivery system. Design concentrations for specific hazards must be determined in accordance with the system manufacturer's approval or listing.

Safety Factors

The safety factor requirement in NFPA 2001 used for developing design concentrations should be considered a minimum. It can reasonably be expected to account for minor errors arising from the design and installation process, such as errors in room volume calculations, cylinder filling/agent weight, and cup burner MEC values.

The 20 percent minimum safety factor required in previous editions of NFPA 2001 has been increased under certain conditions. Systems protecting Class B or any system exclusively operated by manual means now requires a 30 percent safety factor. The ISO standard requires a minimum safety factor of 30 percent for all systems. The increase in safety factor resulted from a combination of theoretical analysis and fire testing. The ISO standard requires a 30 percent safety factor in all cases.

Analysis by Schlosser[38] indicated that the probability of failure of a system was reduced from approximately 15 percent to 10 percent when the safety factor increased from 20 percent to 30 percent. In addition to these data, the variation in cup burner values used as a basis for design concentration was significant due in part to a lack of standardization in the method. Some full-scale test results[39] also indicated a need for higher design concentrations.

The safety factor was also increased in response to increasing uncertainty concerning the determination of extinguishing concentrations for Class B fuels by the cup burner method. One concern was the observed increase in extinguishing concentration for inert gases as the cup burner flow rate was increased. VdS also reported a significant increase in extinguishing concentration for inert gases as the cup burner was increased in size.[40] The extinguishing concentration for all agents was observed to increase when the fuel pan was either thin-gauge metal or allowed to heat excessively. In addition to these small-scale test observations, difficulties were observed in full-scale tests in which long preburn times (for both Class A and Class B fuels) and compartment venting schemes may have resulted in higher than expected extinguishing concentrations.[41]

The increase in the safety factor was, therefore, judged prudent for application to future system installations. There is no evidence whether or not systems designed and installed prior to these changes are adequate. There have been no reported incidents in which an existing system failed to extinguish a fire using the 20 percent safety factor.

In addition to increased safety factors, the concept of design factors was introduced into the 2000 edition of NFPA 2001. A

design factor is used to increase the agent quantity for a specific installation or design that has attributes for which the minimum safety factor may not be sufficient. The only variable for which design factors have been quantified is for systems with multiple flow splits protecting more than four enclosures simultaneously. The motivation for a design factor in these very rare cases is the uncertainty in the split of agent mass flow at unbalanced tee junctions and the compounding of that error with more than four tees in series.

Table 17.6.15 gives the required additional design quantity or design factor for systems with a large number of unbalanced flow divisions at tee splits. Note that the inert gas factor is always less than the halocarbon agent factor, reflecting the higher calculation uncertainty due to the complex two-phase behavior at flow splits for the halocarbon agents.

Consideration should be given to increasing the safety factor and, hence, the minimum design concentration when any of the following conditions apply:

1. When the nozzle is installed at or near its maximum listed ceiling height or area coverage
2. For the protection of combustible or flammable liquid hazards when limiting the quantity of thermal decomposition products (for halocarbon agents) and/or rapid (less than 15 seconds) extinguishment times are required
3. When a large number of highly imbalanced flow splits occurs in a piping network protecting large and small enclosures simultaneously (use design factors approach)
4. When the floodable room volume is highly variable (e.g., record storage), unless the maximum floodable volume is used
5. Where unenclosable openings exist or pressure-relief vents are provided and located such that excessive agent loss during discharge will occur
6. When excessive postdischarge agent leakage is expected

Increasing the safety factor or design concentration is not warranted in many applications and may not substantially improve the reliability or performance of the system. For example, increasing the safety factor will not improve system reliability if doors are not closed. The design safety factor is not a panacea and cannot be used in lieu of other system design requirements.

Agent Quantity

Once the design concentration is established, the quantity of agent necessary to achieve that concentration is determined. The quantity of halocarbon agent necessary is determined by the following equation:

$$w = \frac{V}{S}\left(\frac{C}{100 - C}\right) \tag{1}$$

where

w = Specific weight of agent required

V = Net volume of protected space

C = Design concentration (%)

S = Specific volume (ft^3/lb or m^3/kg), and is determined by

$$S = k_1 + k_2(T) \tag{2}$$

where

T = Minimum ambient temperature of the protected space

k_1 and k_2 are constants

Values for k_1 and k_2 used in Equation 2 are given in Table 17.6.16.

The flooding factor in Equation 1 implies that the agent/air mixture "lost" during discharge is well mixed and has an agent concentration of C. This formula makes no assumption regarding leakage of the enclosure. During UL/FMRC approval testing, the agent is evaluated with a flooding factor of (C/100), essentially assuming that losses during discharge are 100 percent air.

For inert gases, the following formula is used:

$$X = 2.303\,\frac{V}{S}\log\left(\frac{100}{100 - C}\right)V_s \tag{3}$$

where

X = Volume of inert gas required at 70°F (21°C)

V_s = Specific volume at 70°F (21°C)

V = Net protected hazard volume

S = Specific volume at ambient temperature in protected volume (from Equation 2)

The flooding factor used here is derived assuming that leakage from the compartment during discharge occurs with a varying concentration of agent from zero to C from beginning to end of discharge. It is identical to the expression used in CO_2 system

design. It assumes that the displaced atmosphere is freely vented from the enclosure.

Discharge Time

The maximum discharge time permitted for halocarbon clean agent systems is 10 seconds. This discharge time is taken to be the point at which all liquid agent has cleared the nozzle. The total discharge time will be longer as agent vapor and nitrogen are expelled from the system.

The 10-second discharge time limitation for halocarbon agents is designed to aid the following four objectives:

1. Provide high flow rates through nozzles to ensure adequate mixing of agent with air inside the enclosure
2. Provide sufficient velocity through pipes to ensure homogeneous flow of liquid and vapor
3. Limit the formation of agent thermal decomposition products
4. Minimize direct and indirect fire damage, particularly in fast-developing fire scenarios

The most important of these objectives relative to discharge time is the minimization of agent thermal decomposition product formation. Items 1 and 2 alone are determined by the piping system design.

The discharge time requirement for inert gases is currently 60 seconds. Longer discharge times are typically used for these systems in Europe. The primary reasons to constrain the discharge time of inert gas agents that form no decomposition products are to limit the direct and indirect fire damage and to minimize the length of time that the fire burns in a depleted oxygen atmosphere. As more information is developed on the effect of discharge time on inert gas agent performance, this 60 second limit may be increased for certain applications.

In some applications, such as flammable liquid hazards and explosion inerting, it is necessary to discharge the agent quickly to minimize direct fire damage or to ensure that the agent concentration is achieved prior to the lower explosive limit (LEL) being reached.

Thermal Decomposition Products

All of the halocarbon replacement agents form higher levels of decomposition products than Halon 1301 under similar conditions. For a given fuel, the primary variables determining the level of decomposition products are (1) the size of the fire at the time of discharge, (2) the time required to reach an extinguishing concentration in the compartment, and (3) the agent design concentration.

The dependence of thermal decomposition product formation on discharge time and fire size has been extensively evaluated.[31–33,42–46] Figure 17.6.7 is a plot of peak HF concentration as a function of fire size to room volume ratio. The data encompass room scales of 1.2 to 972 m^3. The 526 m^3 results are from USCG testing; the 972 m^3 results are based on Naval Research Laboratory testing.

These fires include diesel and *n*-heptane pool and spray fires. The design concentrations in all cases, except HCFC Blend A (at 8.6 percent), are at least 20 percent above the cup burner value. For fires in which the extinguishment times were greater than 17 seconds, the extinguishment time is noted in braces. Note that excessively high extinguishment times (greater than 60 seconds), generally an indication of inadequate agent concentrations, yield qualitatively higher HF concentrations. In addition, Halon 1301 will yield bromine or bromine acids as well as HF. Likewise, HCFC Blend A will produce HCl in addition to HF.

The quantity of HF formed is approximately three to eight times higher for all halocarbon replacements relative to Halon 1301. There may be differences between the various HFC/HCFC compounds tested, but it is not clear from these data whether (1) such differences occur, (2) the differences are attributable to agent mixing and distribution, or (3) the differences are attributable to locally high velocities or concentrations of agent from the nozzle. In all of the data reported, the fire source, *n*-heptane pans of varying sizes, was baffled to prevent direct interaction with the agent jet.

Whereas these results are based on flammable and combustible liquid fires, solid polymeric fires of similar size will

generally produce lower HF concentrations. Figure 17.6.8 reports 10-minute average HF concentration data for the 1.2 and 29 m^3 enclosures as opposed to the peak values shown in Figure 17.6.7. These 10 minute average values show HF concentrations 50 percent (or less) of the peak values.

Figure 17.6.9 shows the dependence of the quantity of decomposition products formed on the discharge time. Increased discharge time will also result in longer extinguishment times. The relationship is approximately linear with a doubling in discharge time resulting in a 100 percent increase in HF production. Clearly, increasing the amount of time the flame is exposed to a subextinguishing concentration of agent will increase the amount of agent decomposition expected.

Sheinson[47] has shown that increasing the design concentration of HFC-227ea from 8 percent (approximately 1.2 × cup burner) to 9.8 percent (1.8 × cup burner) results in a decrease in peak HF concentration from 8000 ppm to 2500 ppm for real-scale large combustible liquid fires. He also found HF concentrations 4 to 5.5 times higher than the peak HF concentration of Halon 1301 under similar conditions. He did not report HBr or bromine formation in these tests.

Although other thermal decomposition products have been identified in some cases, it appears that HF is the primary decomposition product of interest relative to human safety and equipment damage.

One of the characteristics of HF, like HCl, is that it is an irritant gas, detectable at very low concentrations; however, there is a very large difference between the human detection threshold, the severe sensory irritant threshold, and the ALC (approximately two and three orders of magnitude, respectively).

Fire sizes necessary to generate short-term lethal concentrations of HF in an enclosure (on the order of 1000 ppm) are large enough in some cases that the hazard posed to personnel in the protected space during a discharge in a fire incident is primarily from the fire and its effects rather than the secondary impact of agent decomposition products. This outcome,

however, should be verified for a particular application under a range of fire scenarios using engineering methods discussed by Hanauska et al.[48,49]

The impact of decomposition products on electronic equipment is another area of concern. There are not sufficient data at present to predict the effects of a given HF exposure scenario on all electronic equipment. Several evaluations of the impact of HF on electronic equipment have been performed relative to the decomposition of Halon 1301, where decomposition products include HF and HBr. One of the more notable evaluations was a NASA study where the space shuttle *Orbiter* electronics were exposed to 700, 7000, and 70,000 ppm HF and HBr. In these tests, exposures up to 700 ppm HF and HBr caused no failures. At 7000 ppm, severe corrosion was noted; there were some operating failures at this level.

Dumayas[50] exposed IBM-PC-compatible multifunction cards to environments produced by a range of fire sizes as part of an evaluation program on halon alternatives. He found no loss of function of these boards following a 15 minute exposure to a postfire extinguishment atmosphere up to 5000 ppm HF, with unconditioned samples stored at ambient humidity and temperature conditions for up to 30 days. Forssell et al.[51] exposed multifunction boards for 30 minutes in the postfire extinguishment environment; no failures were reported up to 90 days posttest. HF concentrations up to 550 ppm were evaluated.

Although no generic rule or statement can be made at this time, it appears that short-term damage resulting in electronic equipment malfunction is not likely for exposures of between 500 and 1000 ppm HF for up to 30 minutes. This outcome, however, is dependent on the characteristics of the equipment exposed, postexposure treatment, exposure to other combustion products, and relative humidity. Important equipment characteristics include its location in the space, existence of equipment enclosures, and the sensitivity of the equipment to damage.

All HCFC, PFC, and HFC clean agents form more decomposition products than Halon 1301, given similar fire sizes and discharge times. The primary variable controlling the quantity of decomposition products is the size of the fire at the time of agent discharge. Through evaluation of the fire size at the time of system actuation, the potential hazard posed can be adequately managed.

Hanauska et al. have indicated that the degree of decomposition products in electronic applications of agents can be safely managed when automatic detection and actuation are provided. Full-scale testing with typical Class A fuel packages in conjunction with typical detection system installation[51] has shown that the level of decomposition products is acceptable in typical computer/electronics spaces. For installation in hazard areas where very rapidly developing large fires are likely, the degree of thermal decomposition formation should be evaluated in the context of the hazard posed by the fire and the performance of alternative fire protection systems.

The production of HF and other agent decomposition products forms a potential hazard for occupants. Table 17.6.17, from *Toxicology of Substances in Relation to Major Hazards: Hydrogen Fluoride,*[52] summarizes potential health effects in healthy individuals. Note that exposure above 200 ppm may begin to impair escape particularly at exposure times exceeding 5 minutes.

Emergency Response Planning Guidelines (ERPG) values, developed by the American Industrial Hygiene Association, for 10 minute exposures are as follows: ERPG-2, a level at which mitigating steps such as evacuation should be taken is 50 ppm; and ERPG-3, the maximum nonlethal exposure concentration for 10 minutes is 170 ppm. The ERPG values are in contrast to an analysis by Melchrum, which indicates a dose of 12,000 ppm/

TABLE 17.6.17 Potential Human Health Effects of Hydrogen Fluoride in Healthy Individuals

Exposure Time (min)	*Hydrogen Fluoride (ppm)*	*Reaction*
2	<50	Slight eye and nasal irritation
	50–100	Mild eye and upper respiratory tract irritation
	100–200	Moderate eye and upper respiratory tract irritation; slight skin irritation
	>200	Moderate irritation of all body surfaces; increasing concentration may be escape impairing
5	<50	Mild eye and nasal irritation
	50–100	Increasing eye and nasal irritation; slight skin irritation
	100–200	Moderate irritation of skin, eyes, and respiratory tract
	>200	Definite irritation of tissue surfaces; will cause escape impairment at increased concentrations
10	<50	Definite eye, skin, and upper respiratory tract irritation
	50–100	Moderate irritation of all body surfaces
	100–200	Moderate irritation of all body surfaces; escape-impairing effects likely
	>200	Escape-impairing effects will occur; increasing concentrations can be lethal without medical intervention

min based on 1 percent lethality in exposed animals. Additional health effect and risk assessment data have been reported.[53–56]

For large flammable or combustible liquid fire hazards utilizing manual system operation, the concentration of thermal decomposition products may be high enough to preclude entry into the space without special precautions. The use of an inexpensive water spray, wash-down cooling system in conjunction with a gaseous suppressant will provide substantial cooling, a reduction in the total decomposition products generated, and a reduction in the postdischarge decomposition product concentration due to scrubbing. Although the enhanced cooling would benefit all total flooding gases, the reduced decomposition product potential applies only to halocarbons. The provision of such a system would permit more rapid reentry into the space and may be of particular benefit for shipboard engine room protection.

Hydraulic and System Discharge Characteristics

All of the halocarbon replacement agents will exhibit two-phase flow behavior. Since all, except HFC-23, are used in cylinders pressurized to 360 or 600 psig (2482 or 4137 kPa) with nitrogen, they are also multiple component flows. Inert gases and blends will be single-phase compressible fluid flow problems. Most of the following discussion will not apply to inert gas systems; the testing and approval of flow calculations are similar with emphasis placed on flow parameters relevant to compressible gas flow, ignoring phase separation issues such as the orientation. As in the case of engineered Halon 1301 systems, all flow calculation procedures used must be listed or approved by a third-party laboratory and within the limitations of the flow calculation method determined during the engineered system approval process.

The characteristics that differentiate two-phase pipe flow from incompressible fluid (e.g., water) pipe flow is the existence of gas and liquid phases simultaneously in the pipe network. This coupled with the relatively short flow times results in significant challenges to correctly predicting the flow. Among the important factors are the change in density of the fluid with pressure, the release of nitrogen in the cylinder and pipe as the fluid pressure and temperature change, differences in agent mass delivered caused by the flow time imbalances between nozzles, and preferential distribution of phases (and subsequently agent mass) at tee splits.

The need for accurate flow predictions is driven by the following three design requirements:

1. Control of agent discharge time
2. Maintenance of adequate nozzle flow and pressure to ensure agent distribution and mixing at the listed coverage area
3. Delivery of adequate, but not excessive, agent quantities to different rooms within the same protected area, when such rooms are flooded simultaneously

In addition, agent flow rate and thermodynamic state properties are necessary for estimating compartment pressurization levels during agent discharge.

For preengineered systems, limits on discharge time and nozzle pressure are built into the limits on piping system geometry. Agent distribution is handled by constraining preengineered systems to balanced flow conditions (i.e., the same agent mass is distributed from each nozzle). For adequate design of preengineered systems, accurate methods for predicting these elements are required.

Figure 17.6.10 is an idealized plot of cylinder and nozzle pressure during discharge.

Testing and Approval of Design Methods

The approval or listing of a clean agent flow calculation procedure including inert gases is part of the approval granted for engineered systems. Since some aspects of two-phase flow calculations are empirically based (e.g., flow regime, pressure drop, flow splits) and all calculation procedures have some bounds on their validity, testing is performed to verify the predictions and establish the limits of the calculation procedure. These limitations are crucial in helping to ensure that system designs do not exceed verified limits of calculation.

One of the most rigorous approval procedures used in verifying design methods is outlined by Underwriters Laboratories Inc. UL 1058, *Halogenated Agent Extinguishing Systems Units,* was used for evaluating engineered Halon 1301 systems, but the same approach is taken for all clean agent alternatives. Design method limitations are described by the following 10 parameters, and tests are required to verify the accuracy of the calculation procedure at all of these limits (some of these parameters will not apply to inert gas systems):[35,36]

1. Percent of agent in piping (maximum)
2. Minimum and maximum discharge times
3. Minimum pipeline flow rates
4. Variance of piping volume to each nozzle

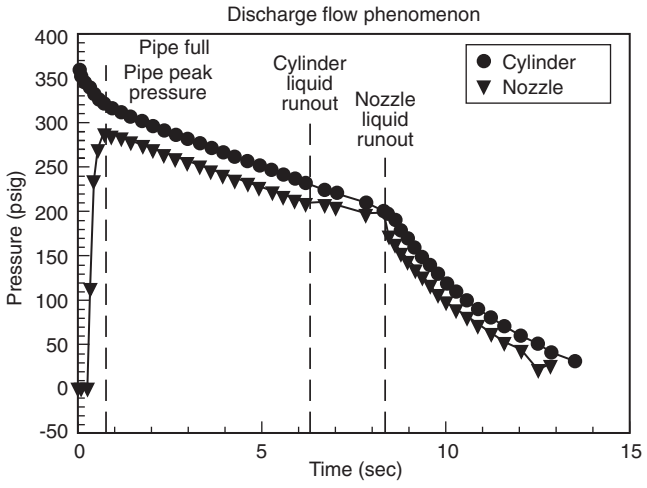

FIGURE 17.6.10 Idealized Cylinder and Nozzle Pressure Time Curves for Halocarbon Agents. For SI units: 1 psi = 6.895 kPa.

5. Maximum variance of nozzle pressures within a piping arrangement
6. Maximum ratio of nozzle diameter to inlet pipe diameter
7. Arrangement most likely to exhibit vapor time–imbalance condition at nozzle
8. All types of tee splits, including through tees, bullhead tees, and tee orientation (vertical versus horizontal)
9. Minimum and maximum container fill density
10. Minimum and maximum flow split for each type of tee

These parameters are related to the important attributes of the agent discharge process previously discussed. Full-scale testing is performed to evaluate the performance of the design method. The limits on flow calculation method performance are as follows:

1. Actual versus predicted discharge time (second)
2. Actual versus predicted nozzle pressure (percent)
3. Actual versus predicted mass flow through a nozzle (percent)

The accuracy limits required for mass flow rate through a nozzle, particularly the –5 percent allowable variation, are quite challenging given the complex nature of the problem. This allowable variation points to an area where increased agent quantity (or safety factor) may be appropriate. For networks in which a small fraction of the total agent flow is directed to a simultaneously protected but segregated enclosure *and* a large number of tees or flow splits are involved, the provision of additional agent to provide an allowance for the mass flow accuracy through greater than five or six tees should be considered. This is generally not a problem when all of the agent is discharged into the same enclosure.

Testing in conjunction with a particular manufacturer's hardware is important. Two critical hardware-dependent verifications are (1) ensuring that pressure drop through a particular valve assembly is calculated properly and (2) evaluating the nozzle orifice discharge coefficient.

In order to preserve a 10-second discharge time, the mass flow rate of these clean agents must be higher than Halon 1301. The increased density of some of the alternative agents in the piping, caused by lower vapor pressures and nitrogen solubility differences, may result in high enough mass flow rates to retrofit existing Halon 1301 systems. Although agent cylinders and nozzles will require changeout, it is often possible to preserve the existing Halon 1301 pipe network and often requires the use of lower fill density cylinders to increase the average system pressure throughout the discharge time. Any such retrofit using existing Halon 1301 piping must be carefully evaluated with respect to hydraulic performance with particular care given to preserving minimum required nozzle pressures and flow divisions at tees.

Nozzle Area Coverage and Height Limitations

One of the most important requirements of a gaseous total flooding fire suppression system is the ability of the system to deliver a uniform concentration of agent throughout the protected enclosure. The nozzle design and minimum nozzle pressure are critical in ensuring this distribution of agent. The performance of the nozzle is evaluated by full-scale approval testing.[57,58] The basic testing performed to evaluate nozzles is as follows:

1. Establish minimum nozzle pressure and maximum nozzle height by ensuring extinguishment of *n*-heptane fires located throughout a space with a height equal to the maximum allowable at the minimum allowable nozzle pressure.
2. Establish maximum nozzle coverage area by extinguishing tests in a plenum at the minimum height (generally less than 1.6 ft [0.5 m]) at the maximum nozzle coverage area (on the order of 1076 ft^2 [100 m^2]) and minimum nozzle operating pressure.

There are substantial differences among hardware manufacturers relative to minimum nozzle pressure, maximum ceiling height, and maximum average coverage. All nozzle orientations should be evaluated. In general, maximum nozzle heights are on the order of 13 to 16 ft (4 to 5 m), nozzle area coverage on the order of 97 to 108 ft^2 (9 to 10 m^2), and minimum nozzle pressures between 3 and 6 bar. It is critical to ensure that the nozzle spacing, height, and minimum pressure limits are not exceeded for a particular manufacturer's hardware in a specific design.

The flow, mixing, and distribution of an agent from a nozzle into an enclosure can be predicted theoretically for relatively simple nozzle designs by using sophisticated computer models.[59] Further development of such methods for complex nozzle designs and compartment geometries may eventually form the basis of a design procedure. At present, however, the primary means of ensuring adequate nozzle performance is the hardware approval process and real-scale testing.

Since many of the halocarbon replacements have lower vapor pressures than Halon 1301, there is often a much higher percentage of liquid at the nozzle. This makes the task of vaporizing and mixing the agent in the compartment more difficult. In general, nozzle designs used for Halon 1301 systems are not adequate for the halocarbon replacement agents. Due to the increased liquid fraction at the nozzle, it is critical to ensure that no unenclosed openings exist along the trajectory of the nozzle orifices. This may result in significant preferential loss of agent through these openings. This further emphasizes the need for third-party approval testing of nozzle performance. In any retrofit situation, the nozzles will need to be replaced even if the piping is adequately sized to deliver adequate agent flow rates.

Compartment Pressurization

The rapid discharge of agent into a compartment will cause rapid changes in the compartment pressure. Depending on the agent and rate of discharge, the initial pressure change may be negative. Figure 17.6.11 is a plot of compartment pressure versus time for the discharge of HFC-227ea into a 989 ft^3 (28 m^3) room with a 56 $in.^2$ (360 cm^2) leakage area.[44] Immediately after discharge, the pressure in the compartment drops below ambient to a minimum of –0.3 kPa; at approximately 1.5 seconds after discharge starts, the pressure begins to increase to a maximum of approximately 0.14 kPa after nozzle liquid runout. Similar results were obtained for FC-3-1-10. HFC-23 discharge exhibited much higher compartment overpressurization without the

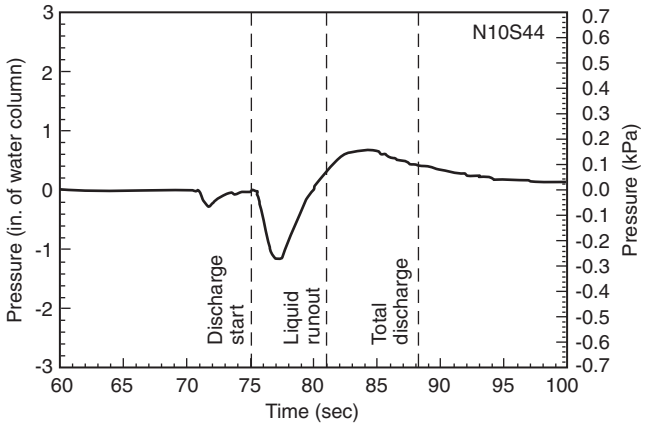

FIGURE 17.6.11 Pressure Measured in 989 ft^3 (28 m^3) Enclosure During HFC-227ea Discharge with Nominal 15 sec Discharge Time and 10 in. (254 mm) Pan of *n*-Heptane (Source: Forssell, E. W., and DiNenno, P. J., "Evaluation of Alternative Agents for Use in Total Flooding Fire Protection Systems," Contract NAS 10-1181, National Aeronautics and Space Administration, John F. Kennedy Space Center, FL, Oct. 1994)

marked initial negative pressure. The maximum overpressure for HFC-227ea and FC-3-1-10 discharge was similar to that of Halon 1301. Inert gas agents will, in general, result in positive pressure throughout the discharge.

As the halocarbon agent is discharged into the space, it vaporizes rapidly, cooling the compartment and lowering the pressure. As the agent/air mixture gains heat from the walls or other objects in the space, the pressure recovers and, as additional agent is added, the pressure increases over ambient as mass is added to the compartment.

The expected maximum and minimum compartment pressure during discharge will be a function of the following:

1. Thermodynamic state of the agent at the nozzle (determined by the agent and piping arrangement)
2. Nozzle design
3. Compartment volume and wall surface area
4. Size of fire
5. Initial conditions in space
6. Leakage area from compartment
7. Agent flow rate

For inert gases, significant compartment overpressurization can occur during discharge, unless adequate free vent area is provided. Calculation of required open area for venting is a part of the design manual for IG-541 systems.[60]

No generalized design procedure for calculating under/overpressurization has been established. Forssell and DiNenno[44] have developed a procedure for estimating the compartment pressure as a function of agent, agent flow rate, agent thermodynamic state at the nozzle, compartment volume, and surface area and leakage area. For inert gases utilizing relatively high agent concentrations, the required vent area calculation used for CO_2 systems is often used.

One area of concern with respect to vents is the possibility of preferential leakage of agent (as opposed to leakage of an agent/air mixture). This leakage can occur when an unenclosable opening or vent opening during discharge is located where a jet (from the nozzle) with a high agent concentration directly impinges on the opening. In this case, the possibility of higher than expected (in the flooding factor assumption) agent losses during discharge may occur. This outcome is particularly important for small rooms or areas with high wall area/room volume ratios and is probably more a problem for liquified halocarbon agents. Direct impingement by horizontal projection nozzles is most problematic where vents are located high on the walls.

Note that this preferential agent loss will not occur with the distributed leakage normally found in a room. A simple fix is to baffle any unenclosable opening or vent opening so that direct impingement by a nozzle jet on the opening is avoided. Ductwork attached to the relief vent discharge will also help prevent excessive agent loss.

Agent Hold Time and Leakage

Traditionally, total flooding gas systems were required to maintain a minimum concentration for a specified time period (10–20 minutes) after discharge. The minimum required hold time was a function of the following:

1. Soak time required for deep-seated Class A fuels
2. Response time of emergency personnel
3. Time required to prevent reflash due to presence of hot surfaces and other reignition sources, particularly in flammable and combustible liquid applications

Currently, there is no specified minimum hold or soak time for clean agents. The variables described earlier will vary among installations, and there is no significant database on the performance of these agents on "deep-seated" fires other than wood cribs. The designer will be required to specify the minimum soak time consistent with the requirements of the hazard being protected. A practical minimum of 10 minutes is generally recommended, with some applications requiring substantially longer hold times.

The ability of a compartment to maintain adequate agent concentration is a function of the leakage of the compartment. Historically, leakage testing was done with Halon 1301 through the use of discharge tests. Discharge testing for this purpose was rendered unnecessary by the introduction of door fan pressurization leakage tests. Annex B of NFPA 2001 describes a complete procedure for evaluating agent hold time as a function of compartment leakage measured by the door fan pressurization method.

The only difference between alternative agents and Halon 1301, in this regard, is the density of the agent/air mixture that is the driving force for leakage in quiescent environments. The mixture density can be estimated as follows:[1]

All agents, except inert gases, have higher mixture densities than Halon 1301 at 5 percent when used at their design concentrations. This will require slightly more leaktight enclosures to maintain the same hold time.

Note that IG-541 and IG-55 have densities very close to air. Such densities will result in excellent concentration retention or, conversely, relatively high allowable leakage areas, minimizing

problems associated with leak integrity testing and required hold time.

Based on actual room testing with halogenated agents, the allowable leakage area calculated from the enclosure integrity test procedure given in Annex B of NFPA 2001 will be conservative. The actual hold time can be expected to be quite longer than the calculated hold time. This conservatism arises from the necessary, conservative simplifying assumption that the total equivalent leakage area measured by the door fan is evenly distributed at the top and bottom of the enclosure being tested.

Recent work by Dewsbury and Whitely[61,62] and Klocke[63] indicates interface between the air and the agent/air mixture may result in shorter than expected agent retention times due to the development of a wide interface of a subextinguishing concentration mixture of the agent. This more conservative method as modified has been adapted by ISO.

SUMMARY

A wide range of inert gas and halocarbon total flooding clean agents has been introduced over the past several years. More will be commercialized in the near future. The use of an agent must be consistent with applicable environmental regulations. The selection of an agent is driven by its fire performance characteristics; agent and system space and weight concerns; toxicity, particularly for use in occupied areas; and the availability of approved system hardware.

The design of clean agent systems must be carefully done in accordance with third-party listing and approval limitations on both agent and hardware. Given the relative lack of experience with systems employing these new agents, particular care in design, installation, inspection, testing, and maintenance is warranted. Design and installation standards, such as NFPA 2001 and the associated hardware approval standards, form the minimum requirements for these new technologies.

As generalized design methods and more detailed requirements evolve, the ability to design and install systems on a performance basis will increase. A critical part of the installation process is postinstallation inspection and testing. NFPA 2001 contains requirements for the approval and postinstallation inspection and test of clean agent systems. Bearing in mind the relative complexity of these systems and the importance of the detection system and enclosure integrity, postinstallation inspection and testing should be rigorously performed.

Fundamentals of Special Hazards
Characteristics of Special Hazards
Types of Gaseous Agents
Characteristics of Gaseous Agents
Performance-Based Analysis in Agent Selection

Key Terms

automatic sprinkler system, clean agent, design fire scenario, gaseous fire-extinguishing agent, halogenated agents, inert clean agent, performance-based design, special hazard

For purposes of this chapter, a *special hazard* is defined as a fuel array that for one or more reasons cannot be effectively protected by standard spray sprinklers.

Many alternatives to standard spray sprinklers have been developed to protect special hazards, each having certain characteristics uniquely suited to effectively protect the specific aspects of certain special hazards. Special hazard fire protection systems employ every known fire extinguishant, including water.

This chapter examines the key characteristics of special hazards that are particularly relevant to the use of gaseous fire-extinguishing agents (i.e., carbon dioxide, Halon 1301 and clean agents). *Gaseous fire-extinguishing agents* are chemicals or chemical compounds that are discharged on or about a fire hazard in their gaseous phase.

Until the late 1980s, there were two predominant gaseous agents to choose from to protect significant mission-critical hazards that required either a local application approach (carbon dioxide) or total flooding approach (Halon 1301 and carbon dioxide). However, since the advent of the Montreal Protocol and the U.S. Clean Air Act of 1990, production of new Halon 1301 has ceased. Chlorofluorocarbon (CFC) agents, including Halon 1301, have been identified as contributors to depletion of the ozone layer and targeted for phaseout. However, many new Halon 1301–like gaseous agents have been developed, and regulations have emerged aimed at safeguarding human health from exposure to gaseous fire extinguishants.

Halon 1301 is no longer manufactured in most industrialized nations and new fire-extinguishing systems that employ Halon 1301 are generally not allowed except for certain specific national defense applications. Halon 1301 is, however, still in use in existing systems and recycled Halon 1301 is readily available to refill them should they discharge for any reason.

NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems,* lists 13 gaseous extinguishing agents that have been developed with the hope of filling, at least in part, the market once held solely by Halon 1301. Nine of these agents are halocarbon chemical compounds or mixtures of them, and four are inert gases or mixtures of them.

For new systems, how does one choose the optimal gaseous agent for a particular fire hazard? Should it be carbon dioxide, one of the nine halocarbons, or one of the four inert agents? This chapter provides information aimed at helping to evaluate a given fire hazard and select one or more gaseous extinguishing agents that can provide an optimum fire protection solution for that hazard.

Also provided is information that will assist in effectively and safely maintaining existing Halon 1301 systems in service, so they will continue to provide effective fire protection that is safe for personnel in close proximity.

See also Section 2, Chapter 7, "Theory of Fire Extinguishment"; Section 3, Chapter 11, "Overview of Performance-Based Fire Protection Design"; Section 17, Chapter 1, "Carbon Dioxide and

Application Systems"; and Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems."

FUNDAMENTALS OF SPECIAL HAZARDS

Fire and Fuel Classification

The performance objective of any special hazard fire-extinguishing system, of course, is to effectively extinguish the fire. It is critical, therefore, to select an extinguishing agent that is well suited to this task.

The nature of a potential fire is influenced by the type of fuel as classified in accordance with the definitions given in NFPA 10, *Standard for Portable Fire Extinguishers.* These definitions are summarized in Table 17.7.1 and are also discussed in Section 17, Chapter 5, "Fire Extinguisher Use and Maintenance."

Applicability of Sprinklers

In general practice, if standard spray sprinklers discharging plain water can adequately protect a fuel array using an occupancy hazard fire control approach, then that fuel array is not considered a special fire hazard. An occupancy hazard fire control approach, in general, utilizes standard spray sprinklers at the ceiling in a rectangular pattern, and is further detailed in NFPA 13, *Standard for the Installation of Sprinkler Systems.*

Class A fuel arrays are commonly protected by standard spray sprinklers discharging plain water, usually using the occupancy hazard fire control approach. An administrative office area is an example of this. This same approach is used to protect small Class B fuel arrays such as might be stored in a cleaning supply closet within the administrative office area. Certain Class C fuel arrays can also be protected using this approach. NFPA 13 requires sprinkler protection in electrical rooms, while allowing exemption from this requirement if certain conditions are satisfied.

If for any reason a fuel array is considered unsuitable for sprinkler protection using the occupancy hazard fire control approach and plain water, then it is often deemed to be a special hazard. In some instances, a water-based sprinkler system may be considered inappropriate for a particular fuel array because the water by itself may be ineffective or could cause unacceptable collateral damage. An example of the former is a flammable liquid pool array where plain water may not be an effective flame extinguishant. An example of the latter is a highly critical computer operations hub where water may result in significant collateral damage and extensive interruption of critical operations.

Standard spray sprinklers should never be used to protect Class D fuels because water is not an effective extinguishant and can cause violent reactions. Class K fuel arrays are normally protected by wet chemical extinguishants. Sprinklers can be used effectively, but a special design method is needed.

In summary, a special fire hazard might consist of a fuel array that meets the definition of any one, or a combination of, the standard classifications of Class A, B, C, D, or K. The hazard will need to be protected as a special fire hazard if it possesses one or more characteristics that make it unsuitable for protection by standard spray sprinklers using the occupancy hazard fire control approach and plain water.

Gaseous fire-extinguishing agents, among other options, are often considered and chosen as the primary fire extinguishant to protect certain special fire hazards where they can be effective, and where water is deemed inappropriate or used as a secondary protection method.

TABLE 17.7.1 Fire Classification and Fuel

Fire Classification	*Fuel*
Class A	Ordinary combustible materials, such as wood, cloth, paper, rubber, and many plastics
Class B	Flammable liquids, combustible liquids, petroleum greases, tars, oils, oil-based paints, solvents, lacquers, alcohols, and flammable gases
Class C	Energized electrical equipment
Class D	Combustible metals, such as magnesium, titanium, zirconium, sodium, lithium, and potassium
Class K	Combustible cooking media (vegetable or animal oils and fats)

Examples of Special Hazards Protected by Gaseous Agents

Examples of special hazards protected by gaseous agents include the following:

- Aircraft engine nacelles
- Cargo holds
- Computer data centers
- Dip tanks and coating machines
- Electrical equipment cabinets
- Electrical transformers and transformer vaults
- Engine rooms aboard ships
- Flammable liquid storage rooms
- Gas and oil processing facilities
- Hot oil industrial food fryers
- Industrial ovens
- Machine lube oil pits
- Offshore oil platforms
- Printing presses
- Process control room
- Steel rolling mills
- Telecommunications centers
- Turbine generator lube and seal oil systems
- Valuable electronic media storage vault
- Valuable paper records storage vault
- Wave soldering machines

Note that several of these examples are covered in more detail in relevant chapters of Section 8 ("Special Equipment") and Section 9 ("Processes and Facilities").

CHARACTERISTICS OF SPECIAL HAZARDS

The choice of the most appropriate fire-extinguishing agent for a special fire hazard depends on its specific characteristics. The most influential hazard characteristics commonly evaluated when making this choice include fuel properties, dimensional orientation, enclosure around the hazard, physical location, and occupancy.

Fuel Properties

Fuel properties that are particularly germane to special hazards fire protection include class and form of fuel and the presence of an oxidizer.

Classification of Fuel. Careful identification of the fuel related to the hazard being protected is a key first step in selecting an appropriate gaseous fire-extinguishing agent. One should collect as much information as possible, including the elemental materials involved, such as wood, paper, plastic, chemical, and so on. Then the fuel array should be classified using the system previously described (Class A, B, C, D, or K).

If the hazard involves electronic equipment, such as data processing or telecommunications equipment, determine whether power to the equipment will be interrupted prior to agent discharge, in which case the fuel classification might well be Class A (surface burning). Otherwise, the fuel classification would more accurately be Class C (energized electrical).

Class A—Surface Flame or Smoldering Combustion Tendency. Class A fuel arrays often burn with a predominant surface flame and negligible smoldering combustion. Materials made of plastic or rubber often produce this type of fire, which is often referred to as a Class A surface fire. A surface flame propagates in the gas phase in close proximity to the fuel surface, but not actually in contact with it.[1] Heat from the flame vaporizes the solid or liquid fuel just ahead of the flame front. The flame then ignites the vaporized fuel at the lower flammability range of the vapor mixture, and the flame advances, vaporizing more solid or liquid fuel in a continuing process. Surface-type flame spread can occur in solid, liquid, or gas fuels.

In Class A fuel arrays comprising cellulosic material in fibrous or particulate form, smoldering may be the predominant form of combustion, either in the absence of any surface flaming or after the surface flaming has subsided. Smoldering is a form of combustion without flame that occurs in fuel comprising finely divided fibers or particles that have a relatively large surface area to mass ratio.[2] Wood, pressed fiber insulation board, corrugated paper board, paper, and natural textile fabrics are examples of cellulosic materials or products that will produce significant smoldering combustion. The fuel aggregate must be permeable, allowing oxygen transport to the combustion reaction zone below the surface of the fuel. The fuel aggregate must also be dense enough to form an effective insulation layer that slows down heat losses from the reaction zone. Smoldering combustion can occur only in solid fuels.

Class C—Energized Electrical Equipment. Many special hazards protected by gaseous fire-extinguishing systems involve electrically energized equipment. Examples include telecommunication switches, satellite uplink transmitters, data processing equipment, and industrial process control rooms. When a fire in such hazards results in interruption of power to the equipment, the fuel is immediately converted from a Class C to a Class A–type hazard. The polymeric materials used in electric cable insulation and printed circuit boards are inherently Class A materials. When these materials burn, the flame is predominantly a surface burning phenomenon. Extinguishing a surface burning fire in Class A materials with gaseous agents is a relatively straightforward process.

These same materials are considered Class C fuel if the electrical power is not interrupted during the extinguishing process. One can easily conclude that fires in Class C fuels are more difficult to extinguish and prevent rekindling due to the presence of a persistent electrical energy input, which can add heat to the combustion zone. Various building and fire codes that may apply to a particular project could require electrical equipment to be de-energized prior to agent discharge, effectively converting the Class C fire into a Class A surface fire. Examples are found in NFPA 70, *National Electrical Code®*, and NFPA 75, *Standard for the Protection of Information Technology Equipment.*

Form of Fuel. For a given special fire hazard, the fuel array may be in solid, liquid, or gas form, or a combination of these forms. The fuel form plays a major role in determining the nature of the fire hazard. For example, solid cellulosic fuels can foster smoldering combustion that spreads very slowly with no visible flame. A flammable liquid pool, on the other hand, can produce a surface fire that spreads very rapidly with a high heat release rate. The fire characteristics, which are determined by the fuel characteristics, will influence the most appropriate choice of gaseous extinguishing agent.

Gaseous extinguishing agents are also suitable as inerting agents when a fuel exists in gaseous form. Such an atmosphere can be inerted by certain gaseous agents to prevent a fire or explosion.

Presence of Oxidizer. NFPA 430, *Code for the Storage of Liquid and Solid Oxidizers,* defines an oxidizer as any material that readily yields oxygen or other oxidizing gas, or that readily reacts to promote or initiate combustion of combustible materials and can undergo a vigorous self-sustained decomposition due to contamination or heat exposure. Generally, gaseous extinguishing agents are not suitable for use on hazards that contain oxidizers.

Dimensional Orientation

Gaseous extinguishing agents are particularly well suited to protect hazards that have three-dimensional fuel characteristics or where the fuel may be shielded. An example of this is a computer cabinet where the fuel is located inside a closed cabinet in the form of printed circuit boards and electric cable insulation. A gaseous extinguishing agent can flood the area surrounding the cabinet and permeate the cabinet interior through gaps and holes in concentrations sufficient to surround the fuel and extinguish a fire inside.

Enclosure Around the Hazard

Many fire hazards are surrounded partially or completely by an enclosure, such as a room. If the enclosure is complete, and any openings can be effectively closed, then the hazard may be protected by a total flooding gaseous extinguishing system. If the enclosure cannot be effectively sealed to accommodate total flooding, then partial flooding or local application systems using gaseous agents may be possible. Where no enclosure exists, and the hazard is not concealed or shielded, gaseous extinguishing agents might be applied as local applications or they simply may not be the most suitable choice.

Total Flooding Application. A total flooding configuration is one where the fire hazard being protected is surrounded completely by an enclosure, usually consisting of a floor, four walls and ceiling. A total flooding extinguishing system is designed to quickly fill the entire enclosure with a concentration of agent sufficient for fire extinguishment. The system should also be designed to maintain the concentration for a period of time to prevent rekindling and enable a manual emergency response.

Total Flooding Enclosure Integrity. When a total flooding gaseous extinguishing system discharges into an enclosure with no fire present, rapid pressure changes occur, that exert significant forces on the enclosure boundaries. With a fire present, the pressure forces produced will likely be even greater.[3] The enclosure construction elements must be capable of withstanding the peak pressures produced during agent discharge, or damage to the enclosure—and even catastrophic failure—could occur. This could in turn lead to failure of the fire protection system to extinguish the fire. Any failure of the enclosure's integrity could also endanger personnel in the immediate vicinity.

Evaluation of Peak Pressures During Agent Discharge. The discharge of halocarbon agents, both halocarbon clean agents and Halon 1301, causes an initial drop in pressure within the enclosure followed by a temporary rise in pressure. Shortly after the completion of agent discharge, the enclosure pressure reaches equilibrium, just slightly above the pressure value prior to discharge. The enclosure pressure changes during halocarbon agent discharge are shown schematically in Figure 17.7.1. (Note that the graphic does not, however, apply to HFC-23 [FE-13].)

The discharge of inert clean agents and carbon dioxide causes a positive pressure change within the enclosure. This pressure change can be quite large, exceeding the strength of most common enclosure elements. Thus, inert clean agent and carbon dioxide total flooding extinguishing systems will normally require the installation of enclosure pressure relief vents to protect the integrity of the enclosure during agent discharge. The enclosure pressure changes during inert agent discharge are shown graphically in Figure 17.7.2.

Evaluation of Enclosure Strength. During the development of heptafluoropropane (HFC 227ea), several studies evaluated various aspects of the enclosure pressure dynamics during agent discharge and the inherent strength of various construction elements to resist these pressure forces.[3] These studies found that the enclosure walls for the majority of total flooding applications using HFC 227ea are either gypsum wallboard on studs or masonry units such as concrete block and/or brick. Findings from these studies of particular interest follow:

- The peak pressures developed during agent discharge ranged from –8 psf (–383 Pa) to 8 psf (383 Pa).
- The peak pressures developed in an enclosure with gypsum wallboard on studs was less than that developed with walls of concrete block, because gypsum wallboard on studs flexes in response to pressure changes, which dampens peak pressure development. Concrete block walls do not flex, thus enabling peak pressure magnitudes to be greater.

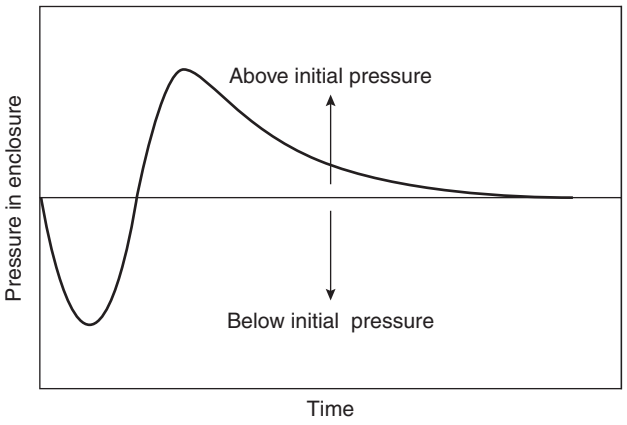

FIGURE 17.7.1 Variation in Room Pressure During Halocarbon Agent Discharge (Source: *Room Pressure Venting Guideline with FM-200®—Application Guide,* 93-1001, Fenwal Protection Systems, Ashland, MA, Dec. 2003)

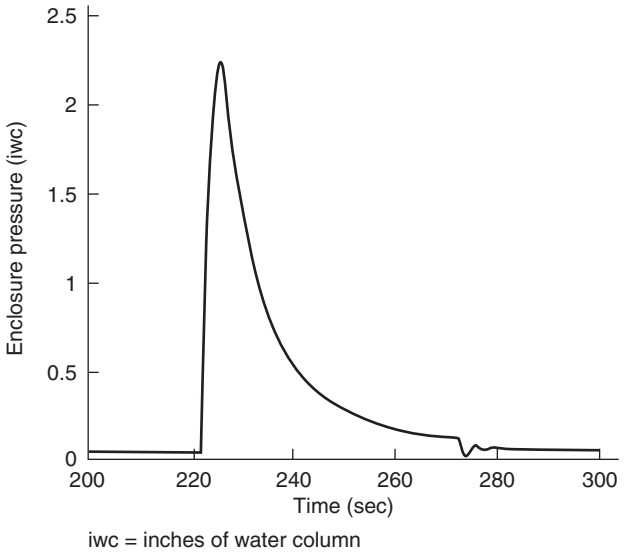

FIGURE 17.7.2 Variation in Room Pressure During Inert Agent Discharge (Source: Robin, M. L., Forssell, E. W., and Sharma, V., "Pressure Dynamics of Clean Agent Discharges," Halon Options Technical Working Conference, 2005)

- The metal studs most commonly used in gypsum wallboard construction can resist a peak pressure of over 25 psf (1197 Pa) before reaching their yield strength. This value can vary depending on such variables as wall height and stud spacing.
- The wood studs most commonly used in gypsum wallboard construction can resist a peak pressure of about 11 psf (527 Pa) before reaching their maximum tensile strength. This value can vary depending on such variables as wall height and stud spacing.
- Additional investigation is warranted on other construction materials and assemblies commonly used in protected enclosures, such as concrete, other masonry units, doors, and windows.
- For very tight enclosures, that is, those with predicted agent retention times significantly exceeding 10 minutes, and for enclosures significantly higher than 12 ft (3.7 m), the pressures developed during agent discharge could reach or exceed the maximum strength of the construction elements.

It is advisable to consult a qualified structural engineer for assistance with the determination of enclosure strength. Likewise, the gaseous extinguishing system manufacturer should be consulted to assist with the determination of peak discharge pressure values. Once the peak pressure load and enclosure strength values are determined, the need for enclosure relief venting or strengthening the enclosure should be evaluated.

Partial Flooding Application. A partial flooding configuration is one where the fire hazard being protected is surrounded only partially by an enclosure. An example of this is a flight simulator. Flight simulators are large boxes elevated above the floor on sophisticated hydraulically operated supports. The hydraulic oil system is usually located on the floor directly beneath the simulator box. Because a hydraulic oil fire could endanger the occupants of the box during simulation exercises, a partial height wall is constructed beneath the box, completely surrounding the hydraulic oil equipment and completely sealed to the floor, gastight. This partial enclosure is then equipped with an automatic gaseous extinguishing system that will flood the partial enclosure like filling a bathtub. The burning fuel will be submerged in an extinguishing concentration of gaseous agent and the fire will be extinguished.

Local Application. Where the fire hazard being protected is not surrounded by an enclosure, a local application extinguishing system is designed to discharge extinguishing agent in predominantly liquid form directly onto the burning fuel surfaces in sufficient quantity to extinguish the fire and very often cool the fuel. See "Carbon Dioxide" later in this chapter under the section "Local Application Capability" for more information. A printing station on a large commercial printing press is an example of a fire hazard that is commonly protected with a local application gaseous extinguishing system.

Physical Location

The physical location of a hazard to be protected has an influence on the most suitable fire-extinguishing system for the application. Gaseous clean agent systems have been employed in just about every location imaginable with great success. For example, gaseous agent systems protect engine and machinery spaces on cargo ships, gas compressor rooms at the North Slope in Alaska, telecommunication rooms at the top of air traffic control towers, and cargo compartments on commercial aircraft. Carbon dioxide systems have also been used in many of these same locations.

The physical location of the hazard should be carefully evaluated. Different variables associated with the hazard location may favor the use of one gaseous agent over another. For example, some locations may experience extreme low or high temperatures. Others may be relatively remote, providing a challenge to the process of refilling and restoring a system to full operation following a system discharge. These and other factors related to hazard location can favor one gaseous extinguishant over others.

Occupancy

One clear objective of the NFPA standards addressing gaseous extinguishing agents is to design and install systems in a manner that prevents human exposure to the extinguishing agent. This objective was emphasized with EPA involvement in the process to find safe new alternatives for fire protection halons such as Halon 1301 and Halon 1211 that were deemed harmful to the stratospheric ozone layer. All gaseous agents currently used, other than Halon 1301 and Halon 1211, are included in the Safe New Alternatives Policy Program (SNAP), EPA's program to evaluate and regulate substitutes for ozone-depleting chemicals being phased out under the stratospheric ozone protection provisions of the U.S. Clean Air Act.

EPA has stated, "The Administrator has determined a large number of alternatives that exist to reduce overall risk to human health and the environment. The purpose of the program is to allow a safe, smooth transition away from ozone-depleting compounds by identifying substitutes that offer lower overall risks to human health and the environment." It is clear that EPA intends not only to reduce environmental risk, but also human health risk.

NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems,* NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems,* and NFPA 2001 provide various requirements to reduce human health risks from potential exposure to the gaseous agents listed in these standards. Table 17.7.2 presents several definitions related to occupancy and human health exposure.

In general, requirements in the standards are designed to provide protection against human exposure to the gaseous agents in direct proportion to the likelihood of human occupancy in the protected room or space. The risk of human exposure to the agent is relatively high in a space that is "normally occupied" and relatively low in a space that is "unoccupiable."

TYPES OF GASEOUS AGENTS

Although there are many gaseous fire-extinguishing agents to choose from for a given application, the three main types of gaseous agents are clean agents, carbon dioxide, and Halon 1301. NFPA publishes design, installation and maintenance standards for each type in NFPA 2001, NFPA 12, and NFPA 12A respectively.

TABLE 17.7.2 Human Health Exposure Terms and Definitions Related to Occupancy

Term	*Definition*
Normally occupied area	An area that is intended for occupancy
Normally occupied	An enclosure where, under normal circumstances, persons are present
Normally unoccupied	An area or space not normally occupied by people that could be entered occasionally for brief periods
Unoccupiable	An enclosure that cannot be occupied due to dimensional or other physical constraints

Clean Agents

Clean agents are in the gaseous state in the vicinity of the fire hazard. As gases, they quickly surround the fuel and permeate the fire, even if physical barriers or complex fuel geometries exist. They are electrically nonconductive and leave no residue.

Clean agents were developed and commercialized in direct response to the phaseout of Halon 1301 initiated by the Montreal Protocol. The Montreal Protocol was adopted into U.S. law through the Clean Air Act of 1990. The aim of the Montreal Protocol was to reduce the emissions of chemicals that destroy stratospheric ozone. Compounds that contain bromine and, to a lesser extent, chlorine, were known to be especially detrimental to the ozone layer. Clean agents are addressed in NFPA 2001 as well as several other international standards.

Clean agents are categorized into two chemical groups, halocarbon and inert.

Halocarbon compounds are chemicals in which one or more carbon atoms are linked by covalent bonds with one or more halogen atoms: fluorine, chlorine, bromine, or iodine. Nine halocarbon agents are currently listed in NFPA 2001. None of these contain bromine, and only two contain chlorine. All contain fluorine and one contains iodine. See Table 17.7.3.

Inert clean agents consist of one of several naturally occurring inert chemicals, or mixtures of them. Four inert agents are currently listed in NFPA 2001 (see Table 17.7.4).

Carbon Dioxide

Carbon dioxide is a naturally occurring atmospheric gas. At normal room temperature and atmospheric pressure, carbon dioxide is a gas. Under certain conditions of temperature and pressure, carbon dioxide forms a liquid. For fire protection systems, it is stored as a liquid in steel containers, either by applying high pressure or by cooling the gas and applying a lower pressure.

Halon 1301

Halon 1301 is a halocarbon compound that contains bromine, and has, therefore, been deemed harmful to the stratospheric ozone layer. The Montreal Protocol targeted Halon 1301 for phaseout. Many countries have ceased production of Halon 1301 and prohibit its use in new fire-extinguishing systems. For example, the U.S. Clean Air Act of 1990 required that no new Halon 1301 be manufactured after January 1, 1994.

TABLE 17.7.3 Halocarbon Clean Agents Listed in NFPA 2001

Halocarbon Clean Agents	*Chemical Name*	*Chemical Formula*
FC-3-1-10	Perfluorobutane	C_4F_{10}
FK-5-1-12[a]	Dodecafluoro-2-methylpentan-3-one	$CF_2CF_2C(O)CF(CF_3)_2$
HCFC Blend A[b]	Dichlorotrifluoroethane HCFC-123 (4.75%)	$CHCl_2CF_3$
	Chlorodifluoromethane HCFC-22 (82%)	$CHClF_2$
	Chlorotetrafluoroethane HCFC-124 (9.5%)	$CHClFCF_3$
	Isopropenyl-1-methylcyclohexene (3.75%)	
HCFC-124	Chlorotetrafluoroethane	$CHClFCF_3$

	Argon (40%)	Ar
	Carbon dioxide (8%)	CO_2
IG-55	Nitrogen (50%)	N_2
	Argon (50%)	Ar

Notes:
1. Other agents could become available at later dates.
2. Composition of inert gas agents are given in percent by volume.

CHARACTERISTICS OF GASEOUS AGENTS

Common Characteristics

All gaseous extinguishing agents share certain properties that are considered generally advantageous for special hazard fire-extinguishing applications. These include the following:

- They are applied to the hazard in gaseous form that is electrically nonconductive and leaves no residue.
- As a gas, these agents are able to extinguish fires even in the presence of physical barriers or obstructions.
- They are able to surround and penetrate three-dimensional fuel arrays.
- They are able to totally flood an enclosure about a hazard and be held at a design concentration to extinguish a fire.
- They are able to inert an enclosed volume for a period of time to prevent a fire or explosion from occurring.
- They do not cause direct collateral damage to equipment or materials in the protected area.

Specific Characteristics

It is important to carefully evaluate the specific characteristics of one or more gaseous extinguishing agents when looking for the optimal choice for a specific fire hazard. The characteristics most relevant to this task are the following:

- Fire extinguishing effectiveness
- Health and safety
- Environmental impact
- Cost
- Temperature range
- Collateral damage (direct or indirect)
- Availability for recharge
- Discharge pressure effects
- Local application capability

Table 17.7.5 summarizes these characteristics for each type of gaseous agent. The following sections discuss some of these characteristics in more detail.

Fire Extinguishing Effectiveness

For a given halocarbon clean agent, care must be taken to apply the minimum extinguishing concentration value for the actual Class A or B hazard to achieve the desired extinguishing effectiveness.

Class A Deep-Seated Fires. There are no standardized tests to determine the minimum extinguishing concentrations for Class A deep-seated fires. NFPA 2001 cautions that deep-seated Class A fires may require substantially higher design concentrations and longer holding times than for surface burning Class A fires. No quantified recommendations are provided by the standard. The designer should seek guidance from the system manufacturer where deep-seated Class A fires may be a concern.

Class C Fires. NFPA 2001 addresses Class C fire hazards only briefly by stating that the minimum design concentration for Class C fires should be no less than that for Class A surface-type fires. Additional guidance is provided in Annex A, which suggests that higher initial design concentrations and extended agent discharge be considered when electrical equipment cannot be de-energized. Testing of certain halocarbon clean agents on Class C fires has revealed the following:

- After initial flame extinguishment, the flame can rekindle due to the persistence of the heat energy source via the continuation of electrical energy to the fuel array.[4]
- Flame rekindling can be prevented by raising the design concentration above the minimum value required for Class A surface-burning type fires.[5,6]
- The minimum extinguishing concentration for a particular halocarbon agent is dependent on numerous variables, including the form of electrical heat energy (i.e., electric arc, ohmic, or conductive), the absence or presence of a pilot ignition source, the quantity of electric energy involved, and so forth.

Only a few of the many possible combinations of variables have been tested for some of the available halocarbon agents. Although these tests are not sufficient to be conclusive for all possible configurations of Class C hazards, two definitive recommendations are offered regarding Class C fires as follows:

- Make every possible effort to arrange for electric energy to be interrupted prior to or during agent discharge.
- If it is not possible to interrupt electric energy, consider increasing the quantity of agent for the hazard to compensate for the continuous energy being supplied to the hazard, seeking guidance from the system manufacturer.

Health and Safety

As seen in Table 17.7.5, the four types of agents vary in safety for use in normally occupied spaces. Clean agents are assigned several values used to help determine the relative health risk in the event of human exposure to a clean agent. One such value is termed "No Observed Adverse Effect Level" (NOAEL) and the other, "Lowest Observed Adverse Effect Level" (LOAEL). In the case of halocarbon clean agents, the LOAEL value is the

TABLE 17.7.5 Characteristics of Types of Gaseous Agents

	Halocarbon Clean Agents	*Inert Clean Agents*	*Carbon Dioxide*	*Halon 1301*
Fire Extinguishing Effectiveness				
For Class A and B fuels[a]	Excellent	Excellent	Excellent	Excellent
Additional agent needed for extinguishment for Class C fires	Sometimes[b]	Sometimes[b]	No	Sometimes[b]
For Class D and K fuels	May not be effective	May not be effective	May not be effective	May not be effective
Health and Safety[c]				
Primary health risk	Cardiac sensitization leading to heart arrhythmia and possibly death	Hypoxia	Death from asphyxiation	Cardiac sensitization leading to heart arrhythmia and possibly death
Considered safe for use in normally occupied spaces	Yes, when the design concentration is less than or equal to the agent's NOAEL value[d]	Yes, when the design concentration is less than or equal to the agent's NOAEL value	Only at low design concentrations	Yes, when the design concentration is 7% or less and human exposure can be limited to 15 minutes or less
Environmental Impact				
Approved for use by U.S. Environmental Protection Agency	Yes[e]	Yes[e]	Yes[e]	Generally, new systems are not allowed except in certain applications deemed essential to national defense[f]
Ozone depletion potential (ODP)	ODP = 0 for most systems and agents	ODP = 0 for all systems and agents	ODP = 0	Highest ODP of any man-made ozone-depleting substance
Global warming potential and atmospheric lifetime characteristics	Vary among agents; the impact of each agent should be evaluated individually	One agent contains a small percentage of CO_2 (see next column)	Regulated in some countries as a contributor to global warming	Has characteristics that can contribute to global warming
Cost				
Generalized system cost[g]	Agent = 25.0%; mechanical = 12.5%; electrical = 12.5%; labor = 50%	Agent = 5% mechanical = 22.5% electrical = 12.5% labor = 60%	System cost varies greatly and cannot be generalized	New systems are generally not allowed[h]
Cost of fire-resistant enclosure[i]	Can be substantial[i]	Can be substantial[j]	Can be substantial[k]	NA
Cost impact of proximity of hazard to agent refill supply	Consider a connected reserve supply of agent if the refill time from the closest supply sources is considered excessive or unacceptable	Consider a connected reserve supply of agent if the refill time from the closest supply sources is considered excessive or unacceptable	Consider a connected reserve supply of agent if the refill time from the closest supply sources is considered excessive or unacceptable	Consider a connected reserve supply of agent if the refill time from the closest supply sources is considered excessive or unacceptable
Cost impact of cylinder footprint size	Relatively small	Relatively large	Relatively large (for cylinders or tanks)	NA
Cost impact of distance between agent storage and protected hazard	Limited; increasing distance increases cost	Limited; increasing distance increases cost	Limited, but to a lesser degree than with clean agents	NA

[a]Additional extinguishing agent needed for smoldering combustion (deep-seated fires) involving Class A fuels.
[b]Additional agent is needed in certain Class C fires (i.e., the required agent quantity generally increases as the electrical energy and related heat energy input to the fire increases).
[c]General guidance during system maintenance is to avoid human exposure.
[d]PBPK (physiologically based pharmacokinetic) modeling can be used to determine safe use in normally occupied spaces above the NOAEL value.
[e]Listed as acceptable alternative to Halon 1301 in EPA's SNAP program.
[f]Existing systems are allowed to remain in service in the United States; however, some countries have required that they be decommissioned.
[g]Cost of detection system increases as size of fire to be detected decreases.
[h]The costs associated with Halon 1301 systems are related to maintenance of existing systems.
[i]On rare occasions, may need to protect the enclosure from damage due to overpressure during agent discharge (total flooding systems).
[j]Usually need to protect the enclosure from damage due to overpressure during agent discharge (total flooding systems).
[k]Always need to protect the enclosure from damage due to overpressure during agent discharge (total flooding systems).
[l]For typical operating temperature range, see manufacturer's listing or approval documentation.
[m]When used outside of this temperature range, agent quantity must be adjusted.
[n]Each location needs to be evaluated for ability to recharge.
[o]Postdischarge pressure inside the enclosure reaches an equilibrium point just slightly higher than the original starting point.
NA = Not applicable.

lowest agent concentration by volume percent in air where adverse health effects were first noticed in animals being tested, which in these tests were beagle dogs. The adverse health effect observed is the onset of heart arrhythmia.

In the case of inert clean agents, the LOAEL value is the agent concentration by volume percent in air where adverse health effects are expected to occur in humans as determined by a panel of experts organized by the EPA. The panel reviewed pertinent literature regarding adverse health effects in humans exposed to hypoxic (low oxygen concentration) atmospheres and drew conclusions based on this existing body of knowledge. All inert agents are considered to be the same in relation to the determination of an appropriate LOAEL and NOAEL value.

Halocarbon Clean Agents. Table 17.7.6 provides the NOAEL and LOAEL values for the halocarbon clean agents.

Table 17.7.7 provides safe exposure limits in the unlikely event that halocarbon clean agent is discharged while one or more persons are still in the protected area.

The following example is presented to help illustrate the criteria in Tables 17.7.5 and 17.7.7 related to the use of PBPK data. Halocarbon clean agent X is proposed for use in a normally occupied space at a design concentration of 10 percent. The NOAEL value for this agent is 8 percent and the LOAEL value is 9.5 percent. Under the original human exposure rules, this proposed design could only be used for a space not normally occupied because the design concentration exceeds the LOAEL

TABLE 17.7.6 NOAEL and LOAEL Values for Halocarbon Clean Agents

Halocarbon Clean Agent	*NOAEL (Agent % by Volume)*	*LOAEL (Agent % by Volume)*

TABLE 17.7.7 Safe Exposure Limits for Halocarbon Clean Agents

Agent Design %	*Occupancy*	*Exposure Time Limit*	*Comments*
≤ NOAEL	Normally occupied	Up to 5 minutes	No PBPK data needed
> NOAEL and LOAEL	Normally occupied	PBPK model limit corresponding to design concentration and 5 minute exposure	PBPK data needed
> NOAEL and LOAEL	Normally occupied	PBPK model limit corresponding to design concentration and *less than* 5 minute exposure	Conditions: 1. Authority having jurisdiction (AHJ) approval 2. Egress time calculations 3. Adhere to PBPK model exposure time limitation
> LOAEL	Not occupied	PBPK model limit corresponding to the design concentration	PBPK data needed
≤ LOAEL	Not occupied	Up to 60 seconds	No PBPK data available
> LOAEL	Not occupied	Up to 30 seconds	No PBPK data available

value. Furthermore, the design would have to ensure that occupants of the room would evacuate before agent discharge.

Application of the PBPK model allows additional flexibility. The PBPK model needs, as input, the arterial blood level measured in the beagle dog that experienced a heart arrhythmia at the LOAEL concentration of 9.5 percent. This value is loaded into the PBPK model, as is the desired design concentration of 10 percent. The PBPK model calculates the human exposure time that will allow the human arterial blood concentration of agent to reach the same level as the input value from the dog. The result is 6 minutes.

In this example, the PBPK model determines that a human being can be safely exposed to an agent concentration of 10 percent for up to 6 minutes. The second row of Table 17.7.6 applies to this case. This result indicates that the proposed design is safe for use in normally occupied spaces, and no special approvals are needed nor do any special conditions apply. The system design must limit human exposure to 5 minutes, even though the PBPK model predicts that 6 minutes is safe.

Altering this example slightly will illustrate other provisions in the safe exposure rules. Assume that the PBPK model determines that a human being can safely be exposed to an agent concentration of 10 percent for only 3 minutes. For this case, the third row of Table 17.7.7 applies. Special conditions must be satisfied to allow this proposed design to be used in a normally occupied space. Egress calculations must be performed to demonstrate that all occupants of the space can egress within 3 minutes corresponding to the PBPK model result. Widely accepted calculation methods are available and applicable for this purpose.[7–9] Furthermore, special approval from the authority having jurisdiction (AHJ) must be obtained.

Design concentrations greater than the NOAEL may be used in normally occupied spaces using PBPK modeling results corresponding to a minimum safe human exposure time of 5 minutes.

Halocarbon clean agents are considered conditionally safe for use in normally occupied spaces when design concentration exceeds the agent's NOAEL value using PBPK modeling results corresponding to a human exposure time of less than 5 minutes. This requires special approval by the AHJ. See Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems," for more information on PBPK modeling.

Inert Clean Agents. Table 17.7.8 provides the NOAEL and LOAEL values for the inert clean agents.

Table 17.7.9 provides safe exposure limits in the unlikely event that an inert clean agent is discharged while one or more persons are still in the protected area.

TABLE 17.7.8 NOAEL and LOAEL Values for Inert Clean Agents

IG-01	43.0	52.0
IG-100	43.0	52.0
IG-541	43.0	52.0
IG-55	43.0	52.0

TABLE 17.7.9 Safe Exposure Limits for Inert Clean Agents

Agent Design %	*Oxygen %*	*Occupancy*	*Exposure Time Limit*
≤ 43	≥ 12	Normally occupied	Up to 5 minutes
> 43 and ≤ 52	≥ 10 and < 12	Normally occupied	Up to 3 minutes
> 52 and ≤ 62	≥ 8 and < 10	Not occupied	Up to 30 seconds
> 62	< 8	Not occupied	No exposure allowed

Carbon Dioxide. At a concentration of about 9 percent, most humans will become unconscious. At 25 percent to 30 percent, respiration will suddenly stop and death will soon follow.

Collateral Damage

Halocarbon clean agents and Halon 1301 contain fluorine (F), which breaks down during flame extinguishment and forms hydrogen fluoride. Hydrogen fluoride (HF) is a weak acid that in small concentrations can cause mild irritation in exposed humans in the upper respiratory tract and eyes. HF in sufficiently high concentrations can be debilitating to humans and cause damage to exposed equipment.

Availability for Recharge

The many halocarbon clean agents and several inert clean agents differ in their availability for recharging a system after it has discharged. Some are widely available throughout the world. Some are not as widely available and may require a significant amount of time to accomplish a system recharge.

Discharge Pressure Effects in a Protected Enclosure

In the case of Halon 1301 systems with extremely tight or tall enclosures, enclosure damage due to pressure spikes during total flooding system discharge has been rare. This is due in large part to the fact that Halon 1301 enclosures have a relatively high vent to volume ratio. That is, they are much leakier than enclosures that are protected by halocarbon or inert clean agents.

Local Application Capability

Halocarbon Clean Agents. Historically, halocarbon clean agents have been used primarily in total flooding applications. NFPA 2001 applies only to total flooding systems. Local application systems are, therefore, excluded. One halocarbon agent has been developed for use in hazard-specific local application and partial-flooding applications. These systems are typically proven by individual test to the satisfaction of the purchaser or approval authority.

Inert Clean Agents. Inert clean agents discharge from the nozzles as a gas with no liquid component. It is very difficult to direct this gaseous discharge precisely for any distance from the nozzle. Inert clean agents, therefore, have not been developed for local application use.

Carbon Dioxide. Carbon dioxide is stored in liquefied form inside pressure containers. In high-pressure systems, carbon dioxide is stored at 70°F (21°C) at a pressure of 850 psi (5860 kPa). In low-pressure systems, the carbon dioxide is stored at a controlled low temperature of 0°F (–18°C). At this temperature the pressure in the container is 300 psi (2068 kPa). As carbon dioxide liquid flows from the storage containers to the discharge nozzles, it absorbs heat and begins to gasify. It does not fully gasify in the pipe network; therefore, a portion of the discharge from the nozzles is still in liquid form. This characteristic enables carbon dioxide to be configured in local applications systems and to protect hazards that are partially enclosed or completely unenclosed.

Halon 1301. Halon 1301 gasifies in very close proximity to the discharge nozzles; therefore, it is not well suited for use in local application systems. Local application systems using Halon 1301 have been very uncommon. Those that exist now, or existed in the past, most likely were protecting hazards with enclosures that had uncloseable openings making it impossible for the agent to be retained for at least 10 minutes, as was commonly required of total flooding applications. These systems are typically proven by individual test to the satisfaction of the purchaser or approval authority.

PERFORMANCE-BASED ANALYSIS IN AGENT SELECTION

Steps in Performance-Based Analysis and Design

The *SFPE Engineering Guide to Performance-Based Fire Protection: Analysis and Design*[10] offers an excellent performance-based engineering methodology that can easily be adapted to the process of selecting clean agents. The *Guide* defines performance-based design as follows:

> An engineering approach to fire protection design based on (1) agreed upon fire safety goals and objectives, (2) deterministic and/or probabilistic analysis of fire scenarios, and (3) quantitative assessment of design alternatives against the fire safety goals and objectives using accepted engineering tools, methodologies, and performance criteria.

Performance-based analysis and design offers a number of benefits over other design methods, including maximized value, reliability, and effectiveness. The process of performance-based analysis and design, as detailed in the guide, includes eight generic steps, preceded by a preliminary unnumbered step of identifying stakeholders. Table 17.7.10 lists those steps and presents the first two steps of an example related to gaseous agent selection for a generic corporate data center that incorporates sophisticated electronic data processing and telecommunications equipment. It also contains some limited administrative office space for occupants with responsibilities for the operations. The operations are contained within a single room on the first floor of a two-story building of noncombustible construction. The room is fully sprinklered using a double-interlock preaction configuration. The data center room is cut off from surrounding spaces by 1 hour fire rated, full-height walls, and contains an 18-in. (46-cm) raised access floor and a suspended acoustical ceiling at the 10 ft elevation. The room covers 20,000 feet^2 (1858 m^2) and is occupied by 18 persons during the day shift, 8 persons during the evening shift, and 3 persons during the night shift. All occupants are well-trained, full-time employees of the end user. All occupants are capable of self-preservation without assistance.

TABLE 17.7.10 Steps in Performance-Based Analysis and Initial Application to Gaseous Agent Selection

Step	*Activity*
1	Define the project scope. Select the optimum gaseous extinguishing agent for this corporate data center.
2	Identify the project goals and prioritize them. a. Minimize interruption of the company's business operations where such interruption would harm a customer's business, harm a customer's relationship with the company, harm the company's brands, or otherwise prevent accomplishment of the mission. b. Prevent loss of life or serious injury to building occupants and emergency responders. c. Minimize damage to the company's physical assets.
3	Define the project objectives.
4	Develop the performance criteria.
5	Develop design fire scenarios.
6	Develop trial designs.
7	Evaluate and modify the trial designs.
8	Select the final design.

Stakeholder Identification

The purpose of the preliminary step is to identify key stakeholders so that all primary system performance objectives can be identified and evaluated.

Step 1: Define the Project Scope

The project scope defines the boundaries of the performance-based analysis or design. If the scope of the project were more complex, it would be advisable to identify all of the stakeholders and solicit their input in defining project scope. Developing a consensus of the stakeholders relative to the project scope will improve the quality and overall acceptance of the results. The guide defines stakeholder as "one who has a share or interest in an enterprise. Specifically, an individual (or representative) interested in the successful completion of a project."

A list of stakeholders typical to a gaseous extinguishing system design project might include, but not necessarily be limited to, the following:

- Business owner (end user)
- Design team
- AHJs (building, fire, insurance)
- Construction team (construction manager, general contractor, subcontractors)
- Gaseous extinguishing agent and system manufacturers

Step 2: Identify and Prioritize the Project Goals

One or more of three general goals is commonly assigned to most fire protection analysis or design projects: (1) prevent loss of life or serious injury due to fire or its effects, (2) minimize loss of property due to fire or its effects, and (3) minimize interruption of business operations due to fire or its effects (also referred to as mission preservation).

All three of these general fire protection goals are applicable to most projects that consider the use of gaseous extinguishing agents. In the performance-based example that follows, the goal of minimizing business interruption is considered by the stakeholder group to be the biggest challenge (see Table 17.7.10). Therefore, this goal is listed first. Gaseous extinguishing agents, for example, are widely used to protect operations that utilize computerized electronic data processing, telecommunications, and broadcasting equipment. It is paramount to keep interruptions to such operations to an absolute minimum in the event of a fire. Preserving the mission is critical. Accomplishing this goal will usually also substantially achieve the second goal of preventing loss of life or serious injury. Protecting people is always important. For many gaseous extinguishing agent applications, such as those mentioned above, the expected fires are relatively low-energy fires that are not likely to threaten the occupants in the immediate surrounding areas before they are able to escape safely. However, gaseous extinguishing agents are also commonly employed to protect hazards involving flammable or combustible liquids, such as engine rooms on ships, where fast large fires are expected.

Step 3: Define the Project Objectives

This step involves identification of the stakeholder objectives to meet the project goals. The various stakeholders might define these objectives in different terms; however, they should be clear and agreed to by all stakeholders. In the example begun in Table 17.7.10, there are multiple goals. Table 17.7.11 presents hypothetical stakeholder and design objectives related to those multiple goals, as well as performance criteria.

Minimize Interruption of the Company's Business. For example, the company can establish an objective to limit interruption of telecommunication operations to no more than 4 hours. The insurance stakeholder may state an objective to limit interruption

TABLE 17.7.11 Hypothetical Objectives and Performance Criteria

Stakeholder Objective	*Design Objective*	*Performance Criteria*
Minimize interruption of the company's business operations where such interruption would harm a customer's business, harm a customer's relationship with the company, harm the company's brands, or otherwise prevent accomplishment of the mission.		
1. Limit interruption of all critical telecommunications operations to no more than 4 hours. 2. Limit interruption of all noncritical telecommunications operations to 48 hours. 3. Maintain power to all critical telecommunications equipment during a fire to minimize interruption of operations and customer services.	1. Limit damage to all critical equipment from a fire, fire effects, and suppression effects to one, or several, individual components that can be replaced or restored to full service in less than 4 hours. 2. Limit damage to all noncritical telecommunications equipment from a fire, fire effects, and suppression effects to equipment, or equipment components, that can be replaced or restored to full service in less than 48 hours. 3. Supply power to all critical telecommunications equipment independently from any manual or automatic emergency power off (EPO) systems. The gaseous extinguishing agent must be capable of extinguishing fires in energized electrical equipment.	1. Extinguish the fire at or below 2 kW (1.9 Btu/sec).* 2. Limit the production of halide acids to a concentration within the protected space of 200 ppm or less. 3. Extinguish a fire in energized electrical equipment and prevent re-ignition for the specified hold time or at least 10 minutes.
Prevent loss of life or serious injury to building occupants and emergency responders.		
1. No loss of life and no serious injuries to occupants of the protected enclosure from fire or products of combustion. 2. No loss of life and no serious injuries to occupants of the surrounding areas from fire or products of combustion. 3. No loss of life and no serious injuries to occupants of the protected enclosure from direct exposure to the gaseous extinguishing agent or its decomposition products. 4. No loss of life and no serious injuries to occupants of the surrounding areas from direct exposure to the gaseous extinguishing agent or its decomposition products. 5. Minimize short-term and long-term harm to the natural environment from the gaseous extinguishing agent or arising from the process of accomplishing final fire extinguishment.	1. The smoke layer and radiation heat flux from all feasible and reasonably conservative design fire scenarios must not cross thresholds harmful to the occupants of the protected space before they are able to exit the space. 2. The smoke layer, and radiation heat flux, from all feasible and reasonably conservative design fire scenarios must not cross thresholds harmful to the occupants of the areas surrounding the protected space before they are able to exit these areas to the building exterior. 3. The gaseous extinguishing agent selected must not be harmful to the occupants of the protected space in the required design concentration, and must not produce acidic decomposition products during the extinguishing process that could be harmful to an occupant inadvertently remaining in the protected space following gaseous extinguishing agent discharge. 4. The gaseous extinguishing agent selected must not be harmful in the required design concentration	1. The design concentration for the gaseous extinguishing agent for Class C fires (energized electrical equipment) must be at or below the level corresponding to a maximum 5-minute human exposure time as defined in NFPA 2001. 2. Extinguish the fire at or below 2 kW (1.9 Btu/sec). 3. Limit the production of halide acids to a concentration within the protected space of 200 ppm or less 4. The negative and positive pressure changes during the discharge of the gaseous extinguishing agent must be controllable to a magnitude of 5 psf (239 Pa) or less. 5. The gaseous extinguishing agent must have an ozone depletion factor (ODP) of 0, a relatively low atmospheric lifetime and global warming potential, and must not contain HFC compounds, or carbon dioxide.

TABLE 17.7.11 Continued

Stakeholder Objective	*Design Objective*	*Performance Criteria*
	to the occupants of the areas surrounding the protected space, and must not produce acidic decomposition products during the extinguishing process that could be harmful to occupants that remain in the building following gaseous extinguishing agent discharge. The integrity of the enclosure construction surrounding the protected area must remain during and following gaseous extinguishing agent discharge. 5. The selected gaseous extinguishing agent must be approved for use in normally occupied spaces by the U.S. EPA's SNAP program, and must not be targeted for reduction or phaseout in the Kyoto Protocol.	
Minimize damage to the company's physical assets.		
Minimize the loss of physical assets (real and personal property) to no more than $1,000,000.	Limit damage to all critical equipment from a fire, fire effects, and suppression effects to one, or several, individual components that can be replaced in less than 4 hours, or noncritical equipment components that can be replaced in less than 48 hours. Do not allow an entire piece of equipment, equipment cabinet, or equipment rack to be destroyed by a fire or fire effects.	1. Extinguish the fire at or below 2 kW (1.9 Btu/sec).* 2. Limit the production of halide acids to a concentration within the protected space of 200 ppm or less. 3. Extinguish a fire in energized electrical equipment and prevent reignition for the specified hold time or at least 10 minutes.

*For more information, see Meacham, B. J., "Factors Effecting the Early Detection of Fire in Electronic Equipment and Cable Installations," *Fire Technology,* first quarter 1993.

of telecommunication operations to no more than 24 hours. By selecting a final limit of 4 hours, both stakeholders are satisfied.

Once the consensus stakeholder objectives have been identified, the design engineer translates them into concise design objectives. Design objectives are stated in terms that can be subsequently quantified in fire protection engineering terms and used to develop specific performance criteria.

For the goal of minimizing business interruption, the third stakeholder objective of maintaining power usually does not find easy consensus among all stakeholders. Typically the end user and the insurance authority might be in agreement that electric power should not be interrupted to critical equipment. The building and fire code authorities might prefer automatically interrupting power to all equipment prior to application of the gaseous extinguishing agent. After negotiations, the building and fire code authorities may agree to allow power to remain uninterrupted. The design engineer may assist in reaching consensus on this objective by offering to select and design a gaseous extinguishing agent system such that it is capable of extinguishing fires in electrical equipment that remains continuously energized.

Prevent Loss of Life or Serious Injury. The fifth stakeholder objective for this goal is to minimize harm to the natural environment. Normally, only the end user stakeholder would identify an objective such as this. The other stakeholders might easily reach consensus to include this objective, since it likely will not conflict with their interests. Some end users have set such objectives to achieve harmony with their corporation's environmental policies. It is shown here to illustrate that environmental factors can be a strong determining factor in the selection process of a gaseous extinguishing agent and should always be considered in the performance-based analysis process.

Step 4: Define the Performance Criteria

Performance criteria for the gaseous extinguishing agent must be developed that will satisfy the design objectives (listed in

Step 3) and be used to evaluate the trial designs (candidate gaseous extinguishing agents). Table 17.7.11 presented sample performance criteria for the hypothetical example.

Step 5: Define the Design Fire Scenarios

The purpose of a gaseous extinguishing system is to extinguish a fire. It is therefore necessary for the design engineer to analyze the possible fire scenarios that are plausible for the protected space. These are then reduced to a reasonable number and called *design fire scenarios* that represent the boundaries of the conditions present. Only then is it possible for the design engineer to begin evaluating possible gaseous extinguishing agents for selection.

Possible fire scenarios should address the heat sources and fuel involved in fire ignition and growth. They should address the building construction, service equipment, and spatial relationships that might influence or be affected by the fire. They should address the human element, such as the number and distribution of occupants, their emergency response training and commitment, and their physical and psychological conditions related to self-preservation abilities.

Listed below are summaries of possible fire scenarios for the example of the corporate data center used to illustrate performance-based analysis and design, as summarized in Table 17.7.10.

Possible Fire Scenario 1. An electric drive motor in a high-speed data storage unit overheats due to an internal failure. Insulation on the internal windings ignites, leading to a fire that spreads to adjacent combustibles inside the equipment enclosure.

Possible Fire Scenario 2. A manufacturer's defect on a printed circuit board inside a telecommunications equipment module within an equipment rack leads to localized overheating and ignition of the board. The fire spreads to adjacent boards until it involves the entire module, and then spreads until it involves the entire rack.

Possible Fire Scenario 3. Two electrical extension cords are connected to a wall outlet and extended to a nearby work desk module where four workers share its power simultaneously. The two cords are draped over the top of an open box of paper forms. Their interconnection point is only partially engaged and is resting on top of the paper forms. The connection point overheats and ignites the box and the paper forms. Initially, this fire is a Class A surface fire but, if not extinguished early, has the potential to become a deep-seated Class A fire. The fire could then spread to involve the entire box of forms and begin heating adjacent racks of telecommunications components.

Possible Fire Scenario 4. An electrical fault in a power circuit within a data processing equipment enclosure results in sustained electrical arcing, which is not interrupted by the circuit fault protection device. The heat from the continuous arcing ignites cable insulation that spreads to other cables and combustible components within the equipment cabinet. If not extinguished early, this fire could spread to fully involve the original equipment cabinet and spread to adjacent equipment and other combustibles. Ultimately, the spreading fire would have enough energy to activate the sprinkler system in the room. This is a Class C fire. It would become a Class A surface fire on interruption of electrical power to the equipment involved.

The preceding fire scenarios are just a few representative examples of the relatively large number of those possible for such an operation. The full range of possible fire scenarios must be identified, then reduced to a smaller, more manageable number of design fire scenarios, which will be used to evaluate trial designs to select a final, optimized design. For this example, the four possible fire scenarios are narrowed down to a single design fire scenario, which will be used to evaluate the suitability of the trial designs. In this case the design fire scenario 5 is the same as possible fire scenario 4.

Step 6: Develop Trial Designs

Trial designs should be developed that have the potential to achieve the performance criteria. The design fire scenarios are used to test the effectiveness of each trial design, with the results being analyzed to help narrow the trial designs to one or two that are most effective. Applying this process to the task of selecting a gaseous extinguishing agent is relatively simple, since it involves only one of the several subsystems that are part of a complete gaseous extinguishing agent fire-extinguishing system. In the context of this example, a single agent is a trial design. Multiple trial designs (i.e., agents) should be considered. Each agent should be evaluated to ensure it meets the stated goals and objectives.

Step 7: Evaluate and Modify the Trial Designs

The trial designs should be evaluated to determine if they satisfy the performance criteria when challenged by the design fire scenarios. If a trial design is successful, the next trial design would be evaluated, and so on. If a trial design is not successful, it might be modified and retested or eliminated from consideration. In this manner, all trial designs are optimized (i.e., evaluated, modified, or eliminated) until one or more acceptable designs are developed.

Step 8: Select the Final Design

The acceptable designs should be further evaluated and one chosen as the final design. All performance criteria should be reviewed and compared to the capabilities of each acceptable design. Secondary criteria that are important to any stakeholder should also be evaluated in an effort to identify the design that is optimal for this particular project. Considerations include availability of agent, agent storage and space requirements, cost of system, complexity of system, and life cycle costs of the system.

SUMMARY

Until the late 1980s, there were predominantly two gaseous agents to choose from to protect significant mission-critical

hazards that required either a local application approach (carbon dioxide) or total flooding approach (Halon 1301 or carbon dioxide). Since the advent of the Montreal Protocol and the U.S. Clean Air Act of 1990, several new gaseous agents have been developed, and regulations have emerged aimed at safeguarding human health relative to exposure to gaseous fire extinguishants.

Fire hazards and gaseous fire extinguishants possess certain characteristics that make it possible to optimize the selection of one or more agents to protect a given fire hazard. A performance-based decision methodology was developed that can provide a consistent and repeatable framework for the selection of gaseous extinguishants and systems optimized for a particular hazard.

The performance-based analysis and design process illustrated in this chapter summarized the steps necessary to selecting a gaseous extinguishing agent that is best suited for the example project. The gaseous extinguishing agent must have the capability to enable all primary, and some secondary, performance criteria to be achieved, assuming that the remaining subsystems are properly designed and installed.

The examples used to illustrate the performance-based analysis and design process were greatly oversimplified. The reader is encouraged to review the *SFPE Engineering Guide to Performance-Based Fire Protection: Analysis and Design* in detail and study the many design variables that influence the performance of gaseous agent fire-extinguishing systems using each of the available gaseous extinguishing agents. Each of them have performance strengths and weaknesses that, when properly evaluated, would result in one or more agents being an acceptable candidate for each particular application.

Explosion Prevention and Protection

Erdem A. Ural ■ Henry W. Garzia

Chapter Contents

Events Leading to an Explosion
Explosion Hazard Analysis
Deflagration Prevention
Enclosure Integrity and Strength
Explosion Protection

Key Terms

deflagration, dust explosion, explosibility, explosion, explosion control, flame arrester, flame front diverter, flammable limit, flammable mixture, fuel control, hazard analysis, ignition control, inert gas, limiting oxidant concentration (LOC), minimum ignition energy (MIE)

In literature, the word *explosion* is used to express a number of different chemical or physical processes. Some of these processes are outlined in Section 2, Chapter 8, "Explosions." This chapter focuses only on deflagrations where, by definition, the combustion reaction front propagates through a nearly premixed fuel-air mixture at a velocity less than the speed of sound in the unburnt mixture. The fuel may be in the form of a gas, vapor, dust, mist, or a combination. The definition provided in NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* and NFPA 69, *Standard on Explosion Prevention Systems,* further limit the meaning of the word *explosion* to "the bursting or rupture of an enclosure or a container due to the development of internal pressure from a deflagration."

For related topics, see Section 2, Chapter 8, "Explosions"; Section 6, Chapter 8, "Dusts"; Section 9, Chapter 7, "Storage and Handling of Grain Mill Products"; and Section 18, Chapter 6, "Deflagration (Explosion) Venting."

EVENTS LEADING TO AN EXPLOSION

Explosions often have catastrophic consequences. Fortunately, explosions occur only when a number of preceding events take place almost simultaneously. Table 17.8.1 lists a generic chain of events that can lead to an explosion. Examples of the hazard tests to characterize the material, equipment, or process, as well as the possible means of engineering intervention that can be used to break the chain are also listed in Table 17.8.1. It should be pointed out that the generic list provided in Table 17.8.1 might not cover all possible processes and that not all steps listed play a key role in each situation.

Unless dust is kept suspended in the air by design, most dust explosions start with a disturbance that raises dust into suspension. The disturbance could be as simple as the rupture of a compressed air line, a mechanical jolt to beams where dust layers have accumulated, or a small explosion somewhere else in the plant. Once subjected to the disturbance, the amount of dust removed from the deposit is a property of the dust and how the layer was formed.[1] These steps obviously do not play a role in gas or vapor explosions.

Once the fuel is released into an enclosure, it mixes with air and forms flammable volumes. The size of the flammable volume is controlled by the fuel supply rate and the ventilation/recirculation conditions inside the enclosure; it directly affects the severity of the explosion, if ignited. Therefore, control of the fuel supply rate and proper ventilation are frequently practiced methods of explosion prevention or protection.

A flammable fuel-air mixture can be ignited by a number of possible ignition sources. In critical applications, credible strength of ignition sources can be evaluated and compared to the

Erdem A. Ural is an independent explosion protection/investigation consultant for Loss Prevention Science and Technologies, Inc., in Stoughton, Massachusetts. Previously, he worked at FM Global and Fenwal. He is chair of the ASTM E27.04 Subcommittee on Ignitability and Flammability of Chemicals, a member of the NFPA Technical Committee on Explosion Protection Systems, and the chair of the American Institute of Chemical Engineers (AIChE) Committee on Loss Prevention.

Henry W. Garzia is the systems design manager of the Industrial Explosion Protection Group of Fenwal Protection Systems. He is a member of the NFPA Technical Committee on Handling and Conveying of Dusts, Vapors, and Gases.

TABLE 17.8.1 Generic Chain of Events That Can Lead to an Explosion

Steps of Explosion (Gas, Vapor, Dust, Mist)	*Material/Enclosure/Process Hazard Characterization*	*Possible Means of Engineering Intervention*
Disturbance	Maximum credible leak size	Avoid disturbances
	Maximum credible pressure	Redirect disturbances to a safe location
Entrainment of dust deposits	Particle size distribution	Eliminate/limit dust deposits (refer to p. 17-150, "Housekeeping")
	Critical shear stress	Spray dust deposits (with oil or water)
Fuel dispersion	Turbulence inside enclosure	Minimize fuel source
	Ventilation/recirculation	Improve ventilation
	Localization of flammable mixtures	
Mixture flammability	LFL and UFL for gases and vapors	Fuel control (refer to p. 17-149, "Fuel Control")
	MEC for dusts	Oxygen control
	Limiting oxygen concentration	
Credible ignition sources	Open flames	Eliminate ignition sources (refer to p. 17-150, "Ignition Source Control")
	Heated volumes or surfaces	
	Static electricity	
	Lightning	
	Stray currents	
	Mechanical sparks, friction, impact and vibration	
Material ignitability	Electrostatic ignition (MIE)	Material additives
	Hot surface ignition	Change particle size distribution
	Hot volume ignition temperature	
Material reactivity	Peak pressure	Material additives
	Peak rate of pressure rise	Change particle size distribution
	Burning velocity	
	Deflagration-to-detonation transition propensity	
Flame propagation	Turbulent flame speeds	Arrest flame propagation
	Flame accelerations induced by geometry	Explosion suppression (refer to p. 17-155, "Deflagration Suppression")
		Explosion isolation (refer to p. 17-157, "Deflagration Isolation")
Pressure development	Heat released by combustion	Pressure containment (refer to p. 17-154, "Pressure Containment")
		Explosion suppression (refer to p. 17-155, "Deflagration Suppression")
	Heat lost by radiation/convective cooling	Explosion venting
	Mass lost by venting	
Damage to	Mechanical damage due to overpressure	Improved mechanical design
People	Projectiles	Projectile control
Equipment	Thermal damage (people are vulnerable)	Thermal protection (passive or active)
Physical		
Plant	Chemical damage	
Environment	Environmental damage	

ignition requirement of the fuel-air mixtures. Such an exercise may reveal whether elimination of ignition sources is a viable prevention method for the particular application.

Once ignition takes place, the reaction front (flame) moves toward the unburnt fuel-air mixture with a well-defined velocity, called the burning velocity. If the enclosure is practically unvented, the maximum explosion pressure is related to the heat of combustion of the fuel-air mixture. Fully confined deflagrations commonly develop pressures in the range of seven to ten times the initial absolute pressure, or 100 to 140 psig (7 to 10 barg). If the enclosure has large openings, then the maximum explosion pressure is also related to the burning velocity and the maximum flame surface area. Pre-existing turbulence conditions inside the enclosure, turbulence induced by flame propagation, and the geometry of the enclosure can increase both the burning velocity and the maximum flame surface area.

Process enclosures are seldom designed for pressure containment. Pressures at which enclosure failure occurs can be quite low, particularly for enclosures of rectangular sheet metal construction. These can fail completely at internal pressures of a few pounds per in.^{2} (psi [1 psi = 6.895 kPa]). Typically, buildings can tolerate only a fraction of 1 psi pressure. Active and passive suppression and isolation methods can be used to limit the extent of flame propagation and magnitude of the pressure increase caused by an explosion.

If allowed to proceed uncontrollably, an explosion can cause harm to the physical plant, to people, and to the environment. In addition to the pressure damage considered in the NFPA 68/69 definition, an explosion can do the following:

- Hurt people (by skin burns,[2] eardrum rupture, lung collapse, body translation, toxic unburnt/burnt material)
- Create projectiles and fireballs that can lead to domino effects
- Pollute the environment
- Interrupt production
- Start fires

EXPLOSION HAZARD ANALYSIS

Conducting a thorough and competent process hazard analysis is perhaps the most important task of any explosion prevention or protection project. Such an analysis should consider the entire process chain, all the buildings, enclosures, and interconnections. The process analysis generally includes, but is not limited to, review of the general scope of work, process design criteria, process description, material flow diagrams, bases for fire and explosion protection methods and systems, basis for the physical and chemical properties of the process materials, equipment layouts, detailed mechanical drawings and specifications, supporting engineering calculations, and process and instrumentation diagrams. This analysis should consider startup, normal operation, normal shutdown, temporary operations, and emergency shutdowns. The analysis should also consider the hazards that can be created by the explosion prevention and protection systems. It is essential to update this analysis periodically, as well as each time changes are made to the process and to the protection systems. A detailed description of the explosion hazard analysis is beyond the scope of this chapter. Examples can be found in *Guidelines for Hazard Evaluation Procedures,* American Institute of Chemical Engineers, 1992.[3]

Figure 17.8.1 shows a simplified flowchart for dust explosion prevention and protection philosophy, adapted from material in R. K. Eckhoff's *Dust Explosions in the Process Industries.*[4] Within each appropriate box, the relevant ASTM E27 test method that can be used to characterize material hazard properties is listed. Standardized tests are often performed to characterize the hazard properties of materials. A comprehensive menu of such tests can be assembled from the standards of ASTM (American Society for Testing and Materials International), CEN (European Committee for Standardisation [Comité Européen de Normalisation]), CENELEC (European Committee for Electrotechnical Standardization [Comité Européen de Normalisation Electrotechnique]), DIN (German Institute for Standardization [Deutsches Institut für Normung]), VDI (Association of German Engineers [Verein Deutscher Ingenieure]), IEC (International Electrotechnical Commission), ISO (International Organization for Standardization), NFPA (National Fire Protection Association), and the UN (United Nations). Although a comprehensive review of the tests used to characterize material flammability, ignitability, and explosibility is beyond the scope of this chapter, a tabulation of the ASTM tests pertaining to explosion prevention and protection and simplified conceptual descriptions of key test methods are provided. A more detailed description can be found in "The Role of ASTM E27 Methods in Hazard Assessment."[5]

Fuel-Air Mixture Flammability

The classic notion of the "fire triangle" is that an ignition source must come together with both fuel and oxidant, the latter usually being atmospheric oxygen, in order to initiate and sustain a fire. This representation, although convenient, oversimplifies the more complex requirements needed to sustain a deflagration, particularly regarding fuel and oxygen concentration requirements. A flammability diagram can be used to illustrate, in composition space, the boundary that divides mixtures of fuel, oxygen, and inert components into flammable and nonflammable regions. Figure 17.8.2 is an example of one of the several types of such representations.

The three-component (ternary) diagram is plotted as a triangular graph, with each corner representing fuel, oxidant, or inert gas. Where appropriate, the oxidant may be taken as air, or other separately managed stream containing the oxidizing species, and the inert gas as only added inert components not associated with atmospheric air. Only two components are plotted in some diagrams, the concentration of the third being determined by the difference from 100 percent. The lower and upper flammable limits are two limiting points on such a diagram for compositions having no added inert component. (See Bodhurtha,[6] Lewis,[7] and Strehlow[8] for more detailed discussions on flammability.)

Dust-air mixtures also display a lower flammability limit (often called the minimum explosible concentration [MEC]), which is comparable in magnitude (on the order of 50 g/m^3) to that for gases and vapors. An extensive compilation of MEC data for generic dust samples can be found in Eckhoff.[4] Although

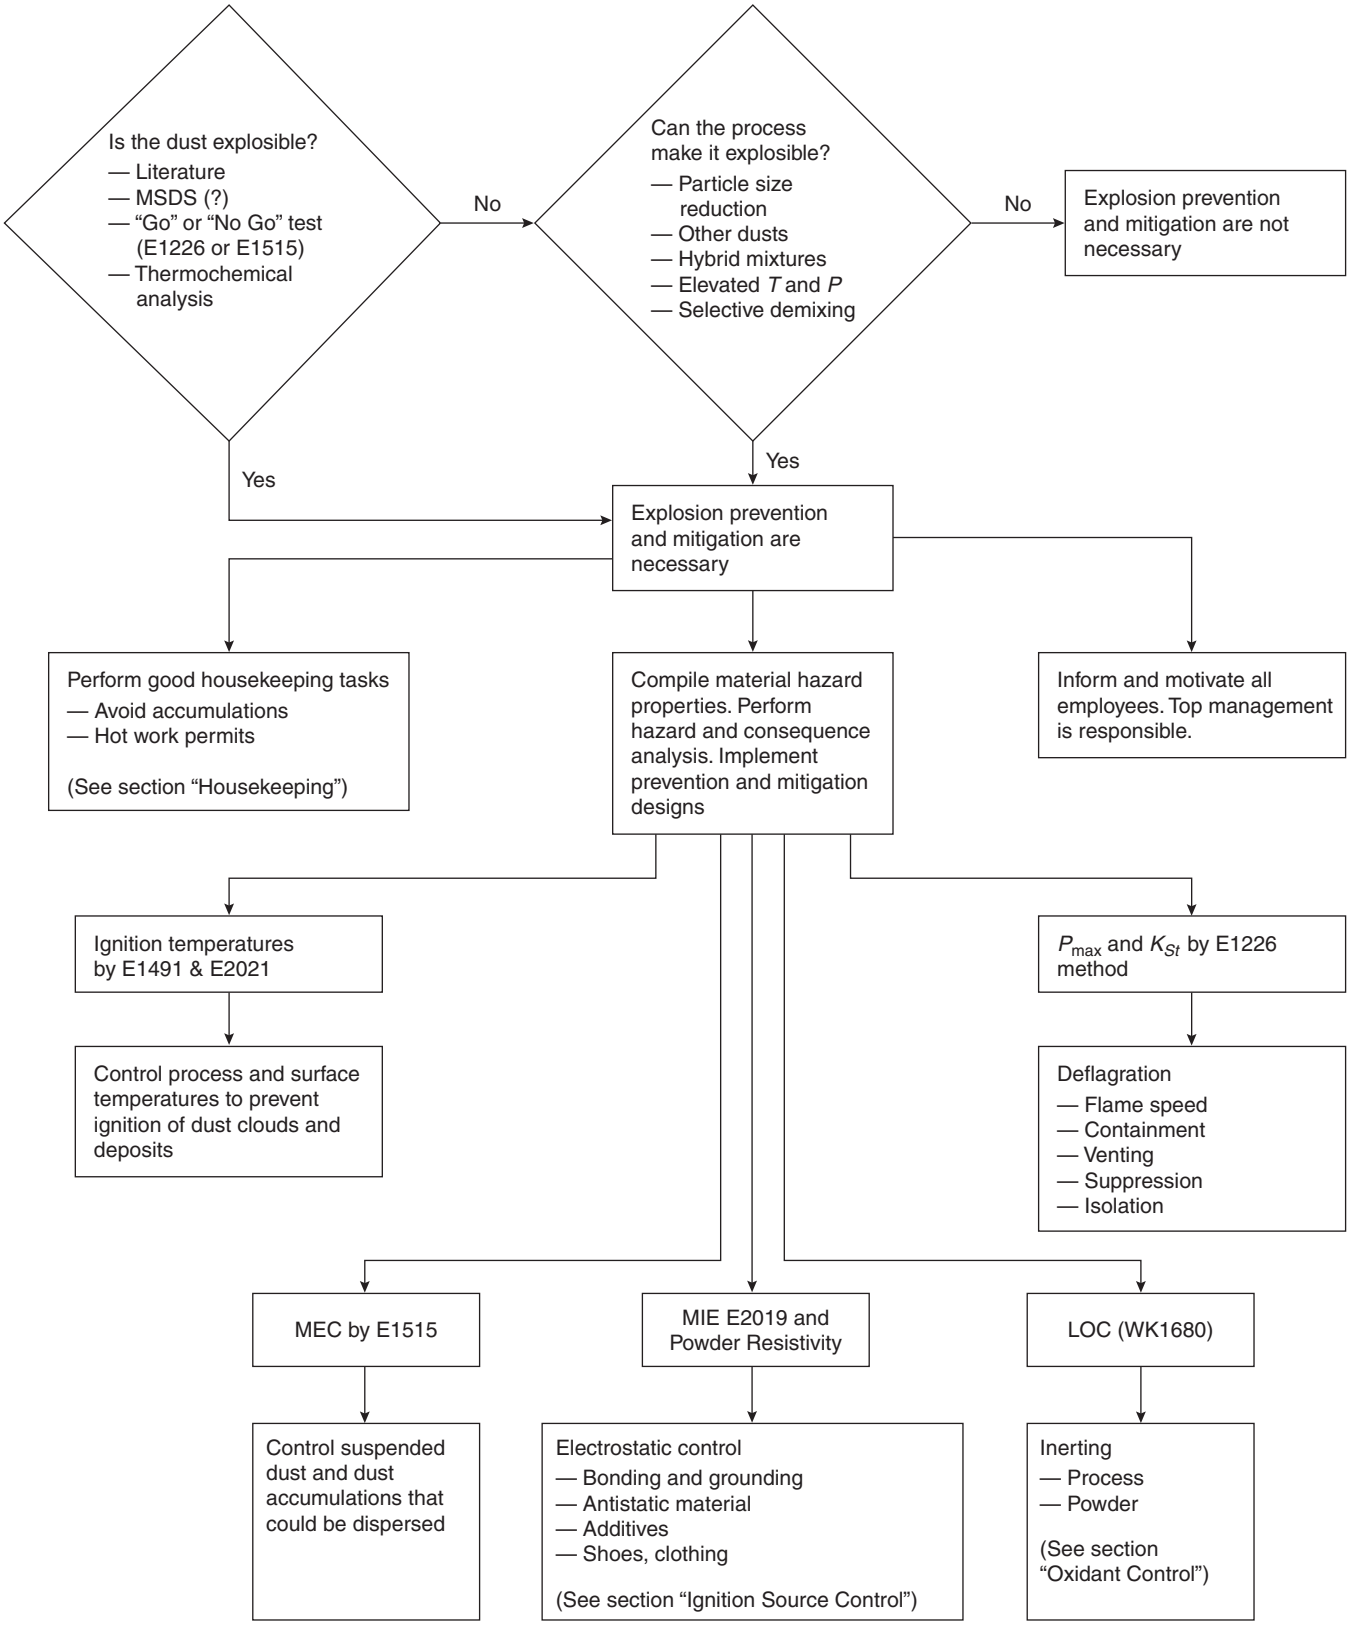

FIGURE 17.8.1 Dust Explosion Protection Philosophy. LOC = Limiting oxygen concentration. WK1680 = The ASTM draft standard for limiting oxidant concentration determination of dust samples. (Source: Adapted from Eckhoff, R. K., *Dust Explosions in the Process Industries,* Butterworth, Heinemann, Boston, 1991)

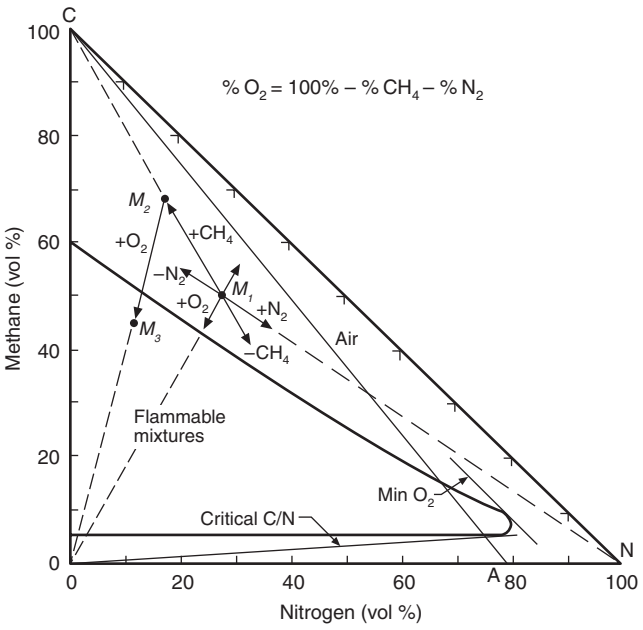

FIGURE 17.8.2 Flammability Diagram for Methane-Air-Oxygen System in Triangular Format (Source: Zabetakis, M. G., "Flammability Characteristics of Combustible Gases and Vapors," Bulletin 627, U.S. Bureau of Mines, Washington, DC, 1965)

sometimes academically debated, there is no practical upper flammability limit for dust-air mixtures because such high concentrations are difficult to produce and control.

An important part of deflagration prevention is maintaining atmospheres in process volumes that are nonflammable. This may be achieved by using any of several techniques, either singly or in combination. These include reduction of airborne concentrations of gaseous, dusty, or misted fuels. Alternatively, the concentration of the oxidant may be reduced. Finally, a nonflammable component, such as inert gas, may be added to the atmosphere. Thus, the composition of the atmosphere within a process volume that has the potential to be in the flammable range is controlled to prevent this condition.

Flammability properties of materials generally depend on temperature and pressure.[9] In the case of dusts, particle size distribution and moisture content can also play a significant role.

Fuel-Air Mixture Ignitability

Ignition of a flammable mixture occurs when a critical mass is heated to a temperature above the ignition temperature of the mixture. For example, all incandescent sparks (e.g., mechanical, electrical, electrostatic) have sufficiently high temperatures to cause ignition, but may lack sufficient energy to heat a minimal propagating mass to its ignition temperature.[10,11] A hot process surface may have a temperature below that required for prompt ignition, but may have large energy content. Dust deposits on such surfaces can be subject to accelerated self-heating and eventual ignition.

As illustrated in Table 17.8.2, there are a number of test methods to characterize the ignition propensity of gases, vapors, and dusts. It is important to note that the minimum ignition energy or minimum autoignition temperature depends not only on the material and the test sample, but also on the details of the test setup. Therefore, when using ignitability data for safety analysis, one should be careful to consider the relevance of the test setup and test conditions to the safety threats being considered.

Table 17.8.3 shows the minimum ignition energy (MIE) of selected gases and vapors in air at 1 atmosphere and 25°C. The MIE for gases and vapors is seen to vary from a fraction of a millijoule (mJ) to joules (J). In pure oxygen, MIE can be an order of magnitude or smaller than that in air.

Table 17.8.4 lists the MIE of dust clouds of selected materials. Since the dust cloud MIE is a strong function of the particle size distribution, particle size distribution as well as the median particle size of the samples are included in the table. A theoretical analysis included in Eckhoff[4] predicts MIE to be proportional to the cube of the median particle size. One of the authors' experience suggests that the relationship is more complex and probably involves additional parameters further characterizing the quantity of the fines. That is why the data in Table 17.8.4 do not seem to support a strong empirical correlation to the cube of the median particle size. In fact, the cubic relation becomes prominent when the data from samples with narrow particle size distributions are analyzed (Figure 17.8.3). A didactic composite diagram of ignition energies of various materials and types of ignition source that may ignite them has been reproduced in Figure 17.8.4.

Fuel-Air Mixture Explosibility

The most commonly used parameters are the maximum unvented explosion pressure, P_{max}, and volume scaled maximum rate of pressure rise, K. The latter parameter is defined as

$$K = V^{1/3}(dP/dt)_{max} \quad (1)$$

where V denotes the volume of the test vessel. K is often used with the subscript St (abbreviation of the German word *staub*)

for dusts and G for gases and vapors. ASTM E1226[12] provides a standard test method for the determination of K_{St} and P_{max} values for dust-air mixtures. An extensive compilation of K_{St} and P_{max} data for generic dust samples can be found in Eckhoff.[4] The K_{St} value is theoretically (e.g., see Ural[13]) proportional to an equivalent turbulent burning velocity for dust-air mixtures.

Although the simple one-third power correction seen in the K definition (Eq. 1) adequately accounts for the effect of the test volume in dust explosions, the prediction of the volume dependence of the maximum rate of pressure rise is complicated by other flame acceleration mechanisms in gas explosions. Nevertheless, K_G values have long been used in explosion protection technology. Although a standard test method for K_G and burning

velocity is not yet available, Annex C of NFPA 68 (2007 edition) provides some data and guidance for testing.

DEFLAGRATION PREVENTION

Oxidant Control

The process of reducing the concentration of an oxidant beyond the flammable zone is also called inerting. Materials other than oxygen can act as oxidants. The selection of a gas for inerting a process atmosphere will be influenced by several factors such as inert gas effectiveness, availability, cost, process conditions, distribution requirements, and toxicity. The heat capacity of a gas is the most important inerting property. This is because a nonflammable condition is achieved when the heat capacity of a fuel-oxygen-inert gas mixture is elevated above about 250 J/mol-K of oxygen in the mixture. Thus, the higher the heat capacity of the inert gas, the lower the quantity required to achieve an inert mixture. Certain halogenated hydrocarbons used in total flooding fire protection systems have also been shown to be useful in inerting flammable atmospheres. Table 17.8.5 shows data on several inert gases.

Minimum inerting concentration for a specific fuel/oxidant/inert system can be determined by performing the limiting oxygen concentration (LOC) tests described by Frurip et al.[5] The LOC depends on the temperature, pressure, and fuel concentration as well as the type of diluent and should be determined at the worst case conditions.

LOC of dust samples can be determined using the ASTM standard draft WK1680. It is prudent to use a sufficiently strong chemical ignition source for dusts to avoid the ignitability effects on the LOC determination. Hence, some of the old LOC values, if they were obtained using spark ignition, may be considered suspect. Some references provide LOC data tabulations. These values should be used with care, since the LOC of dusts depends on the particle size distribution.

Where the fuel is gas or vapor, ASTM E2079 is the contemporary test method of choice. Unfortunately, most data listed in reference publications were obtained decades ago, using flammability tubes. Preliminary results of the ASTM E2079 round robin tests for gases and vapors revealed that the LOC data obtained using different test methods and listed in a majority of reference publications are nonconservative. The old Bureau of Mines data were obtained mostly in a 5 cm diameter flammability tube. This diameter may be too small to mitigate the flame quenching influence, thereby impeding accurate determination of the LOC of most fuels. The 4 L minimum volume specified in ASTM E2079 would correspond to a diameter of at least 20 cm. As a result, some LOC values determined using this standard are

TABLE 17.8.4 MIE Data for Selected Dust Samples in Air

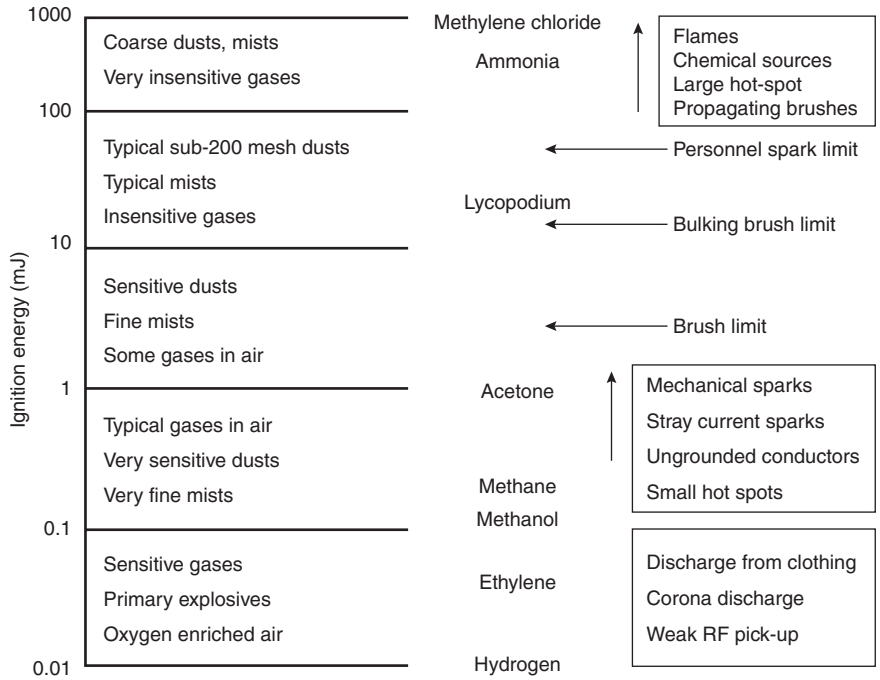

FIGURE 17.8.4 Ignition Energies of Various Materials and Types of Ignition (Source: Britton, L. G., *Avoiding Static Ignition Hazards in Chemical Operations, A CCPS Concept Book,* American Institute of Chemical Engineers, New York, 1999)

approximately 1 percent by volume oxygen lower than the previous values measured in the flammability tube, and a few are even up to 2 percent by volume lower. The lower LOC values obtained in larger chambers are more appropriate for use in fire and explosion hazard assessment studies. A data comparison can be found in Table 17.8.6.

If inerting is used as the primary means of explosion protection, several safety margins are applied to the LOC in order to arrive at the design inerting concentration. Such safety margins are selected to address factors such as mixture nonuniformities, temperature/pressure fluctuations, concentration measurement/alarm system accuracy, response time, and the consequences of false alarms. Where total inerting cannot be achieved due to technical or financial constraints, partial inerting may be considered in conjunction with other explosion prevention and protection methods. Even above the LOC, reduced oxygen concentration generally narrows the combustible range, reduces explosibility parameter *K,* and increases MIE.

TABLE 17.8.5 Heat Capacities of Inert Gases (Values at 25°C)

Gas	C_p *(J/mol-K)*
Argon	20.9
Nitrogen	28.4
Steam	35.4 at 100°C
Carbon dioxide	37.5

Sources: Flammability tube data from J. M. Kuchta, "Investigation of Fire and Explosion Accidents in the Chemical, Mining, and Fuel-Related Industries," Bulletin 680, U.S. Bureau of Mines, 1985. 120 L chamber data from Isaac Zlochower, National Institute for Occupational Safety and Health, Pittsburgh Research Laboratory, 2005, unpublished and not peer-reviewed. The data were obtained in accordance with ASTM test method E2079, at 1 atm and at 20 to 30°C on N2 air-fuel mixtures. Electric spark was created by the discharge of a 1300 μF capacitor, initially charged to 300 V, through 15 kV transformer. The standard criterion (i.e., minimum 1 psi or 7% absolute pressure rise) was used to detect ignition.

Nitrogen is commonly used as an inerting gas. It may be obtained from cryogenically stored liquefied gas. Catalytic combustion of ammonia in air followed by water condensation results in a relatively pure grade of nitrogen for process inerting. Carbon dioxide is somewhat more effective than nitrogen due to its higher heat capacity. It can be stored as a liquefied compressed gas in cylinders or kept in low-pressure refrigerated tanks for use on demand. Flue gas from a combustion system is a mixture of carbon dioxide and nitrogen, usually saturated with water vapor and having a low oxygen concentration. Flue gas is commonly used to inert storage tanks when offloading oil from ships. Carbon dioxide should not be used as an inerting gas for certain refractory metals. Examples are magnesium, silicon, and zirconium. In such cases, it may be necessary to use a noble gas, such as argon, for inerting. Examples of the LOC values for a variety of gases, metals, and carbonaceous dusts can be found in the 2008 edition of NFPA 69, *Standard on Explosion Prevention Systems.*

Since oxygen is essential to sustain life, inerting systems present an inherent risk to personnel safety. It is important to follow the OSHA regulations when entrance is required to the protected equipment. External leakage to other areas that are unventilated can present a hidden risk and must be kept in mind. Adverse health effects of selected gases used for inerting, as well as the corresponding inerting concentrations, can be found in NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems.*

Methods of Inert Gas Application. Inert gas can be applied in three ways: using batch methods, using the continuous methods described below, or using a combination of the two.

Batch Methods. In vacuum purging, the pressure in the process unit is reduced from its initial value, P_1, to a lower pressure, P_2. Inert gas is then added to return the vessel to P_1. If the gas within the process volume is assumed to be well-mixed, then the fraction of original gas remaining after one such purge cycle will be

$$X = \frac{P_2}{P_1} \tag{2}$$

In *pressure purging,* a volume is pressurized from P_1, to a higher pressure, P_2, by addition of purge gas and then vented back to the initial pressure, P_1. The fraction of original gas remaining after each such cycle will be

$$X = \frac{P_1}{P_1 + P_2} \tag{3}$$

The fraction of original gas remaining after n cycles by either batch purge method is

$$X(n) = X^n \tag{4}$$

Continuous Methods. Some enclosures, such as solvent storage tanks, are under continuous use or are not suited to batch purge methods due to structural considerations. Such tanks "breathe" on addition or removal of liquid contents or when their internal temperature changes due to climatic variations. In *fixed-rate* purging, inert gas is added continuously at the maximum anticipated demand rate. This method has the advantage of being simple to monitor and control but at the expense of purge gas consumption and, perhaps more important, results in carrying product vapors out of the enclosure.

Variable-rate purging may involve elements of both pressure demand and load demand gas addition. A small rate of continuous inert gas addition may be used together with pressure monitoring to determine when automatic addition of gas is required to make up for vapor space cooling. Addition of inert gas may also be increased on removal of liquid contents of a tank.

Purging enclosures of volatile liquids can be regulated under Title IV of the U.S. Clean Air Act Amendments of 1990. The capture and recovery, recycling, or incineration of process gas emissions has become common. Vapor recovery systems need consideration with respect to possible explosion risks that may be present. The U.S. Coast Guard has promulgated rules on operation of marine vapor recovery systems pertaining to explosion prevention and control.[14]

Fuel Control

Effective explosion prevention can be ensured if combustible materials are excluded from spaces to be protected. Four aspects of minimizing risks associated with combustibles are (1) containment, (2) ventilation, (3) purging, and (4) housekeeping.

(1) Containment. Special considerations are necessary for each class of combustible material. For example, cylinders and tanks of flammable compressed gases must be properly stored or located to ensure valves and other appurtenances are not subject to accidental damage. Containers and tanks of flammable and combustible liquids need periodic inspection to verify tightness of closures and the absence of damage or corrosion. Filter bags in dust collectors need periodic inspection to locate and replace damaged elements that can allow passage of combustible dusts. It is recommended that conformance be maintained with materials handling and storage requirements as outlined in NFPA codes (such as NFPA 30, *Flammable and Combustible Liquids Code,* NFPA 484*, Standard for Combustible Metals,* and NFPA 654*, Standard for the Prevention of Fire and Dust Explosions from the Manufacturing, Processing, and Handling of Combustible Particulate Solids*) and other codes and practices pertaining to specific flammable and combustible materials.

(2) Ventilation. Where the presence of flammable gases or combustible dusts may be possible as a result of normal operations or upset conditions their concentrations can be kept to a minimum or excluded altogether by general area or localized ventilation techniques. Continuous introduction of clean air to a room may be used to either continually sweep away contaminants or to maintain a room or process space under constant positive pressure to exclude entry of flammable materials. Appendix D of NFPA 69 contains guidance on the concentration control design of ventilation systems, and NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids,* provides guidance on the physical installation of such systems. An improperly designed

dusty operation ventilation system can create dust deposits in most unexpected locations and set the stage for devastating secondary explosions as in the West Pharmaceutical explosion on January 29, 2003.

(3) Purging. Purging is used to prevent development of ignitable atmospheres in enclosures or equipment. Specific methods are recommended for maintaining safe atmospheres inside electrical equipment enclosures. Type X, Type Y, and Type Z purging pertain to reducing the classifications within enclosures from Division 1 to nonhazardous, Division 1 to Division 2, and Division 2 to nonhazardous, respectively. The details of these purging methods can be found in NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment.*

(4) Housekeeping. This is the most obvious yet often the most difficult method of dust explosion prevention. Good practices adopted into NFPA 654 include minimizing dust emission from equipment, from operations, and from cleaning activities, and setting up regularly scheduled thorough cleaning procedures to reduce the probability of primary or secondary dust explosions fueled by dust accumulations. NFPA 654 also provides guidance on housekeeping requirements when they are employed in conjunction with the ignition control method described later in the next section and as shown in Table 17.8.7.

Ignition Source Control

Ignition control techniques can be used successfully to reduce the frequency of fires and explosions. However, ignition control must almost always be used in conjunction with another explosion prevention and protection method. This is because the means by which flammable atmospheres can become ignited are diverse and readily available in industrial settings. Although it is often true that the ignition source of a given event cannot be identified with certainty after the fact, due to the generalized destruction of the scene, a number of important mechanisms of deflagration initiation are recognized and should be carefully considered when conducting a hazard analysis.

Mechanical Sparks. A survey of 357 dust explosions between 1965 and 1980 revealed that, in 29 percent of the cases, the source of ignition was mechanically generated by sparks.[15] It has been shown[16] that sparks generated by grinding handheld steel can have sufficient energy to ignite organic dust clouds. This clearly points to the ignition energy potential when high-

TABLE 17.8.7 Guidance for Area Electrical Classification

Depth of Dust Accumulation (in.)	*Frequency*	*Housekeeping Requirement*	*Area Electrical Classification*
Negligible[a]	NA	NA	Unclassified (general purpose)
Negligible to < 1/32[b]	Infrequent[c]	Clean up during same shift.	Unclassified (general purpose)
Negligible to < 1/32[b]	Continuous/frequent[d]	Clean as necessary to maintain an average accumulation below 1/64 in.[e]	Unclassified; however, electrical enclosures should be dusttight[f,g]
1/32 to 1/8	Infrequent[c]	Clean up during same shift.	Unclassified; however, electrical enclosures should be dusttight[f,g]
1/32 to 1/8	Continuous/frequent[d]	Clean as necessary to maintain an average accumulation below 1/16 in.	Class II, Division 2
> 1/8	Infrequent[c]	Immediately shut down and clean.	Class II, Division 2
> 1/8	Continuous/frequent[d]	Clean at frequency appropriate to minimize accumulation.	Class II, Division 1

[a] Surface color just discernible under the dust layer.
[b] 1/32 in. is approximately the thickness of a typical paper clip.
[c] Episodic release of dust occurring not more than about two or three times per year.
[d] Episodic release of dust occurring more than about three times per year or continuous release resulting in stated accumulation occurring in approximately a 24 hour period.
[e] It has been observed that a thickness of about 1/64 in. of a low-density dust is sufficient to yield a small puffy cloud with each footstep.
[f] For example, National Electrical Manufacturers Association (NEMA) 12 or better. Note: Ordinary equipment that is not heat producing, such as junction boxes, can be significantly sealed against dust penetration by the use of silicone-type caulking. This can be considered in areas where fugitive dust is released at a slow rate and tends to accumulate over a long period of time.
[g] Guidance to be applied for existing facilities. For new facilities, it is recommended that the electrical classification be at least Class II, Division 2.
For SI units, 1 in. = 25.4 mm.
NA = Not available.

energy systems—for example, coal pulverizers or mills of the rolling, hammer, and pin type—cause grinding action on metal or other spark-inducing materials. Where tramp metal is a recognized hazard, the use of magnetic separators is recommended.

Fires. Unexpected open flaming due to ignition of accumulated dust can serve to ignite an ambient dust cloud. There are several mechanisms of causing such fires. Their risk of occurrence can be reduced by both understanding the ignition characteristics of the material being processed and by preventing the accumulation of materials susceptible to ignition by the given mechanism.

Hot Surfaces. Accumulated dust on a motor housing, transformer, high-pressure steam pipe, or other like hot surface can lead to slow pyrolysis of the solids, which can then ignite. The ignition probability is related to the surface temperature, dust layer thickness, and the thermal stability of the dust. A method of characterizing surface ignition temperature for dusts is available.[17] Approved equipment will be marked to indicate the operating temperature. The temperature of equipment operating in Class I or II (discussed later) environments must not exceed the ignition temperature of the gas or dust to which it is exposed. NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas,* provides ignition temperature data on vapors and gases, whereas NFPA 499, *Recommended Practice for the Classification of Combustible Dusts and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas* provides similar data for dusts.

Autoignition. Dusts layers exposed to continuous uniform elevated temperature, or even ambient temperatures, can also undergo self-heating and ignite.[9,10] The temperatures at which autoignition of bulk dusts occurs are much lower than for surface ignition, above, and are dependent on the volume of the heated dust. A small-scale method for characterizing the self-heating tendency of dusts was developed by the U.S. Bureau of Mines.[18] Another method is recommended by the United Nations (originally by the U.S. Department of Transportation) for determination of packaging classification of self-heating materials for purposes of road shipment.[19]

Mechanical Impact. Some materials may be subject to immediate ignition due to sudden mechanical impact. The ASTM E680 drop hammer test method can be used to characterize materials in this regard.[20]

Friction. Frictional heating of combustible materials is possible where moving components are found. Rotating drums and moving belts in bucket elevators are an example of a system that requires special consideration. Regular lubrication of bearings is essential. Use of belt-alignment devices is mandated in some cases.[21]

Embers. Wood-processing operations, such as grinding, sanding, and cutting, can produce glowing wood particles that can be conveyed to a dust collector. Such embers can lead to ignition of a wood–dust layer in which it becomes embedded. Spark detection and extinguishing systems, described in NFPA 69, may be appropriate in such operations.

Electrical Equipment. Electrical motors, switches, lights, heaters, and similar high-current devices may be powerful ignition sources. Such equipment can be constructed for use in hazardous atmospheres and is rated with respect to the type of atmosphere in which it is suited for use. A synopsis of one of the rating systems is given next:

Class I	*Groups*
Flammable gases	A (acetylene) B (hydrogen) C (ethylene) D (propane)
Class II	*Groups*
Combustible dusts	E (metal dusts) F (carbonaceous dusts, e.g., coal, charcoal, coke, etc.) G (flour, grain, wood, plastics, chemicals)
Class III	
Combustible fibers	
Division 1	Flammable gases or combustible dusts may be present at ignitable concentrations, under normal operating conditions.
Division 2	Where hazardous materials may be handled, processed, or used; ignitable atmospheres not normally present due to containment or ventilation of hazardous materials; areas adjacent to Division 1 locations.

The examples given in the preceding groups are representative only. Flammable gases are classified according to the maximum experimental safe gap (MESG), which prevents flame passage, and the minimum igniting current ratio, MIC. NFPA 70, *National Electrical Code®,* determines the group designations whereas NFPA 497 defines the MESG and MIC values for each group. MESG and MIC are determined by tests.[22] Thus, a motor rated as Class I, Division 1, Group D would be rated for use in an environment where a propane-like gas was likely to be present.

Unrated electrical equipment can be employed in hazardous areas, provided such equipment is contained in a pressurized or purged enclosure. The requirements for this approach are given in NFPA 496. Various purging methods are described that can render the classification within an enclosure from Division 1 to nonhazardous (Type X purging); from Division 1 to Division 2 (Type Y purging); and from Division 2 to nonhazardous (Type Z purging).

Electrostatic Ignition. Conveyance of liquids or dusts leads to electron transfer at the boundary of the moving material and a duct or pipe. The flow of electric charge in this manner is called a *streaming current,* I_s. The discharge of the moving material from the conduit to a receiving point (tank or drum for liquids; bin or pile for solids), of capacitance C, results in

charge separation and the development of an electric potential difference, V. The accumulated charge, Q, if not allowed to dissipate or *relax,* will have a stored energy of $E = QV/2 = CV^2/2$. Potentials exceeding 350 V and stored energies exceeding 0.1 mJ are considered hazardous in flammable gas areas. MIE of dust clouds vary widely, but can be less than 10 mJ. Most dusts of organic composition have MIEs in the range of 10 to 100 mJ. Charge potentials of several thousand volts and stored energies sufficient to ignite dust clouds are readily achieved in some solids transfer operations.

Ignition of flammable atmospheres by electrostatic discharges can be avoided by first recognizing process operations that can lead to charge separation. One can then provide conduction paths to maintain process components at low or zero electric potential. Resistance to ground should not exceed 100,000 Ω from any component. It is important to consider all components in a system. A section of pipe may be connected to a system by bolted flanges but electrically insulated by nonconductive gaskets. Such a component has the characteristics of a capacitor and can hold an electric charge. *Bonding* of electrically isolated process components is achieved by connecting a wire between them (see NFPA 70 for guidance). *Grounding* of the bonded components to an earth ground provides a conduction path that prevents charge accumulation. Britton,[11] Jones,[23] Glor,[24] Louvar,[25] and Pratt[26] should be consulted for a more complete discussion of electrostatic hazards. A consensus standard is not available for the control of electrostatic ignition sources. As a result, most companies develop their internal standards. Figure 17.8.5 and Table 17.8.8 show an approach used by Ciba Specialty Chemicals (see Hoppe et al.[10]) for this purpose.

Combined Mechanisms. In any given ignition scenario it is possible that multiple ignition mechanisms were involved. For example, an unlubricated bearing (*friction, hot surface*) in the tension roll in the boot (bottom) section of a bucket elevator conveying grain could generate a smoldering mass of grain dust (*ember*). The burning matter could become dislodged and fall into the general mass of moving grain and be conveyed in a bucket into an upper section of the elevator, during which time

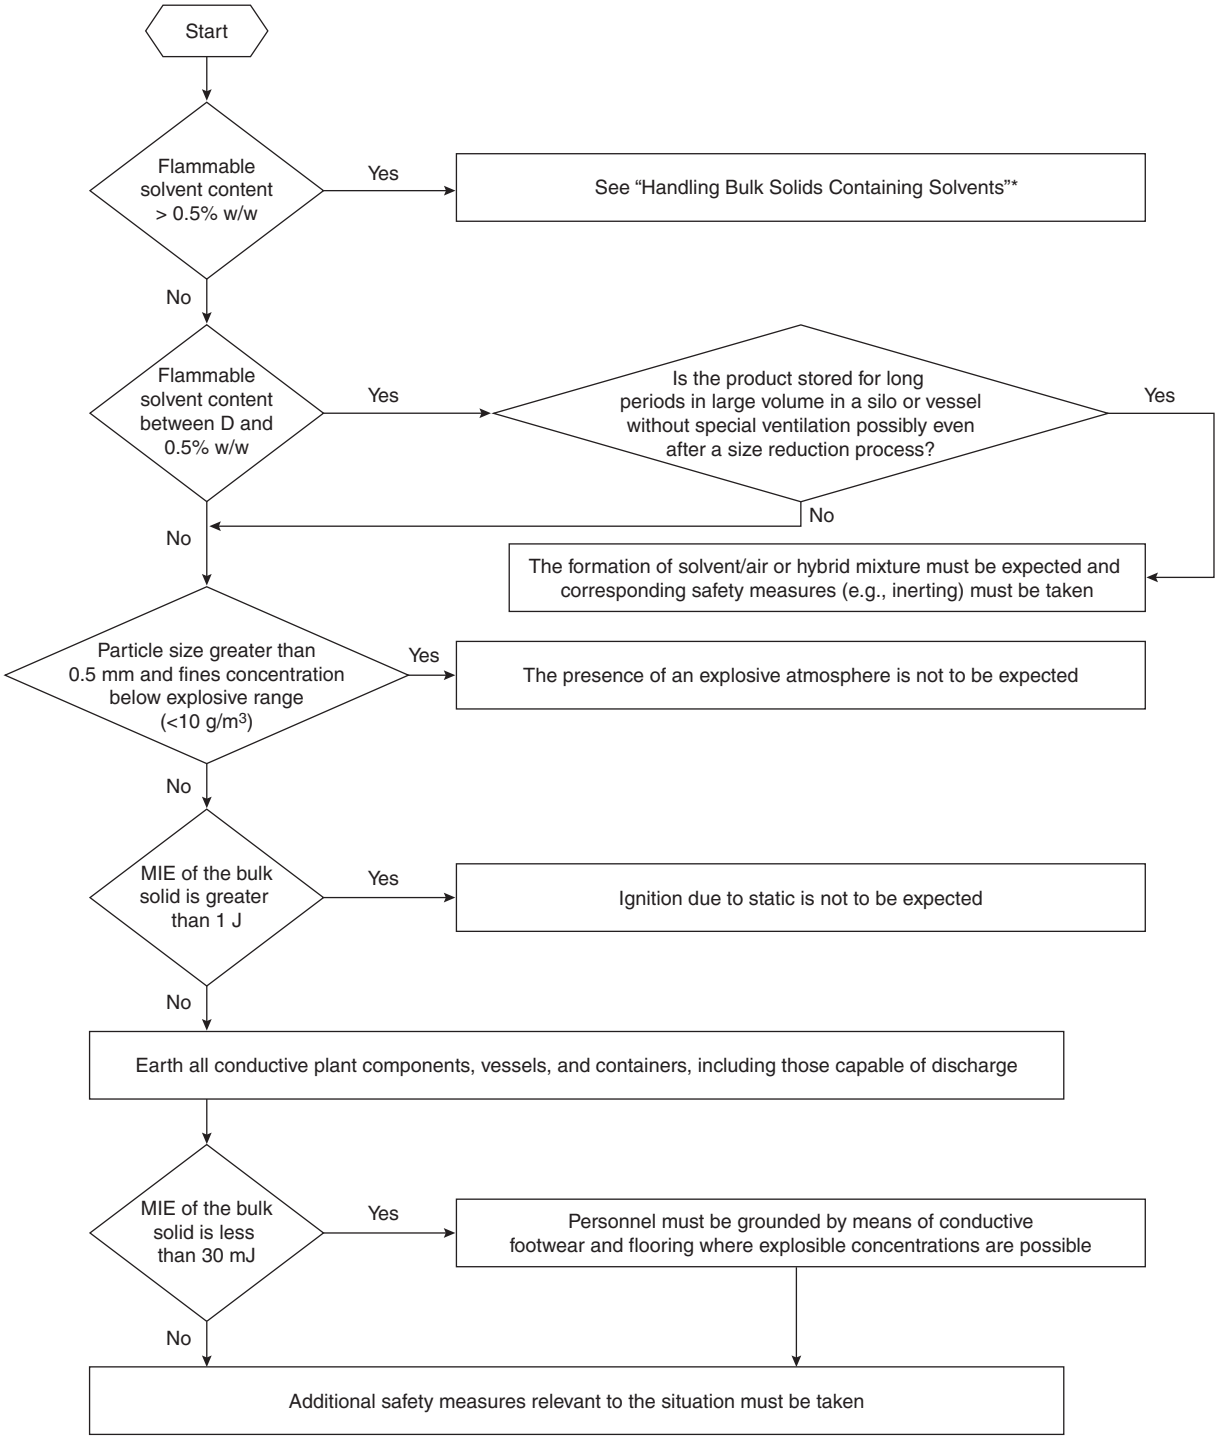
TABLE 17.8.8 Additional Safety Measures Required for Large Containers (Volume > 2 m^3) Where Combustible Powders Are Handled or Stored in the Absence of Flammable Gases or Vapors

Minimum Ignition Energy, MIE (mJ)	*Volume Resistivity (ρ_V) of Powder (MΩ-m)*	*Safety Measures*
MIE < 10 mJ	Any value	All parts of the installation must be conductive and grounded All containers must be conductive or dischargeable and grounded Apply additional explosion protection measures (e.g. inerting, venting, suppression) OR Seek expert advice
10 mJ < MIE < 1000 mJ	10,000 MΩ-m < ρ_V	Use only conductive or dischargeable containers which are grounded, AND Apply additional explosion protection measures (e.g. inerting, venting, suppression) OR Seek expert advice
	1 MΩ-m < ρ_V < 10,000 MΩ-m	Use only conductive or dischargeable containers which are grounded, OR Restrict the filling rate to 5 kg/sec OR Apply additional explosion protection measures (e.g. inerting, venting, suppression) OR Seek expert advice
	ρ_V < 1 MΩ-m	All parts of the installation must be conductive and grounded All containers must be conductive or dischargeable and grounded
1,000 mJ < MIE	Any value	Electrostatic ignition unlikely

Notes: Containers capable of discharge: The leakage resistance from any point to ground must be less than 100 MΩ.
Conductive containers: maximum leakage resistance less than 1 MΩ.

Source: CIBA methodology adapted from Hoppe, T., Jaeger, N., and Terry, J., "Safe Handling of Combustible Powders During Transportation, Charging, Discharging, and Storage," 8th International Colloquium on Dust Explosions, Schaumburg, IL, September 21–25, 1998.

its extent of burning increases. At some moment the ember becomes a flaming mass (*open flame*), and encounters a dust cloud with a concentration greater than its lower explosible limit, thus initiating a deflagration. The pressure developed by the primary deflagration could rupture the elevator leg enclosure. The escaping pressurized blast of gases could cause grain dust on nearby surfaces to become airborne and ignited (*flame jet ignition*). An ensuing secondary deflagration would likely involve



*See section in Hoppe et al.[10]

FIGURE 17.8.5 Decision Tree Used to Evaluate Electrostatic Ignition. (Source: Hoppe, T., Jaeger, N., and Terry, J, "Safe Handling of Combustible Powders During Transportation, Charging, Discharging, and Storage," 8th International Colloquium on Dust Explosions, Schaumburg, IL, September 21–25, 1998, pp. 253–263)

a much larger mass of fuel and air and lead to generalized pressure damage to the facility. Due to failure of a grease fitting, the plant could be substantially damaged. This example does not represent any particular event. Rather, it is a synthesis of many similar actual events that have occurred.

ENCLOSURE INTEGRITY AND STRENGTH

The explosion prevention methods discussed in the previous section and those that will be discussed in the next section rely on the premise that the enclosures will remain intact throughout the prevention and protection missions. This is achieved by determining the loads and by determining the strength of each enclosure and interconnecting piping.

Loads on the Enclosure

Explosion prevention techniques generally impose little or no additional loads on the enclosure, beyond the loads (such as weight, seismic loads, process fluctuations) considered in the conventional design. On the other hand, there are cases where such loads can be considerable. For example, batch methods of inerting create repeated overpressure or vacuum loads by design. A malfunction in an inerting system can conceivably exceed the design loads by a great margin.

The deflagration loads that a protected enclosure experiences are generally significant. For example, a 10 barg (150 psig) overpressure for an explosion containment application, and 0.3 barg (5 psig) overpressure for an explosion venting or explosion suppression application are not uncommon. These loads must be characterized as a part of the explosion protection system design.

Enclosure Strength

Explosion protection standards allow two separate approaches towards the enclosure strength determination. Calculations or design can be based on either of the following:

- Preventing rupture of the vessel enclosure (the ultimate strength of the vessel enclosure), but allowing permanent deformation (also called explosionproof/shock-resistant)
- Preventing permanent deformation (the yield strength of the vessel enclosure, which is also called explosion-pressure/shock-resistant) from internal positive overpressure

NFPA 69 allows loads up to two-thirds of yield or ultimate strength for containment design. If venting is chosen as the protection method, NFPA 68 also allows the same fraction, based on a dynamic loading factor. When enclosures are designed and constructed according to the ASME Boiler and Pressure Vessel Code or similar codes, NFPA 68 and 69 both allow deflagration loading to the same two-thirds fraction of yield or ultimate strength. Since pressure vessel codes include a larger inherent safety factor, this means that the anticipated deflagation loading (i.e., pressure) can be greater than the stamped maximum allowable working pressure (MAWP). The ASME Boiler and Pressure Vessel Code recognizes the NFPA methodology as acceptable for deflagration applications.

EXPLOSION PROTECTION

As used in this chapter, *explosion protection* means the measures adopted to control and mitigate the effects of ignition of the contents of a process volume that may be capable of propagating a deflagration. Thus, although appropriate explosion prevention measures may have been implemented, it is assumed at this point that these steps have only reduced the probability of initiating a deflagration and not eliminated such a possibility altogether. Whether the probability of the occurrence of a deflagration is now so small as to constitute a risk of acceptable magnitude is a matter for evaluation using the methods of risk and consequence analysis, which is beyond the scope of this chapter.

There are essentially only four strategies available as explosion protection options: (1) pressure containment, (2) deflagration venting, (3) deflagration suppression, and (4) deflagration isolation.

Pressure Containment

Equipment can be designed to contain the full brunt of the explosion load for pressure containment. This approach may be required if no emission of vessel contents is tolerable (for concerns relating to toxicity, environmental pollution, or public perception). In some cases, design for pressure containment (DPC) may be the most economical approach.

The use of pressure relief vents on vessels in some processes may be impractical. Where the safety strategy is to allow a possible deflagration to occur, but be contained, the process vessel must be constructed to be able to contain the pressurized gases with no equipment damage or with limited acceptable damage. No credit is taken for pressure relief devices on the vessel. The design pressure to which the vessel must be fabricated is determined by the maximum anticipated deflagration pressure, P_{Cont}, that may develop in the enclosure. This is the maximum deflagration pressure of the combustible material that is used. If the enclosure is operating at atmospheric temperature and pressure, P_{Cont} is equal to the P_{max} determined for standard initial temperature and pressure from either closed vessel test series (e.g., ASTM E1226) or from equilibrium calculations. When the operating temperatures and pressures are different from standard conditions, the pressure load to be contained, P_{Cont}, can be estimated using the following simple equation:

$$P_{Cont} = [(P_{max} + 1) \times (P_i + P_{std}) - P_{std}] \times \frac{298}{273 + T_i} \quad (5a)$$

where

P_i = Initial pressure (gauge in units consistent with other pressure values)

T_i = Initial temperature (°C)

P_{std} = 1 atm = 14.7 psia, standard pressure

T_{std} = 25°C = 298 K, standard temperature

Vessels designed and constructed for pressure containment must conform to the ASME *Boiler and Pressure Vessel Code,* Section VIII, Division I. The design pressure for deflagrations may be calculated, using Equation 5a, to result in a vessel of sufficient strength to either not deform at the maximum defla-

gration pressure or to deform but not rupture. Accordingly, the maximum allowable working pressure, P_{MAWP}, of the enclosure is selected using the following equations:

$$P_{MAWP} \geq \frac{3}{2}\left(\frac{P_{Cont}}{F_u}\right) \quad (5b)$$

or

$$P_{MAWP} \geq \frac{3}{2}\left(\frac{P_{Cont}}{F_y}\right)$$

where

F_u = Ratio of ultimate stress of the enclosure to the allowable stress of the materials of construction of the enclosure per the ASME Boiler and Pressure Vessel Code

F_y = Ratio of the yield stress of the enclosure to the allowable stress of the materials of construction of the enclosure per the ASME Boiler and Pressure Vessel Code

For vessels constructed of carbon steel or low-alloy stainless steel, F_u and F_y are approximately 3.5 and 1.75, respectively. See NFPA 69 for further details.

Design for pressure containment requires further consideration of the eventual release of the pressurized gases. If the vessel is truly leaktight, then pressure reduction will occur as the products of combustion cool, and vacuum may develop. Alternatively, pressurized gases will flow through process openings or pressure relief devices. The essential point here is that hot combustion gases should be prevented from passing to other process units where adverse consequences may occur due to initiation of a fire or another deflagration. Techniques for using deflagration isolation systems to prevent deflagration propagation to interconnecting piping and equipment are discussed later in this chapter.

Deflagration Venting

Deflagration venting is widely used to direct expanding gases and overpressure out of a vessel to a safe location. This protection option may be appropriate when material toxicity and environmental contamination are not a concern and when a safe vent discharge location is available. When appropriate, venting is often the low-cost protection option.

A simplified theory of explosion venting is provided by Ural.[13] The explosion pressure rise is created by the burnt gases heated by the combustion energy. Where vent openings are provided, developing explosion overpressure pushes both unburnt and burnt mixtures outside the enclosure, thereby reducing the maximum pressure.

The simplest postignition method of explosion protection is deflagration venting. Pressure development within a process enclosure in which a deflagration occurs is prevented from attaining damaging levels by allowing the enclosure contents to be ejected, in a controlled way, to a safe location. It is the control and safety aspects of a vented deflagration that differentiate it from an explosion.

A detailed discussion of the design and use of deflagration vents is given in Section 18, Chapter 6, "Deflagration (Explosion) Venting," and in NFPA 68. Venting reduces the maximum deflagration pressure in the protected enclosure to reduced pressure, P_{red}. Documents such as NFPA 68, VDI 3673, and European Standard EN 14491, provide correlations to calculate P_{red} for a given vent opening area and vice versa. These documents and the equations are publicly available and hence subject to thorough peer review and contribution. This approach also allows calculation and verification of proper vent size by any of the stakeholders, including vendors, owner/operators, and authorities having jurisdiction (AHJ).

Deflagration Suppression

Deflagration suppression may be the preferred approach when the consequences of employing other prevention and protection options are unacceptable. Process equipment may be too large to economically construct for DPC, venting may not be possible due to the location or contents of the vessel, or mechanical isolation of the process system may have unacceptable secondary consequences in a complex plant.

Deflagration suppression is the only one of the four explosion protection methods that terminates the combustion process before most of the fuel-air mixture is consumed. Because of this, explosive fuel-air mixture may still exist in the protected enclosure after the suppression system operates as intended, if the suppressant can settle out or condense after discharge. The utility of this approach is that it provides protection in special applications where other methods cannot meet the requirements imposed by the hazard. For example, venting may be inappropriate where toxic or noxious materials are concerned or where equipment vents cannot be discharged to a safe location. Isolation methods, on the other hand, are designed to protect adjacent process units, not the unit where ignition has occurred. Containment is applicable only where the vessel has sufficient pressure resistance.

Deflagration Suppression Defined. Deflagration suppression systems are active systems similar to fire protection systems. These systems typically comprise deflagration detectors (pressure or optical), a control/alarm panel, and suppressors containing the suppressant to be applied. Because a deflagration grows much more rapidly than a fire, the overall system response time is one of the key design parameters. Detection time, suppressor response time, suppressor discharge time, and suppressant travel time in the enclosure all contribute to the overall system response time. The principle of operation is that, once detection of ignition has occurred, the extinguishing agent is delivered to and distributed within the protected volume more rapidly than the rise in demand for the agent (to achieve extinguishment) by the growing flame ball. Deflagration suppression systems reduce the pressure in the protected enclosure to P_{red}, which comprises the sum of the two contributors: pressure rise due to partial burning of the contents prior to total extinguishment and pressure rise created by the agent injection. Using proprietary calculation procedures, a suppression system designer tries to control the suppressant delivery time, nominal concentration, and dispersion uniformity in the protected enclosure by specifying the number of suppressors, their volumes, and discharge cross-sections to achieve desired P_{red}. Increasing the number of suppressors effectively increases the suppressant discharge area, hence decreasing the delivery time and the reduced

pressure. Increasing the number of suppressors also improves the suppressant uniformity in the protected enclosure. If the total rise in pressure that occurs in a vessel during suppression, P_{red} (reduced pressure), is less than the pressure strength of the equipment, then the suppression is considered successful.

Explosibility. Combustion of a flammable mixture in a closed vessel results in a rapid rise in pressure (Figure 17.8.6). Key characteristics of closed-vessel combustion are the maximum pressure attained, P_{max}, and the maximum rate of pressure rise, that is, the $(dP/dt)_{max}$ developed during the event.

The principal quantitative measure of the explosibility of a combustible material is characterized with parameter K_G for gases and K_{St} for dusts as shown previously in Equation 1.

A typical set of data points obtained in evaluating the explosibility of a dust is illustrated in Figure 17.8.7. The term *index of explosibility* is sometimes applied to K_{St}. Explosibility is dependent on chemical composition and, for dusts, physical parameters such as moisture content, particle size, and shape. The K_{St} value of a dust has been found to be nearly invariant with $V^{1/3}$ for vessels 20 L or larger in size. For this reason, it is important that K_{St} values be determined according to an approved standard that employs a vessel of at least 20 L volume.[12]

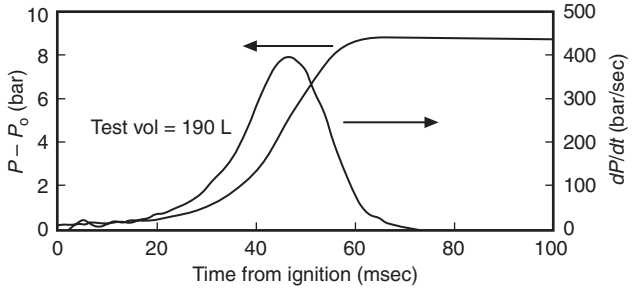


FIGURE 17.8.6 Pressure and dP/dt versus Time at 750 g/m^3 for Closed-Vessel Deflagration of a Proprietary Corn Starch Product. (Courtesy of Kidde-Fenwal, Inc.)

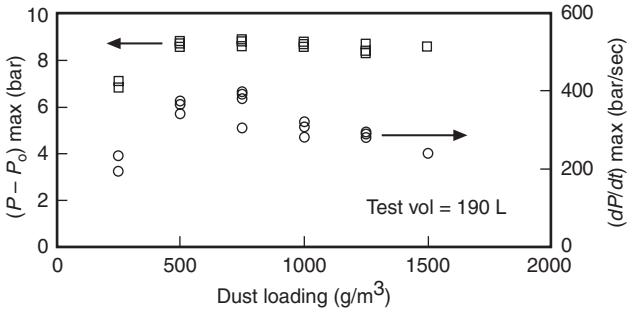

FIGURE 17.8.7 Typical P_{max} and $(dP/dt)_{max}$ Data Obtained in Determination of Explosibility of a Combustible Dust (Corn Starch) (Courtesy of Kidde-Fenwal, Inc.)

It can be shown that the K_{St} value may be used to estimate the effective burning velocity in a flammable dust–air mixture.[13] Thus, the explosibility of a mixture can be related to a burning rate, which can then be compared to the agent delivery characteristics of a suppression system.

Active Deflagration Suppression Systems. Deflagration suppression is a special case of fire extinguishment and may be viewed as a competition between a rapidly rising heat release rate from the combustion zone and the rate of agent delivery. A deflagration will be suppressed when the unburned fuel-air mixture has been rendered noncombustible due to the addition of agent and the flame front has been cooled to the point of extinguishment.

At the onset of ignition there is some minimum uniform concentration of agent that can render the protected space noncombustible; that is the inerting concentration. As deflagration proceeds, larger and larger quantities of agent are required, because the unburned material must be inerted and the burning volume must be quenched. Therefore, the amount of agent that must be dispersed within the protected space to achieve suppression increases with time as the deflagration propagates. Should delivery of agent be delayed too long, the deflagration will pass beyond the point of suppressibility. The result may be the attainment of unprotected deflagration pressures, or even higher pressures. For each application, deflagration suppression system manufacturers resort to propretary design methodologies or test data to ensure adequate system performance. Pressure-time traces of suppressed and unsuppressed deflagrations of a fast-burning dust are shown in Figure 17.8.8. The test was conducted in a 67 ft^3 (1.9 m^3) vessel. A sodium-bicarbonate-based agent was used. This particular case would be considered successful suppression only if the protected equipment could tolerate 8 psig (0.55 bar) over pressure.

Elements of a Suppression System. A deflagration suppression system consists of components for detection, extinguishment, and control/supervision. To ensure suppression success, deflagrations must be detected at a very early (incipient) stage

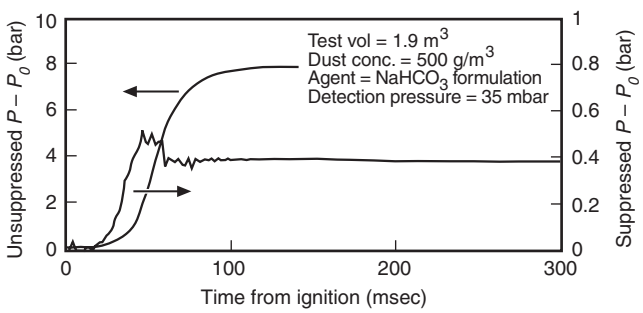

FIGURE 17.8.8 Pressure-Time Traces of Unsuppressed and Suppressed Deflagrations of a Combustible Processed Cellulosic Dust Having a K_{St} Value of 310 bar • m/sec (Courtesy of Kidde-Fenwal, Inc.)

when the volume of the burning material is much smaller than the protected enclosure volume. For this purpose, special pressure detectors, rate-of-pressure-rise detectors, or optical flame detectors are used. Optical detectors, employing ultraviolet (UV) or combination UV and infrared (IR) radiation sensors, are preferred in unenclosed environments with nonabsorbing UV atmospheres. Examples of such environments are solvent storage and pump rooms and aerosol can filling rooms. Pressure and rate-of-pressure-rise detectors are employed in closed process equipment, particularly where dusty atmospheres prevail. Multiple detectors and appropriate detection logic are essential to avoid false actuations.

Extinguishers are of the high-rate-discharge (HRD) type, charged with agent and propelling gas, usually nitrogen. The nitrogen overpressure is normally in the range of 300 to 900 psig (20 to 60 bar), depending on the manufacturer. Explosively or electrically operated high speed valves, usually $^{13}/_{16}$ to 6 in. (30 to 300 mm) in diameter, ensure the high rate of agent delivery necessary for effective suppression. Several types of extinguishing agents are employed, usually selected from among the following:

- Water, with or without additives
- Dry chemical formulations, usually based on sodium bicarbonate or monoammonium phosphate. Other extinguishing powders have also been used.
- Halocarbons (halogenated hydrocarbons). Halon 1301, although no longer manufactured, will continue to be available on a market basis, subject to changes in regulations, for suppression systems meeting critical-use criteria. Chlorobromomethane (Halon 1011) has been used widely, but has come under regulation as an ozone-depleting substance and can no longer be used without special permission from the EPA.* Research continues on the use of environmentally friendly fluorocarbons and hydrofluorocarbons in explosion protection applications.[27]

Extinguishing mechanisms, wherein each agent works as a combination of thermal quenching (100 percent in the case of water) and chemical inhibition, are beyond the scope of this chapter. The selection of agent is usually based on several considerations, such as effectiveness, toxicity, product compatibility, residual inerting, and volatility. Dry chemical agents are most commonly specified in deflagration suppression applications. Distribution of agent within the protected volume is aided by use of nozzles. These may be fixed in position, or of the "pop-out" type that remains recessed until projected into the process volume by the momentum of the discharging suppressant.

*Halon 1011 is environmentally much more benign than Halon 1301. For example, the ozone depletion potential (ODP) of Halon 1011 is a factor of 75 smaller than that of Halon 1301 (i.e. 0.01 for 1011 versus 13.00 for 1301). Similarly, the atmospheric lifetime of Halon 1011 is a factor of 250 smaller than that of Halon 1301 (i.e., 0.23 year for 1011 versus 65 years for 1301). The atmospheric lifetimes of the second generation clean agents (HFC-125, HFC-227ea, and HFC-236fa) range from 36 to 250 years. Therefore, these agents tend to contribute to global warming problems although their ODP is zero, and thus face potential environment regulations limiting their use.

A suppression system is controlled using an electronic power supply having battery backup power. This unit supervises the suppression system circuitry to ensure integrity of the system and supplies the current to explosively or electrically operated valve actuators employed on the extinguishers. Normally the process equipment being protected by the suppression system is automatically shut off on detection of an incipient deflagration. An example of a process layout protected by a deflagration suppression system is shown in Figure 17.8.9.

The protection afforded by a deflagration suppression system depends on several factors, including the size and shape of the protected volume; the explosibility of the material being processed; the initial turbulence scale and intensity; the number, size, and location of HRD extinguishers; and the means, sensitivity, and location of detection devices. The pressure–time profile for a suppressed deflagration of a combustible processed cellulosic dust was shown in Figure 17.8.8.

Deflagration suppression systems are active systems that require periodic inspection and maintenance. The use of deflagration suppression systems is discussed in NFPA 69.

Deflagration Isolation

Deflagration isolation is the strategy of preventing a deflagration initiated in one location from passing to another location where personal injury or additional damage may occur. *It is well known* that deflagration waves allowed to propagate into interconnecting piping and equipment can create much more powerful explosions than the initial explosion. A deflagration may transition to detonation if it is allowed to enter into unprotected piping or equipment. Process equipment such as mills, spray dryers, dust collectors, blowers, and vacuum pumps are regularly connected together by piping, ducts, chutes, or conveyors. (For convenience, such systems will be referred to here simply as "pipes.")

Ducting and Piping. An explosion beginning at one point in the process can propagate through these interconnections to other parts of the process, both upstream and downstream. Generally, isolation techniques are necessary unless a qualified risk analysis is performed and a determination is made based on both probability and consequence that the risk is acceptable. Flame propagation inside ducting or piping is somewhat unpredictable for dusts. Tests have shown that propagation is much less likely under certain conditions. Piping of less than 100 mm (4 in.) in diameter is far less likely to provide a conduit for flame spread than piping of larger diameters.

Dense phase pneumatic transfer (air velocity down near 600 ft/min, and solids loading ratio* greater than 30) is also much less likely to provide a conduit for flame spread propagation than dilute phase pneumatic transfer (air velocity in the region of 2200–3600 ft/min [11–18 m/sec] and solids loading ratio less than 15). As reported by Pineau[28] it is not uncommon for propagation to occur as infrequently as one time in

*Solids loading ratio is the ratio of average solid mass to air mass in the transfer line.

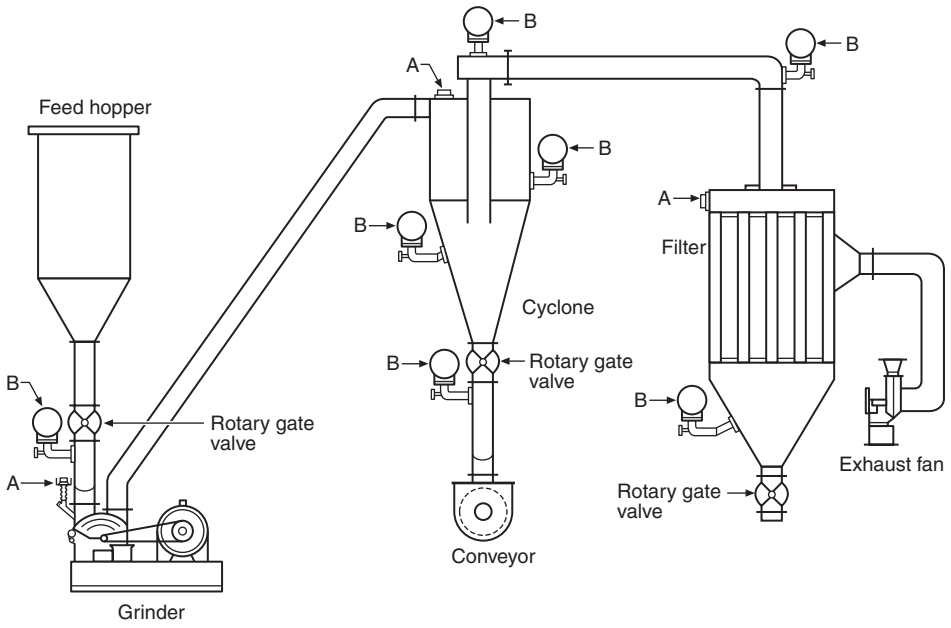

FIGURE 17.8.9 Deflagration Protection System for a Typical Grinding Plant. Deflagration detectors (A) actuate high-rate-discharge extinguishers (B).

ten in controlled experiments for 150 mm piping, even for dilute phase systems. Compared to other dusts, metal dusts and other high K_{St} dusts are more likely to propagate deflagrations through smaller diameter pipes. For interconnected vessels that are relatively close together, measures to reduce P_{red} for each interconnected vessel, taking into account that propagation could occur, would not necessarily eliminate the need for isolation techniques.

Flammable gases and combustible dusts are commonly conveyed between process units in pipe or duct systems. Dust or powdered materials are frequently transported together with air in dilute or dense phase conveying. Combustible vapors may be transported, by design or by accident, in a flammable state. A pipe carrying flammable mixtures can, should ignition occur at one end, act as a fuse. The ignited mixture can propagate flame through the pipe, leading to ignition of a process unit at the other end. Flame propagation, if possible, should be blocked near the point of ignition. Otherwise, the speed at which a flame propagates in the pipe will steadily increase. If the mixture composition is in the detonable range, the flame front can undergo deflagration to detonation transition, developing pressures of about 25 times the initial pressure and reflected pressures (that experienced by an object in the flow path) of up to 50 times the initial pressure.[29] Alternatively, pressure development and flame speeds can be limited with explosion vents placed in accordance with Chapter 9 of NFPA 68. Nevertheless, the flame front can still propagate, though at a moderate speed, through the entire length of the pipes.

Prevention of flame propagation through pipe systems is an important aspect of total protection of a process plant. Isolation methods can be used to interrupt or mitigate flame propagation, deflagration pressure, pressure piling that may lead to blast and shock formation, and flame jet ignition between items of equipment. Each isolation technique has unique application limitations. Some of these limitations are summarized in Table 17.8.9 and are discussed below.

Passive Isolation Devices. Passive protection devices include material chokes (rotary valves), flame front diverters, passive float valves (explosion check valves), static dry flame arresters, and hydraulic-type (liquid seal) flame arresters.

Flame Arresters. Flame arresters are constructed so as to cause the gas flow to pass through small passageways to prevent flame propagation due to thermal quenching. The maximum experimental safe gap (MESG), through which a flame cannot pass, can be determined using a device such as the Westerberg explosion test vessel.[30] These devices are not suitable for dust or saturated vapor service.

Flame arresters are normally placed at the end of a pipeline near a potential source of ignition. Special requirements are placed on flame arresters intended for use at a significant distance from the pipe end, for example, mounted in-line. NFPA 69 includes requirements for installation of in-line flame arresters. The U.S. Coast Guard has promulgated testing requirements for arresters that, when located in mid-pipe positions, may be challenged by a detonation. These requirements have been adopted in ANSI/UL 525, *Standard for Safety Flame Arresters.*[31]

Flame Front Diverters. Pressure piling and flame jet ignition through interconnecting piping can be controlled by means of a flame front diverter. The basic operating principle of this device is to vent the deflagration at a point where the flow direction is typically changed by 180 degrees. Figure 17.8.10 shows

TABLE 17.8.9 Isolation Features of Pipe and Duct Protection Systems

Isolation System	*Type*	*Fuel Type*	*Deflagration Isolation*	*Ignition Source Isolation*	*Flow (Pressure) Isolation*
Chemical barrier	Active	Dust, gas	Yes	Yes	No
Mechanical valve	Active	Dust, gas	Yes	Yes	Yes
Actuated float valve	Active	Gas	Yes	Yes	Yes
Actuated pinch valve	Active	Dust, gas	Yes	Yes	Yes
Rotary valve	Passive	Dust	Yes	*	Yes
Flame arrester	Passive	Gas	Yes	Yes	No
Flame front diverter	Passive	Dust	No	No	Yes
Liquid seal	Passive	Gas	Yes	Yes	No
Float valve	Passive	Gas	Yes	Yes	Yes

*Rotary valves are capable of preventing flame front passage under certain conditions but do not always prevent the passage of burning embers.

several flame front diverter designs. Due to the inertia of the fast flow caused by the deflagration, the flow will tend to maintain its *upward* direction rather than making a sharp turn, as it would when the velocity is low (at normal conditions). When the high-speed deflagration flame continues *upward,* it pushes open either a hinged cover or bursts a rupture disk located at the top of the diverter, allowing the flame to be released to the atmosphere. Some flame front diverters have demonstrated the ability to prevent flame propagation. In most cases, tests have indicated that diverters were not completely effective in preventing flame propagation. Where this has occurred, however, the deflagration severity was reduced; pressure piling did not occur or was less severe.

Siwek[32] discusses some design details concerning flame front diverters. More information about flame front diverters is presented in books by Bartknecht[15] and Eckhoff.[4] Bartknecht

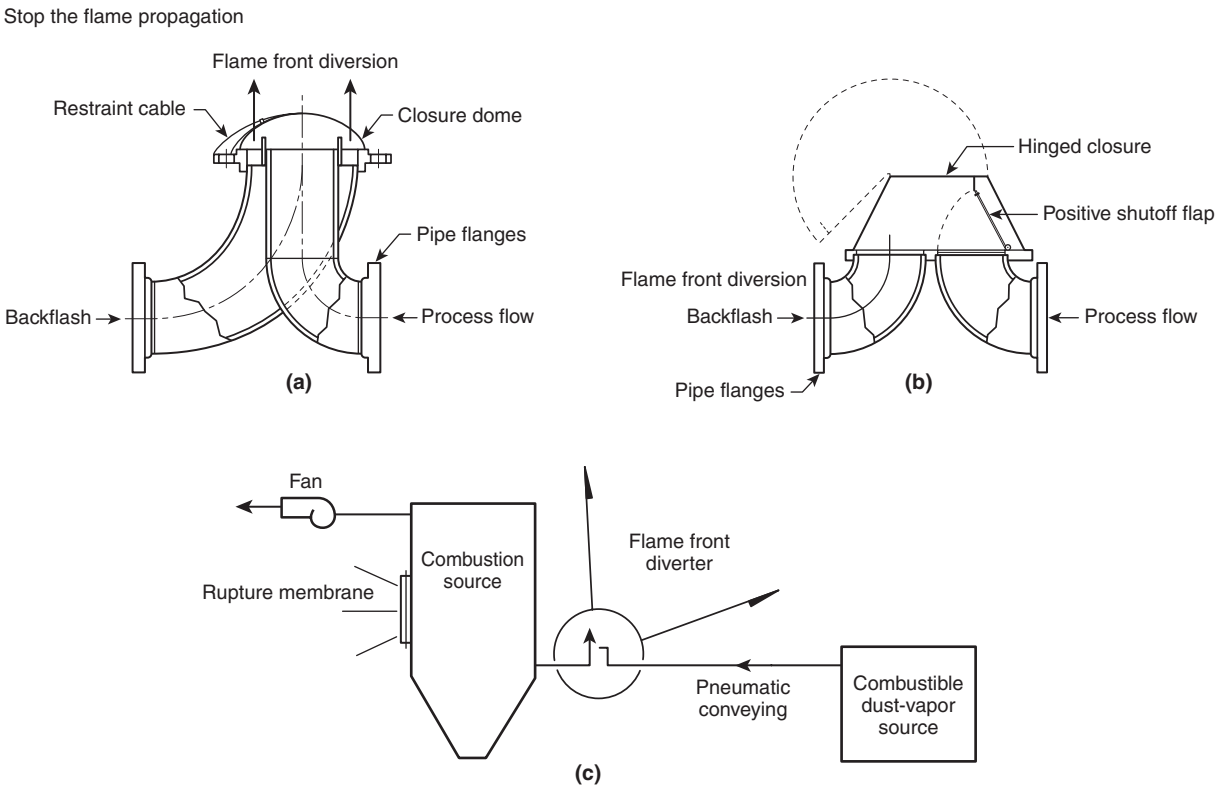

FIGURE 17.8.10 Typical Application and Design of Flame Front Diverters

recommends not using a flame front diverter as the only means of isolation if it is intended to stop flame propagation. Before flame front diverters are specified, they should be tested for the intended application.[32]

Passive Float Valves. A deflagration in pipe can generate flow velocities well in excess of the process flow velocities. Not unlike common check valves in hydraulic systems, passive float valves are designed to close at a specific flow rate, or a rated pressure differential, resulting from the deflagration. Therefore, the deflagration must develop a minimum strength pressure wave in the upstream piping. The valve float seals against a valve seat on closing and is held in place by a retaining device. The float valve remains closed until manually reset. A schematic drawing of a typical flow-actuated passive float valve and its internals is shown in Figure 17.8.11. The float valve typically functions in both directions.

A potential problem with this valve is that an elastomeric seat, if used, could be adversely affected in high-temperature environments. Another possible problem is that powder coating on the seal surfaces can prevent a tight seal, and flame breakthrough is then possible. Since a certain minimum pressure differential is required to close the float valve, the propagation of an explosion through a pipe will not be stopped if its pressure is lower than the minimum actuation pressure of the float valve. The placement of flow-actuated float valves requires a determination of the minimum and maximum distances from the origin of the explosion. Placement at the minimum distance ensures that the float valve closes before flame arrival. Placement at the maximum distance ensures that detonation does not develop in the vicinity of the float valve and that the pressure does not exceed the design pressure of the float valve. These distances are usually recommended by the valve vendor and are affected by the explosibility of the fuel, the pipe diameter, and the expected minimum and maximum P_{red} in the upstream enclosure.

Rotary Valves. Rotary valves are commonly used in process design to maintain pressure differences between interconnecting equipment. They need special operational and mechanical features to perform explosion isolation. If an explosion occurs, the rotary valve has to be automatically stopped to avoid transport of glowing and/or burning material to downstream equipment where it could cause a secondary fire or act as an ignition source to ignite a dust cloud and cause a deflagration.[15]

There are two different isolation concepts from which to chose, either flame quenching by maintaining close clearances or material blocking by maintaining a product layer above the valve. If the close clearance concept is chosen, it is important that actual clearance of such rotary valves is measured before installation and monitored using a preventive maintenance program such that the design clearance is not exceeded due to wear. If the material blocking concept is chosen, it is important that the hopper or vessel located upstream of the valve have a minimum inventory of solids to prevent flames passing through the solids due to the pressure wave from an explosion in the hopper/vessel. To maintain this minimum height of solids in the hopper upstream of the rotary valve, low-level sensors are provided which are interlocked to shut down the rotary valve before the hopper goes empty, thereby maintaining a level of solids above the rotary valve. This level of solids is intended to act as a seal to prevent flame and pressure transfer through the valve. A manual bypass should be provided for the low-level sensor/interlock to allow emptying of the hopper when necessary. However, the rotary valve can still significantly mitigate explosion propagation, even if total isolation is not achieved, by significantly reducing transmission of pressure. Figure 17.8.12 shows a typical rotary valve.

Hydraulic-Type (Liquid Seal) Deflagration Arresters. When an explosive mixture flows through a hydraulic arrester, it is separated into single isolated gas bubbles which rise due to buoyancy. Because of the formation of isolated bubbles continuous channels for the passage of the igniting flame do not exist. If an ignition occurs on the side of the device where the single bubbles reach the surface of the liquid, flame propagation can be blocked. This is the usual direction when hydraulic arresters are applied. In the opposite case, that is, if ignition occurs at the upstream side, separation into single gas bubbles will still take place, but the efficiency of the protection will be low, since the combustion process can be transferred to the surface of the liquid. Typical hydraulic deflagration arrester designs are seen in Figure 17.8.13.

Active Isolation Systems. The design of an active isolation system is based on the relative timing of three key processes: the time required for the detection of an explosion, the time

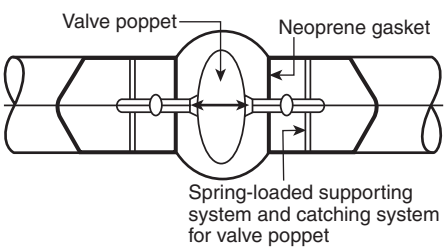

FIGURE 17.8.11 Flow-Actuated Float Valve

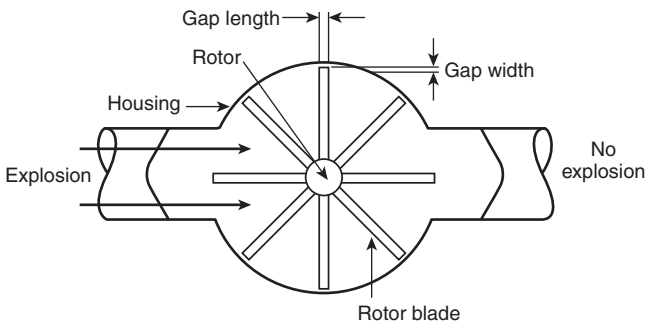

FIGURE 17.8.12 Typical Rotary Valve

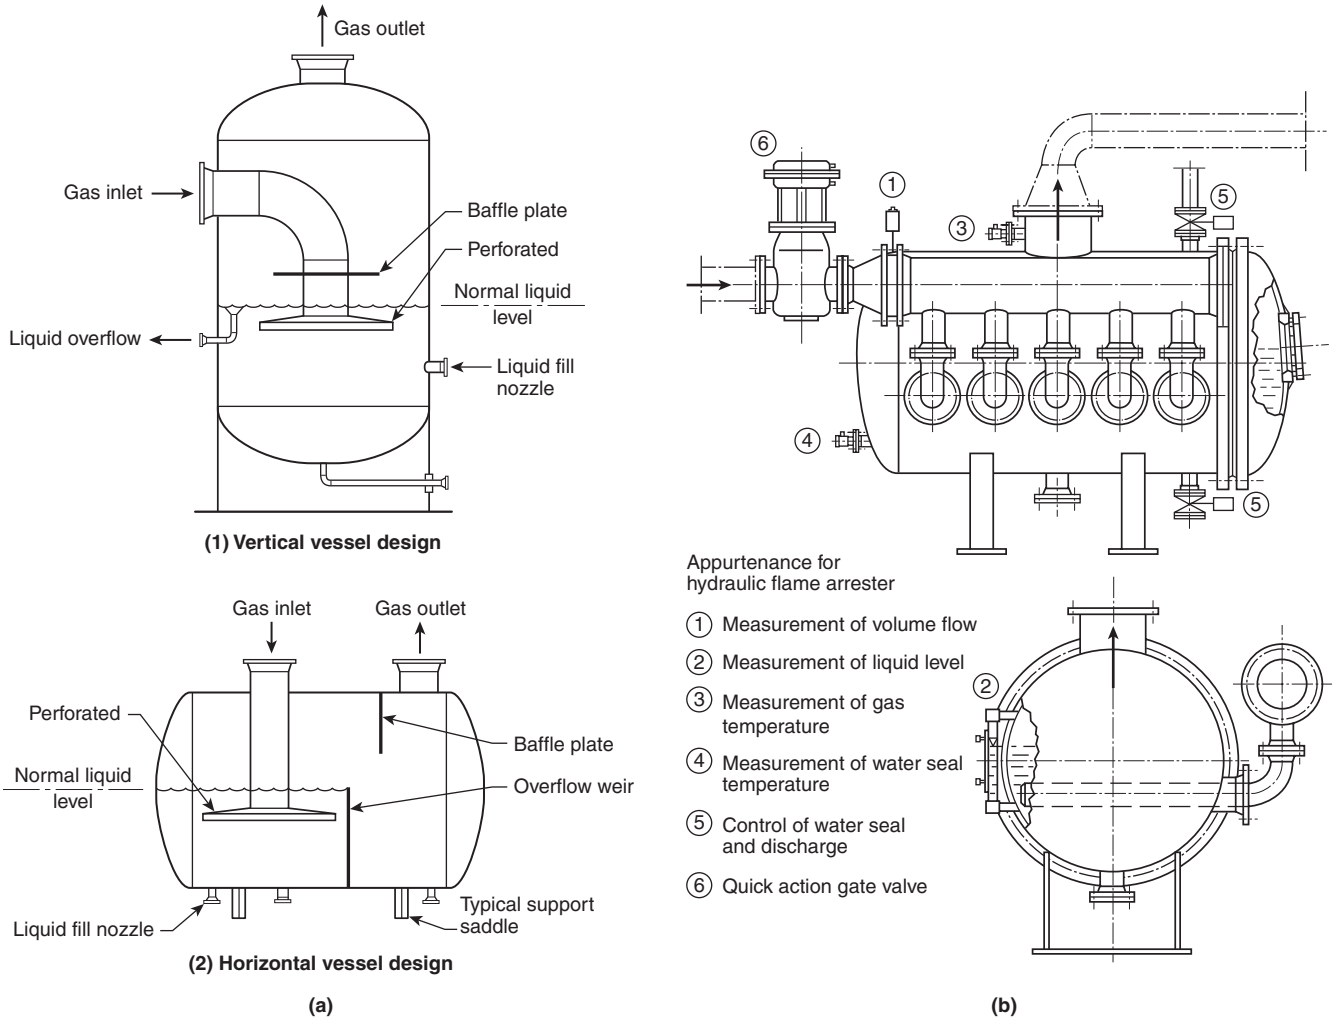

FIGURE 17.8.13 (a) Bubble Screen Hydraulic Flame Arrester; (b) Sparge Tube Hydraulic Arrester

required for the creation of a barrier, and the time it takes for the propagating flame front to reach that barrier. If the flame front can reach the barrier location before a complete barrier is established, then the isolation fails as the flame will travel beyond the barrier location. In such cases, the barrier needs to be placed further downstream to catch the flame front, assuming the pipe is sufficiently long, and the required distance is not too long to promote pressure piling and transition into detonation.

Since the protection is deployed only after the detection of an explosion, the design, fabrication, specification, and installation of these systems pose unique challenges. Establishment of an adequate barrier before the arrival of the flame front is the key to successful protection. The hardware-specific barrier establishment time is one side of this inequality and is carefully controlled as a part of the manufacturing and service quality programs. On the other side of the inequality is the time from the moment of detection to the moment the flame front arrives at the barrier location. Flame travel time is calculated from the three contributors to the flame speed: air velocity in the pipe prior to the explosion, air velocity induced by the explosion pressure rise upstream, and flame acceleration through the pipe. In addition to other occupancy specific parameters, the system design considers both strongest credible explosions, to specify a minimum distance between the possible ignition location and the barrier location, and weakest credible explosions, to ensure detectability.

The time required to create a barrier is the most straightforward to determine when compared to the others and depends on the type of isolation process. For chemical isolation, the time is determined by factors such as the time to initiate discharge, the discharge velocity, and duct diameter. The discharge velocity is affected by the gas pressure used to propel the agent as well as the length and diameter of the discharge piping. Mechanical isolation (fast-acting valves) is characterized by the time required for valve closure, which depends on the closure energetics and duct diameter. Float and pinch valves have similar dependencies. Detection is most often based on the system reaching a preset pressure or a pressure rate of rise. This requires a finite and not insignificant amount of time.

The time required for detection is dependent primarily on the preset conditions, the vessel volume, and the K_{St} or K_G. The detection time will increase as the volume increases and will decrease as K_{St} (K_G) increases. For example, a dust with a low K_{St} in a large volume will take considerably more time for pressure detection than a high K_{St} dust in a small volume. Similarly, ignition near the pipe inlet will be difficult to detect before it is too late. The effect of delayed detection can be to allow the flame to propagate farther and faster before isolation is initiated, and may result in failure of the isolation performance. Optical detection, normally located on the duct close to the inlet, is not affected in this manner. It does, however, require that the flame enter the duct in order to be detected. Optical detection can also be challenging for dust service.

Prediction of the flame propagation time is the most challenging among the three processes. It is well known that flames accelerate in ducts so that flame speed or burning velocity increases as the flame travels. Flame speed and acceleration are affected strongly by fuel characteristic (K_{St}, K_G), turbulence, elbows and other obstructions in the duct, conveyance flow velocity, and the reduced pressure in the primary enclosure. A scientifically valid and universally accepted methodology to predict flame speed and acceleration inside industrial pipes does not exist. As a result, the active isolation system manufacturers have no choice but to resort to using simplified proprietary flame acceleration correlations based on limited data sets. Additional information can be found in Vogl[33], Chatrathi and Going[34], Siwek and Moore[35], Roser et al.[36], Chatrathi et al.[37], Moore and Spring[38], and Pineau[39].

Active protection systems include the following:

- Actuated float valves
- Actuated pinch valves
- Automatic fast-acting mechanical valves
- Chemical isolation systems

Actuated Float Valves. Actuated float valves are similar to the passive float valves described previously. In order to achieve satisfactory performance when low explosion overpressures are expected, these valves are equipped with pneumatic means (such as pressurized gas or gas generator) to effect rapid closure. The system detectors and the control panel logic determines when to close actuated float valves. The actuated float valve typically functions in a single direction.

Actuated Pinch Valves. The valve trim (internals) is an elastomer pinch surrounded by a gas chamber. In the event of a deflagration, an electrical signal is sent from a sensor, typically mounted on a deflagration relief device, to an air tank mounted integral to the valve. The gas tank discharges gas to the chamber surrounding the elastomer pinch and compresses it, which pinches off flow in the pipeline. Because the pinch has relatively little mass, it is both very fast acting and imparts low shock to the piping. The pinch, however, may be adversely affected by sustained high temperatures such as might be encountered in a fire. A schematic of a pinch valve can be found in Figure 17.8.14.

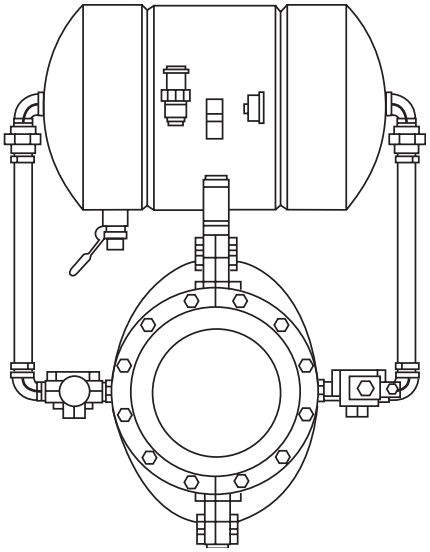

FIGURE 17.8.14 Pinch Valve

Automatic Fast-Acting Mechanical Valves. Positive mechanical isolation of a pipe system is another way to prevent passage of flames or pressure pulses from communicating between process units. Automatic fast-acting mechanical valves are actuated (closed) on a signal from a detector (sensor) in the pipeline between two items of interconnected process equipment. The detector sends a signal to a control device which is relayed to the valve-closure mechanism. Originally this was a compressed gas cylinder which then discharged the compressed gas to a piston-cylinder assembly at the top of the valve, thereby closing the gate. The propellant is generally nitrogen at 33 to 60 barg. The valve separating the compressed gas and the piston must be rapidly opened. Mechanisms for this include rapid pressurization of a rupture disk by pyrotechnical (detonator) devices. In some systems, gas-generating devices have replaced the pyrotechnics. Alternately, gas generators alone have been used to generate the pressure required to rapidly close the valve gate. Plant-air actuated valves are also available. Fast-acting slide gate isolation valves are shown in Figure 17.8.15 and can be mounted in vertical, horizontal, or inclined piping. With this type of valve, the pipe area is completely open and can be built without pockets and dead corners, so that dust will not settle out or accumulate. Special dampers absorb the substantial forces from the closing device and prevent the slide from springing back after closure.

Arrangements of isolation valve systems are shown in Figure 17.8.15 and Figure 17.8.16. A flame sensor is located at a sufficient distance from the valve such that, on detection of flame, the valve has adequate time to close. Fast-closing valves have been tested successfully in these applications to detect and intercept detonations in progress.[40]

Chemical Isolation Systems. Rather than completely blocking a pipe or duct by a valve, an alternative approach is to discharge a chemical extinguishing medium (suppressant) into the pipe,

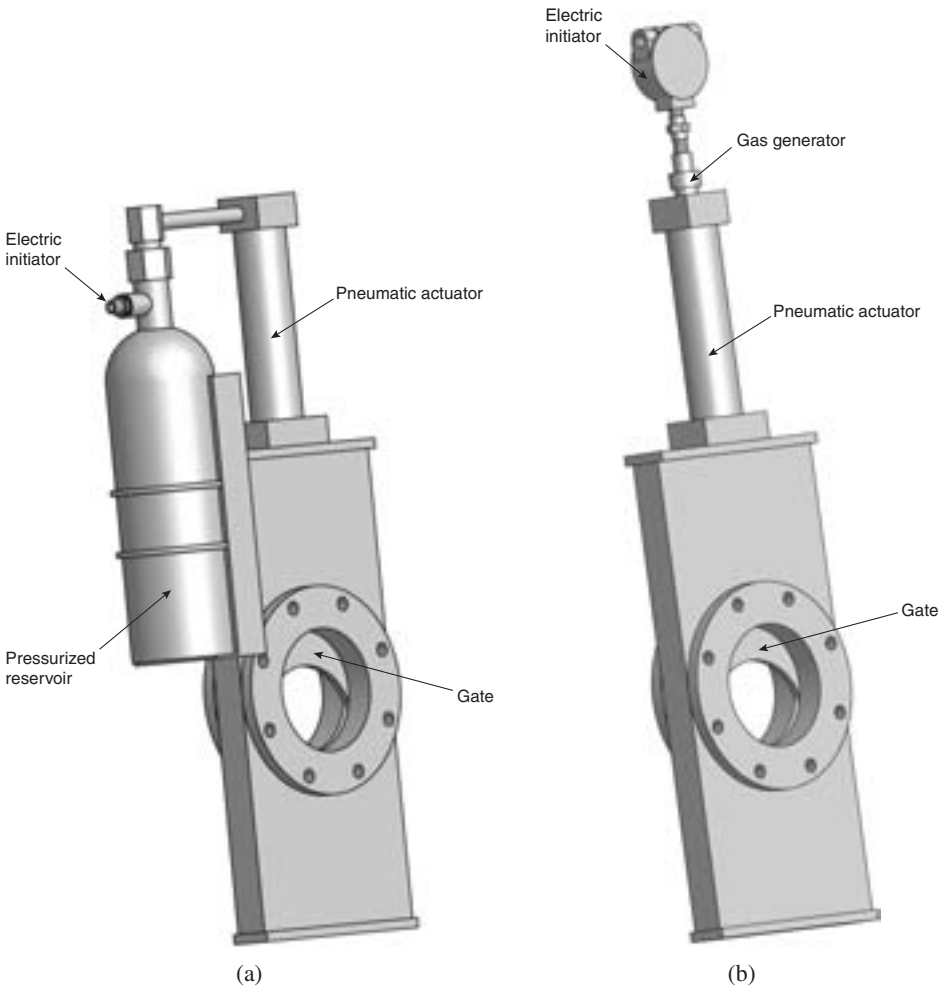

FIGURE 17.8.15 Examples of Automatic Fast-Acting Mechanical Valves

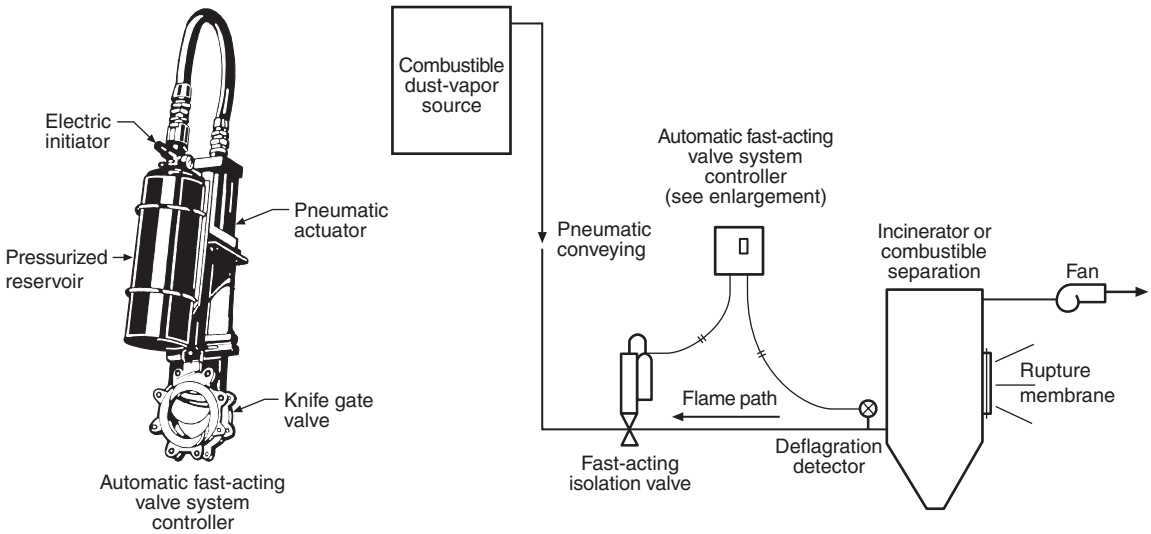

FIGURE 17.8.16 Typical Application of Duct Isolation System Using a Fast-Closing Valve

forming a nonflammable zone. These systems require special consideration in high P_{red} applications, where the induced flow velocity in the pipe can be quite high. As the injected suppressant is free to move with the induced flow, the intended nonflammable zone can be displaced or may have reduced suppressant concentration. Extinguishing compounds such as sodium bicarbonate or ammonium dihydrogen phosphate, chemicals commonly used in fire extinguishers, have been found to be very effective.[41] Halogenated hydrocarbons with low boiling points may be particularly useful, as they provide complete vapor blocks in pipes. Examples of chemicals of this type are HFC-23, HFC-125, HFC-227ea, and HFC-236fa. Halogenated agents leave no residue after discharge, but may form halogen acids upon interacting with flame and hot products of combustion. These acids may be harmful to mechanical components as well as to personnel. Additionally, due to their high global warming potential, these agents face environmental regulations limiting their use. Both dry chemical and gaseous agents have been used successfully in industrial pipe and duct explosion protection systems applications. Applications where chemical barriers are used are often similar to the example shown for fast-acting valves in Figure 17.8.15, where an agent bottle is used in place of a valve to create an inert chemical barrier in the pipe or duct. Chemical isolation systems must be specifically engineered for each application.

SUMMARY

The purpose of this chapter was to provide basic guidance in the prevention of deflagrations and to outline the more commonly employed explosion protection methods. The subject of explosion prevention was presented in the context of deflagration prevention through control or elimination of flammable atmospheres and ignition sources. Careful application of steps to prevent deflagrations is no guarantee that such events will not occur, but only that their likelihood is reduced. Additional protection is afforded through use of any of several explosion mitigation methods. These techniques come into play once ignition has occurred and serve to vent, contain, or redirect the expanding combustion gases, or suppress the combustion process itself. The reader is urged to consult other chapters in this handbook that are relevant to the fundamentals of fires, explosions, and extinguishing systems, and the literature cited at the end of this chapter.

18.1 Confinement of Fire in Buildings
18.2 Interior Finish
18.3 Smoke Movement in Buildings
18.4 Venting Practices
18.5 Penetration Sealing
18.6 Deflagration (Explosion) Venting

The *Fire Protection Handbook*® emphasizes the notion that fire safety must be addressed through system design and analysis of all elements and their relationships to each other. Nowhere is this more essential than in the decisions that determine strength, location, and other features of barriers, surfaces, and spaces in buildings. Confining fires is an important aspect of building fire protection. The six chapters of Section 18 describe construction features, built-in equipment, and techniques for confining or containing fire and fire products to within the barrier of the area where the fire began.

Chapter 1, "Confinement of Fire in Buildings," is an overview chapter that discusses barriers (such as fire doors, fire partitions, and fire walls) that are intended to limit the spread of fire.

Chapter 2, "Interior Finish," reviews the effect of interior finish materials on fire growth, examines the method of application of interior finishes and the effect on fire behavior, and summarizes various fire tests of interior materials.

Chapter 3, "Smoke Movement in Buildings," gives information on the techniques used to evaluate the physical characteristics of smoke and assess its movement in both short and tall buildings. It also covers the approaches that can be used to limit the hazard of smoke in buildings. Chapter 4, "Venting Practices," discusses venting theory, venting in industrial buildings, and automatic heat and smoke venting in sprinklered buildings.

In earlier editions of this handbook, the topic of penetration sealing was covered in a chapter on building services. This edition features an entire chapter on the topic: Chapter 5, "Penetration Sealing." Included are discussions of through-penetration/firestop systems, perimeter fire containment systems, and joint systems.

The section concludes with Chapter 6, "Deflagration (Explosion) Venting." The chapter presents the fundamentals of deflagration, detonation, pressure effects, and explosion venting.

Robert J. Vondrasek, P.E., is a vice-president of NFPA.

People and property not directly exposed to a fire can be protected by confining heat and smoke to the area of origin until the fire either is extinguished or burns itself out. People can also be protected by delaying the spread of fire and smoke until the occupants can be relocated to a place of safety.

Throughout building codes and standards, several terms are used to represent fire separation barriers, including *fire partition* and *fire barrier.* This chapter discusses barriers that are intended to limit the spread of fire. Smoke movement in buildings is discussed in Section 18, Chapter 3, "Smoke Movement in Buildings," and smoke and heat venting in Section 18, Chapter 4, "Venting Practices." The same barriers used to prevent the spread of fire will almost always be the bulwark of systems designed to prevent the spread of smoke. To be contained, a fire must be bounded by barriers that limit the transmission of heat and hot gases. Such barriers must maintain their continuity and stability under the thermal and physical forces of a fire and during the structural distortions and collapse that sometimes occur within the fire area.

The fire resistance required of a barrier depends on its intended purpose and on the expected severity of the fire to which it may be exposed. In most cases, the temperature history of the fire provides an approximate but adequate description of fire severity. If the purpose of the barrier is to limit probable fire size independent of any fire suppression actions, the barrier must then withstand the maximum expected fire that would occur during a burnout of combustibles inside the fire zone. However, if the purpose of the barrier is to contain the fire until occupants are evacuated and the fire department gains access, the time necessary for these actions determines the time that the barrier must hold back the fire, unless the fire is expected to largely burn itself out first.

Properly designed and constructed barriers that satisfy fire endurance test criteria are assigned a fire resistance rating that is measured in hours or fractions thereof. Any breach or unprotected opening in a fire barrier will negate its fire resistance rating and may indeed contribute to rapid fire spread through the barrier.

See also Section 2, Chapter 5, "Basics of Fire Containment"; Section 3, Chapter 5, "Introduction to Fire Modeling"; and Section 6, Chapter 3, "Concepts and Protocols of Fire Testing."

FIRE SEVERITY

The fire severity to which a barrier can be exposed is related to the intensity of a fully developed fire in the space adjacent to the fire barrier. For a room fire, a fully developed fire would be a postflashover fire; however, in large open volumes, such as those found in many industrial plants, a fully developed fire may occur in one area without flashover of the entire volume. It is the fully developed fire that first imposes extensive thermal and physical stresses on fire barriers. The initial possibility of barrier penetration occurs prior to full development. A typical developing fire is characterized by a flame front moving over a surface and/or flames localized to a stationary source.

Hossein Davoodi is a senior fire protection engineer in the Building Fire Protection and Life Safety division at the National Fire Protection Association.

Although such a fire does not massively attack fire barriers, it can spread through faults or openings in the barrier and cause local destruction of barrier fire resistance.

A growing fire may or may not continue to flashover or become a fully developed area-wide fire. Unless it reaches these stages, it is unlikely to threaten fire-resistive barriers except through unprotected openings or serious defects in the construction of the barrier system.

Flashover of an enclosure is likely to occur if the temperature of the upper gas layer reaches approximately 1100°F (600°C). Full-scale fire experiments and energy balance analysis of room fires have shown that the temperature of this upper gas layer depends on the heat released by the burning fire, ventilation of the enclosure, dimensions of the enclosure, and the type of finish material lining the enclosure.[1] These factors are also interdependent with each other to some degree. The larger the enclosure, the higher the heat release necessary to produce the upper gas temperature needed for flashover. The more heat lost through walls, doors, and windows, the larger the fire and/or longer the time needed to produce flashover. Conversely, the greater the combustibility of the enclosure lining, the smaller the fire needed to produce flashover. The combustibility of the lining, or interior finish, is particularly significant. Interior finish in an enclosure can reduce the rate of heat release in the enclosure to below the value necessary for flashover as well as reduce the preburn time before flashover. A practical difficulty in estimating the likelihood of room flashover is in determining a value for the heat-release rate possible from the room contents. Typical heat-release rates from some common furnishings have been summarized from full-scale experimental data.[2] These data can be used in calculating the likelihood of flashover in a particular room.

Combustion

The intensity and duration of a fully developed fire depend on the quantity of combustibles available, their burning rates, the geometry of the material, room geometery, and the air available for combustion. Fire intensity will also be somewhat lower when walls and ceilings absorb significant amounts of energy rather than act primarily as insulation or radiation barriers.

The burning rate of a fully developed fire involving a specific material or grouping of similar materials is determined by either (1) the fuel surface area available to participate in the combustion reaction or (2) the amount of oxygen available for combustion. These are referred to as fuel-surface-controlled and ventilation-controlled combustion, respectively. The maximum rate of heat transfer into fire separation barriers occurs at the point where the ventilation is just sufficient so that combustion is controlled at the fuel surface (*stoichiometric combustion*).[3] At higher ventilation rates, more heat is removed from the fire by the excess air. At lower ventilation rates, the combustion heat-release rate is less, and more unburned pyrolysis products and fuel particles are vented outside the fire area. Burning of unburned pyrolysis products outside fire compartment windows can increase the threat of floor-to-floor and building-to-building fire spread.

The possibility of failure of fire separation barriers can exist long after the fully developed fire begins to decay. However, in many real fires, this threat is mitigated by fire suppression activities. The decay in air temperature in a fire room has been reported as 27 to 36°F (15 to 20°C) per minute after fully developed fires of 10- to 15-minute duration. Other data indicate a decay rate of 18°F (10°C) per minute for longer-duration fires.[4] Cooling can be even slower in large debris piles. Fire endurance testing in the United States does not simulate a fire decay period, although the decay period is simulated by some European testing and has been proposed in U.S. testing. Research has proposed that short-duration, high-temperature fires, followed by temperature decay, should be considered.

Poorly ventilated fires that are encountered in spaces such as basements, ship holds, or enclosed interior rooms can produce sufficient heat over a long period of time to penetrate fire separation barriers. These fires start with or reach flaming combustion and, as the air in the space is consumed, revert to a state of mixed smoldering and glowing combustion with isolated or intermittent flaming. However, at present, there are no adequate experimental data or theoretical approach capable of reliably estimating the effect of these fires on fire-resistive barriers.

Standard Temperature-Time Curve

Fire-resistive barriers are evaluated in a testing furnace by exposure to a fire whose severity follows a time-varying temperature curve known as the standard temperature-time curve. The specified temperature-time history is tabulated in NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials,* and illustrated in Figure 18.1.1. The standard temperature-time curve was adopted by the ASTM in 1918 and has been the basis of almost all fire-resistive testing ever since.

Following adoption of the curve, the National Institute of Standards and Technology (NIST), formerly the National Bureau of Standards (NBS), conducted a number of full-scale fire tests to determine how actual building fires compared with the temperatures represented on the curve.[5,6] The tests included two actual buildings that were allowed to burn to destruction and a series of fires in fire-resistive test buildings containing

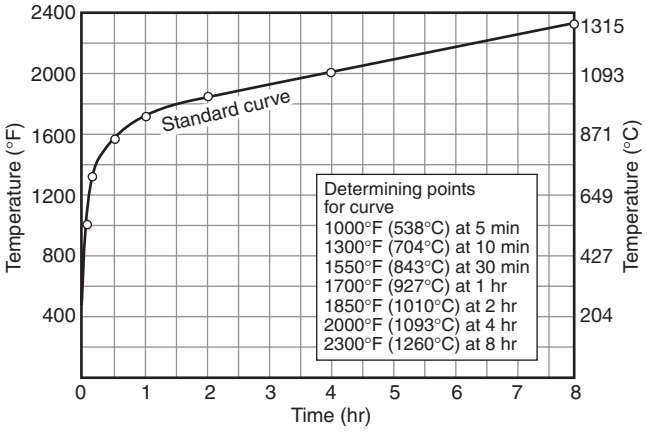

FIGURE 18.1.1 Standard Temperature-Time Curve

contents representative of office, record room, and household occupancies.

The principal variable considered in these occupancy fire tests was the amount of combustible materials present, which is defined as the fire load. Although the ventilation in the test buildings was not reported, the windows were equipped with steel shutters that could be adjusted to control ventilation and maximize fire severity. The quantitative importance of ventilation on fire severity was not identified until the 1950s. These tests conducted by NIST provided quantitative data on the temperature history of fires that were representative of various occupancies and fire load at that period of time. Fire load was expressed as the weight of ordinary combustibles in the room divided by the floor area of the room. Loading is the average amount of ordinary combustible material per square foot (m^2) of floor area. The temperature history of the fully developed fires in three test occupancies was approximately bounded by the standard temperature-time curve.

NIST developed the concept of equivalent fire severity to define the severity of actual fires that had various temperature histories. This concept states that the area above a baseline under the temperature-time curve of a test fire, which is expressed in degree hours, is an approximate representation of the severity of a fire involving ordinary combustibles. The baseline used represents the temperature the materials can be exposed to without impairing their fire-resistive capabilities. Two fires with differing temperature histories are considered to have equivalent severity when the areas under their temperature-time curves are similar. This concept permitted comparison of any fire test data to the standard temperature-time curve by relating the area under the test curve to the area under the standard curve.

TABLE 18.1.1 Estimated Fire Severity for Offices and Light Commercial Occupancies

Total Combustible Content, Including Finish, Floor, and Trim		Heat Potential Assumed*		*Equivalent Fire Severity Approximately Equivalent to That of Test Under Standard Curve for the Following Periods*
(lb/ft²)	*(kg/m²)*	*(Btu/ft²)*	*(MJ/m²)*	
5	24	40,000	454	30 min
10	49	80,000	909	1 hr
15	73	120,000	136	1½ hr
20	98	160,000	1820	2 hr
30	147	240,000	2730	3 hr
40	196	320,000	3640	4½ hr
50	245	380,000	4320	7 hr
60	290	432,000	4910	8 hr
70	340	500,000	5680	9 hr

Note: Data apply to fire-resistive buildings with combustible furniture and shelving.
*Heat of combustion of contents taken at 8000 Btu/lb up to 40 lb/ft²; 7600 Btu/lb for 50 lb; and 7200 Btu for 60 lb and more to allow for relatively greater proportion of paper. The weights contemplated by the table are those of ordinary combustible materials, such as wood, paper, or textiles.
For SI units: 1 lb/ft² = 4.88 kg/m²; 1 Btu/ft² = 1.14 J/m².

FIRE LOADS

Relationship of Fire Load and Fire Severity to Fire Resistance Requirements

The original concepts of fire severity and fire load are very important even though they are technically obsolete. These concepts are the basis for many of the fire resistance requirements of building codes and for government agencies. In many cases, this original fire severity/fire load relationship was more severe than is indicated by more accurate analysis. Such results are conservative since the resultant error is on the safe side.

Analysis of NIST tests developed an approximate relationship between fire loading and an exposure to a fire severity equivalent to the standard temperature-time curve. The weight per square foot (m^2) of ordinary combustibles (wood, paper, and similar materials with a heat of combustion of 7000 to 8000 Btu per lb [16.282 to 18.608 MJ/kg]) was related to hourly fire severity, as described in Table 18.1.1.

The fire severity/fire load relationship was the first method developed to predict the severity of a fire that would be anticipated in various occupancies. It was used to determine resistance required of fire barriers as well as structural components. Although the technique has its limitations, the fire severity/fire load relationship still provides an approximate but conservative estimate of the probable maximum fire severity with combustibles having a high heat-release rate and when fire conditions can produce temperatures significantly higher or lower than the standard temperature-time curve.

Fire load is a measure of the maximum heat that would be released if all the combustibles in a given fire area burned. Maximum heat release is the product of the mass of each combustible multiplied by its heat of combustion. In a typical building, the fire load includes combustible contents, interior finish, floor finish, and structural elements. Fire load is commonly expressed in terms of the average fire load, which is the equivalent combustible weight divided by the fire area in square feet (m^2).

Equivalent combustible weight is defined as the weight of ordinary combustibles having a heat of combustion of 8000 Btu/lb (18,608 kJ/kg) that would release the same total heat as the combustibles in the space. For example, the equivalent weight of 10 lb/ft² (48.8 kg/m²) of a plastic with a heat of combustion of 12,000 Btu/lb (27,912 J/kg) would be

$$10 \text{ lb/ft}^2 \times 12{,}000 \text{ Btu/lb} = 120{,}000 \text{ Btu/ft}^2$$

$$120{,}000 \text{ Btu/ft}^2 \div 8000 \text{ Btu/lb ordinary combustibles} = 15 \text{ lb/ft}^2$$

or

$$48.8 \text{ kg/m}^2 \times 27.9 \text{ MJ/kg} = 1365 \text{ MJ/m}^2$$

$$1365 \text{ MJ/m}^2 \div 18{,}608 \text{ MJ/kg} = 75.36 \text{ kg/m}^2$$

Technically accurate methods for calculating the actual fire severity and fire resistance requirements are available for many common building-occupancy-contents combinations. Technical

TABLE 18.1.2 Characteristic Fire Loads in Office Buildings

	Government Buildings			Private Buildings		
		Total Fire Load (lb/ft^2)			Total Fire Load (lb/ft^2)	
Room Use	*No. of Rooms Sampled*	*Mean*	*Std. Dev.*	*No. of Rooms Sampled*	*Mean*	*Std. Dev.*

For SI units: 1 lb/ft^2 = 4.88 kg/m^2.

limitations are primarily related to availability of input data rather than the analytical tools. These methods have been accepted to varying degrees under performance-based building codes adopted in some countries. Such analytical approaches have not yet been widely or routinely accepted by code authorities in the United States. However, third-party reviews are opening up opportunities for this alternative.

Occupancy Fire Loads

A number of surveys have identified the fire loads found in various occupancies[5,7,8] (Tables 18.1.2 and 18.1.3).

Data from some fire load surveys as well as the inherent nature of combustible contents likely to be encountered suggest that the dispersion of fire load within a certain class of rooms can be approximated by either a normal or moderately skewed frequency distribution curve (Figure 18.1.2). The standard deviation, included in Tables 18.1.2 and 18.1.3, can be used to determine the probability that a particular fire load value will not be exceeded in a class of rooms. A fire load that is one standard deviation above the mean value of a normal distribution curve would represent an upper boundary for 84.13 percent of the fire loads in rooms of that class. Two standard deviations above the mean would bound 97.73 percent of the fire loads in that class of rooms, and three standard deviations, 99.86 percent of the fire loads. Thus, if a fire barrier were to be designed on the basis of two standard deviations above the mean, there would be a 97.73 percent probability that this fire load would not be exceeded in a similar room.

The above percentages consider that the distribution of fire loads is perfectly normal. If the distribution is more accurately defined by a moderately skewed curve, the percentages represent only close approximations.

Derated Fire Loads

Ordinary combustibles that are completely or largely enclosed in steel containers will not burn completely during a room fire and, therefore, will not contribute a full 8000 Btu/lb (18.608 MJ/kg) to the fire load. The General Services Administration (GSA) has developed guidelines for determining a derated fire load for office buildings, which can be applied to other occupancies having similar classes of combustibles.[9] The total contents fire load is divided into three categories: (1) weight of materials completely enclosed in containers, such as steel desks or file

TABLE 18.1.3 Typical Fire Loads

Type of Room	*Contents Fire Load (lb/ft^2)*	*Standard Deviation (lb/ft^2)*
Living room	3.9	1.13
Family room	2.7	0.65
Bedroom	4.3	1.15
Dining room	3.6	1.02
Kitchen	3.2	0.77
Hospital patient room	1.2	0.36
Nursing home patient room	2.6	0.62

For SI units: 1 lb/ft^2 = 4.88 kg/m^2.

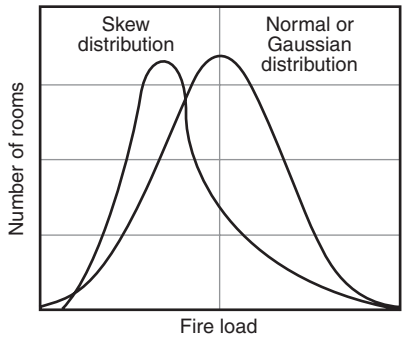

FIGURE 18.1.2 Expected Distributions of Sample Fire Loads

cabinets, (2) weight of materials enclosed on five sides, such as in a steel bookcase, and (3) weight of free combustibles.

Completely enclosed combustibles will be heated by the room fire and pyrolyze, and the escaping pyrolysis products will burn. Therefore, the heat that the enclosed combustibles release depends on the extent to which they are *pyrolyzed.* This is related to the intensity and duration of the room fire, which in turn is related to the total combustibles in the room. The extent to which the enclosed contents are derated is determined by considering the ratio of the total weight of enclosed combustibles to the total weight of all combustibles in the room. Thus,

$$F_T = W_E + W_{PE} + W_{FE}$$

A derating factor is assigned to W_E as tabulated:

Ratio W_E/F	*Derating Factor, K*
Under 0.5	0.4
0.5 to 0.8	0.2
Over 0.8	0.1

Ordinary combustibles enclosed on five sides by steel, such as in a bookcase, are derated to 75 percent of their weight.

The total derated fire load is given by the following equation:

$$F_{DR} = K_{WE} + 0.75W_{PE} + W_{FE}$$

The specific fire load is then computed by dividing by the floor area.

This derating procedure can be applied if other than ordinary combustibles are included in the fire load. The total weight of other combustibles must be expressed in terms of an equivalent weight of ordinary combustibles that would release the same total heat in burning. This is accomplished by multiplying the weight of the other combustibles by the ratio of their heat of combustion in Btu/lb, to 8000 Btu/lb (19 MJ/kg), the heat of combustion of ordinary combustibles.

British Fire Loading Studies

The British also have graded building occupancies according to hazard. Three classifications—low, moderate, and high fire loads—were defined in terms of Btu/ft^2 (J/m^2).

Occupancies of Low Fire Load. The fire load of an occupancy is described as low if it does not exceed an average of 100,000 Btu/ft^2 (1134 MJ/m^2) of net floor area of any compartment, or an average of 200,000 Btu/ft^2 (2268 MJ/m^2) in limited isolated areas, provided that storage of combustible material necessary to the occupancy may be allowed to a limited extent if separated from the remainder and enclosed by appropriate-grade fire-resistive construction. Examples of occupancies of normal low fire load are retail shops, factories, and workshops.

Occupancies of Moderate Fire Load. The fire load of an occupancy is described as moderate if it exceeds an average of 100,000 Btu/ft^2 (1134 MJ/m^2) of net floor area of any compartment but does not exceed an average of 200,000 Btu/ft^2 (2268 MJ/m^2), or an average of 400,000 Btu/ft^2 (4540 MJ/m^2) in limited isolated areas, provided that storage of combustible material necessary to the occupancy may be allowed to a limited extent if separated from the remainder and enclosed by fire-resistive construction of an appropriate grade. Examples of occupancies of moderate fire load are retail shops, factories, and workshops.

Occupancies of High Fire Load. The fire load of an occupancy is described as high if it exceeds an average of 200,000 Btu/ft^2 (6 MJ/m^2) of net floor area but does not exceed an average of 400,000 Btu/ft^2 (4540 MJ/m^2) of net floor area, or an average of 800,000 Btu/ft^2 (9080 MJ/m^2) in limited isolated areas. Examples of occupancies with normal high fire load are warehouses and other buildings used for the bulk storage of commodities of a recognized nonhazardous nature.

Other Fire Loading Studies

Fire loading studies have been conducted in other countries. Results of some of these studies are summarized in Tables 18.1.4 through 18.1.6.

EFFECT OF VENTILATION

The burning rate of fully developed fires may depend on the available fuel surface area or on the air available for combustion. When ample air is available, the burning rate of a fire depends on the exposed surface area and on the properties of the combustible itself. Fully developed fires involving ordinary residential furnishings burn at a rate *R,* which can be approximated by the following equation:

$$R = 0.09A_f \text{ (lb/min)}$$

TABLE 18.1.4 Mean Values of Fire Load and Fire Load Density for the Various Homes

Home Type	*Mean Fire Load (MJ)*	*Mean Fire Load Density Based on Floor Area of 22 m^2 (MJ/m^2)*	*Number of Samples*

where A_f is the exposed fuel surface in ft^2 (m^2).[10] For the general case, the equation becomes

$$R = W_f A_f$$

where W_f = surface rate of burning of the fuel, lb/ft^2 (kg/m^2) of exposed surface per minute.

Typical furniture found in homes and offices has a surface-area-to-weight ratio between 0.55 and 0.90 lb/ft^2 (2.7 and 44 kg/m^2).[11] Loose combustibles, cellular material, hanging clothes, and similar materials have much higher surface-to-weight ratios and are associated with more rapidly developing fires.

When a fire cannot get sufficient air to maintain the burning rate associated with fuel-surface-controlled (stoichiometric) combustion, it will burn at a ventilation-controlled rate. The burning rate for fully developed fires with ordinary combustibles to which air is supplied through broken windows or a doorway is approximated by the following equation:

$$R = 0.62 A_o H_o^{1/2} \text{ (lb/min)}$$

where

A_o = The opening area in ft^2 (m^2)

H_o = The height of the opening in ft (m)[12]

Airflow into the fire, through a single opening, has been found to be approximately equal to the following equation:

$$\dot{m} \simeq 5.06 C_D A_o H_o^{1/2} \text{ (lb/min)}$$

where C_D = the orifice coefficient, normally about 0.5 to 0.7.[13]

Where there are multiple openings or a window wall, the flow is less than predicted by the area, and a coefficient of about 0.35 is recommended.

The maximum fire intensity, from the standpoint of rate of heat input into barriers, occurs at a ventilation rate just sufficient to sustain a surface burning fire. This can be expressed in the following equation:

$$W_f A_f = 5.06 C_D W_a A_o H_o^{1/2}$$

where W_a is the weight of fuel each pound (kg) of air will burn completely. Typical values of W_a are presented in Table 18.1.7.[13]

The preceding relationships assume that wind is not a factor in ventilation. In addition, if the ventilating opening is an interior door, such as from a corridor, adequate combustion air must be available for the fire.

Considerable ventilating area is required for a fully developed fire to burn at a fuel-surface-controlled rate (stoichiometric combustion). For example, over one-fourth of the wall area would have to be open in a 20 ft × 20 ft (6.1 m × 6.1 m) room with an 8 ft (2.4 m) ceiling and an exposed combustible surface of 800 ft^2 (74.3 m^2) of ordinary combustibles. Most building fires will be ventilation controlled during the period when containment is critical from the initial well-developed phase until the start of decay. A fully developed fire can change from

TABLE 18.1.7 Fuel Consumed by 1 Pound of Air at a Stoichiometric Fuel/Air Ratio

Combustible	*lb fuel/lb air*	*g fuel/kg air*
Wood	0.175	175

Polystryene	0.076	76
Polyurethane	0.135	135
Benzene	0.076	76
Methane	0.060	60

a ventilation-controlled to fuel-surface-controlled fire as ventilation changes (such as when windows break out). Fires in modern buildings that have large glass windows may burn at ventilation-controlled rates.

FIRE MODELING

A number of mathematical models have been developed that include calculations of the temperature history of fully developed room fires as a function of ventilation, fuel, and the walls and ceiling of the room.[3,4,11,13–18] Fire models are increasingly being used in design as well as the evaluation of hazards and reconstruction of incidents. An extensive and expanding database is available that provides histories of heat release rates for combustible contents and finishes as well as the physical and thermal properties of construction materials. The most widely used models in the United States are classified as zone models and exemplified by the Consolidated Firegrowth and Smoke Transport (CFAST) component of HAZARD.[16] Zone models are available with varying degrees of complexity and can be run on personal computers. A typical assumption of zone models is the filling of the fire compartment from the top down with hot gases of a uniform temperature. An advantage of zone-based models is their ability to address smoke spread and a variety of fire-growth profiles. Field models do not make such assumptions but use computational fluid dynamics; this requires numerical solution of the differential equations describing the principles of conservation of mass, energy, momentum, and species. Field models examine a fire in two or three dimensions, breaking the compartment into thousands of cells or elements. Performing these calculations demands the use of powerful computers beyond the capabilities of most personal computers. Network flow models such as CONTAM2.4 are used to evaluate airflow paths composed of doorways, window vents, ducts, and leaks in buildings. These systems are often used to evaluate smoke management systems.

Calculations can also be made that yield the temperature rise on the unexposed wall and ceiling surfaces. Such calculations are meaningful only on the types of barriers that have extensive fire test and actual fire experience, because temperature rise is only one of the ways a fire barrier can fail. Mathematically modeling other failures can be difficult with many common constructions. In determining fire severity, this technique represents an improvement over the single-parameter fire load concept; however, it also is an approximation and has definite limitations.

All fire models have limitations and require some assumptions just as do all other engineering models used to design buildings and building systems. For example, the assumption that the temperature is uniform in the fire room is associated with the less complex postflashover fire models. The turbulence associated with a postflashover fire is assumed to mix the hot gases so that no appreciable temperature gradients exist. In fire models, this assumption is used to calculate mass airflow into the room, heat transfer from the room to walls and ceiling, and pyrolysis of the fuel. This assumption is an approximation, because temperature differences of between 250 and 500°F (139 and 278°C) have been measured within a room during postflashover fires; larger differences could be encountered in larger compartments.[19–21]

The maximum intensity of postflashover room fires occurs when the ventilation is just sufficient to permit fuel-surface-controlled (stoichiometric) combustion.[3] At either higher or lower ventilation levels, the maximum fire temperature is lower.[4] At higher ventilation levels, the fire duration will be shorter, and at lower levels, it will be longer. The ventilation necessary to sustain fuel-surface-limited (stoichiometric) combustion will depend on the combustibles in the room, their exposed surface area, surface burning rate, and the amount of air each pound (kg) of fuel requires for combustion. More ventilation would be needed to sustain fuel-surface-controlled (stoichiometric) combustion if a room contains blocks of foam rubber than if it contains an equivalent fire load of ordinary furnishings. The effect ventilation area has on the temperature of a fully developed room fire is qualitatively shown in Figure 18.1.3.

The majority of experimental fires, which form the basis for the previously described relationships, have emphasized one-room fires, fuel consisting of either ordinary household and business furnishings or wood cribs, fuel loads under 10 lb/ft^2 (48.8 kg/m^2), and at least a level of ventilation provided by an open door or large window representing 10 to 15 percent of the room area. The results of these fires have shown the following:

1. Fire room temperatures may rise much faster than the standard temperature-time curve, remain above the curve for a period of time, and then drop below it.
2. Within a normal ventilation range of about 10 to 15 percent of room area on the low end and 25 to 30 percent on the

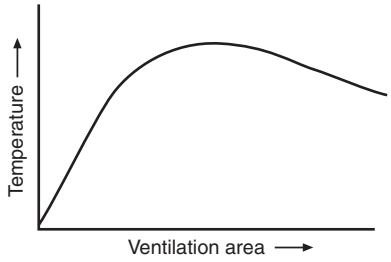

FIGURE 18.1.3 Typical Fully Developed Fire Temperature-Ventilation Curve

high end, the maximum fire temperature depends primarily on fire load, which, in turn, is related to the exposed fuel surface area.

3. Maximum fire temperatures involving ordinary furnishings generally range between 1400 and 1800°F (760 to 982°C). However, ordinary combustible materials with a very high exposed fuel surface area of 8 ft^2/ft^2 (0.74 m^2/m^2) of floor area can result in maximum fire room temperatures over 2000°F (1093°C).

Temperature histories of some typical small room fires in which ventilation was provided by an open corridor door are illustrated in Figure 18.1.4.

Higher temperatures associated with the large fuel surface areas of wood cribs are shown in Figure 18.1.5;[22] the fuel surface area was about 1000 ft^2 (93 m^2) for the 10 lb/ft^2 (48.8 kg/m^2) fire loading.

For more information on fire modeling, see Section 3, Chapter 5, "Introduction to Fire Modeling." For an overview of fire modeling, also see the *SPFE Handbook of Fire Protection Engineering*[23] and *SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings.*[24]

FIRE SPREAD

Fire spread rarely occurs by heat transfer through, or structural failure of, walls and floor/ceiling assemblies. The common mode of fire spread in a compartmented building is through open doors, unenclosed stairways and shafts, unprotected penetrations of fire separation barriers, and nonfirestopped combustible concealed spaces. Even in buildings of combustible construction, the common gypsum board or lath-on-plaster protecting wood stud walls or wood joist floors provides 25 to 30 minutes of resistance to a fully developed fire, as determined by a standard fire test.[25] When such barriers are properly constructed and maintained and have protected openings, they will normally

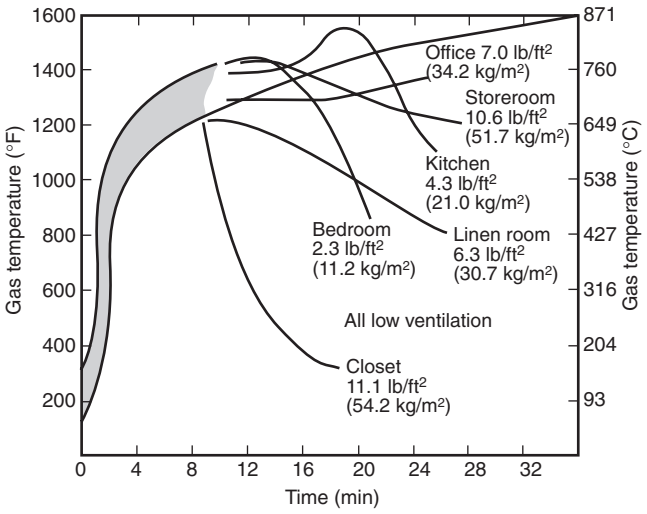

FIGURE 18.1.4 Gas Temperature at Ceiling of Burning Room

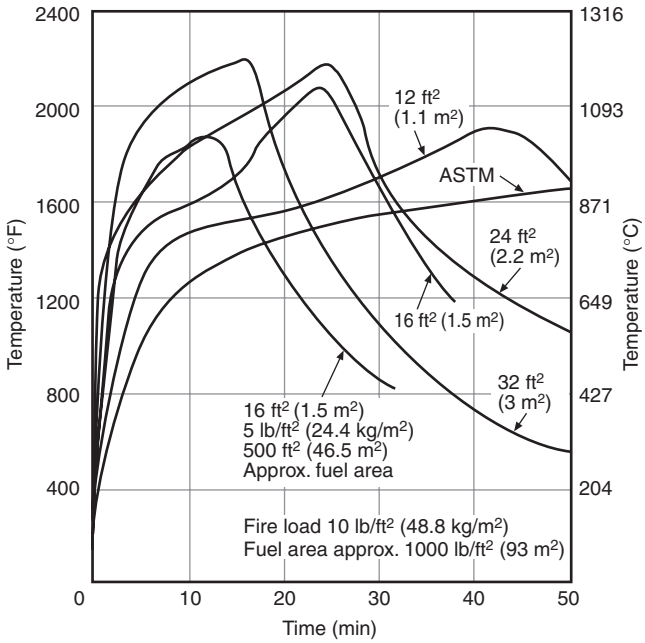

FIGURE 18.1.5 Effect of Window Area on Average Fire Room Temperature

contain fires of maximum expected severity in light-hazard occupancies. However, no fire barrier will reliably protect against fire spread if it is not properly constructed and maintained and openings in the barrier are not protected.

Although typical wall and floor-ceiling constructions generally have adequate inherent fire resistance in light-hazard occupancies, there are practical advantages in requiring rated fire-resistive assemblies in new construction. Materials and construction methods required for fire-rated assemblies provide quality controls not found in typical construction.

Fire can spread horizontally and vertically beyond the room or area of origin and through compartments or spaces that do not contain combustibles. Heated unburned pyrolysis products from the fire will mix with fresh air and burn as they flow outward. This results in extended flame movement under noncombustible ceilings, up exterior walls, and through noncombustible vertical openings. This is a common way fire spreads down corridors and up open stairways and shafts. Similar phenomena have been observed in flame spread underneath the ceiling in industrial and storage buildings. Combustible interior finish in corridors and vertical openings, which by itself may be incapable of propagating flames, will be heated and may produce pyrolysis products. These products add to those from the main fire and increase the intensity and length of flames.

Once a room fire becomes fully developed, fire can spread very quickly to adjacent rooms in the absence of any fire separation barriers. When a building contains similar size rooms, the total volume of the rooms involved in fully developed fires tends to increase at an exponential rate.[26] This is illustrated in Figure 18.1.6, which shows the form of percentage increase in total fire volume, based on the initial room volume as a function of time after the initial room flashed over.

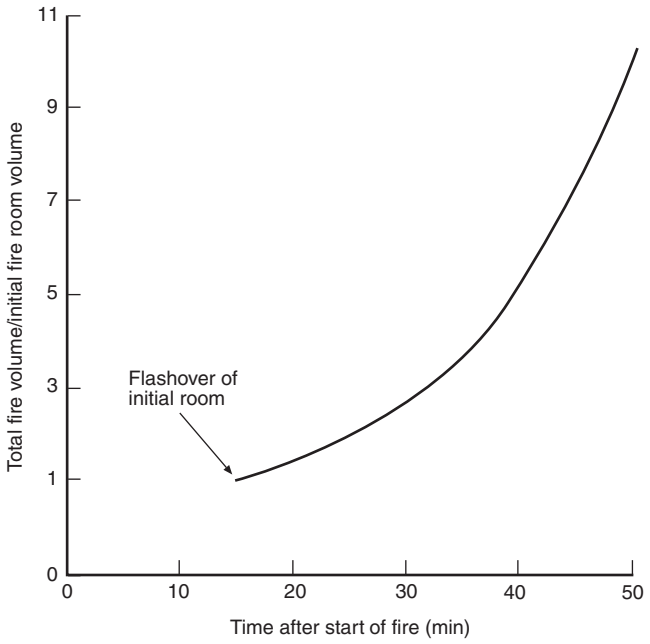

FIGURE 18.1.6 Exponential Fire Volume Increase for a Room Flashover Time of 15 Minutes

Floor-to-floor fire spread along the outside of a building is not a common occurrence, but it can and does occur, such as in the Hilton Hotel fire in Las Vegas, Nevada, in 1981. Glass panes normally break when heated to 550 to 600°F (288 to 316°C), although some breakage may occur at lower temperatures.[27] Glass breakage is actually the result of thermal stress induced by heating the area of the glass panel faster than the area of the frame.[28] The hazard is greater in high-rise buildings because of fire-fighting difficulties and because there are more floors to which fire can spread. Wide spandrels and projections, such as balconies, will reduce the risk of, although not necessarily prevent, external fire spread.

Whether a barrier will or will not contain a fire can be considered as a probability and reliability problem that parallels reliability problems encountered in the operation of electronic, electrical, and mechanical equipment. Using this analogy, barrier failures can be considered to fall into one of three categories: (1) early failures, (2) random failures, and (3) degradation failures. Early failures would be the result of occurrences such as a door not closing or an opening not being protected. Random failures would be the result of faults in materials or construction, a fire of unexpected severity, or design weaknesses not identified by standard testing methods. Random failure probabilities typically follow an exponential law and would predominate until barrier thermal degradation became a factor. Degradation failures would be similar to wear-out failures encountered in electronic, electrical, and mechanical equipment. The probability of a wear-out failure typically follows a normal or Gaussian distribution law, and the probability of barrier degradation failures should be similarly distributed. This technique of considering the three categories of barrier failure probability permits a more realistic comparison to be made between compartmentation and other protective measures. It is also apparent from this analogy that a barrier having a certain fire-resistive rating is not necessarily twice as reliable as one having one-half that rating.

Concealed Spaces

Buildings may contain a wide variety of concealed spaces behind walls, above suspended ceilings, in utility chases, behind soffits, under computer room floors, in attics, and elsewhere. The spaces range in size from 1⅝ in. (41.3 mm) stud spaces to full floor height interstitial spaces. Fires in concealed spaces burn out of sight of building occupants, and detection is frequently delayed. Manual fighting of concealed-space fires can be very difficult because of limited accessibility and inherent venting problems. Vertical concealed spaces also can act as flues to spread fire and hot gases.

Fire development and spread in combustible concealed spaces have long been a cause of large losses in fires. The fire may originate in, or spread into, a combustible concealed space and burn for a long time, spreading throughout the concealed volume. The disastrous Beverly Hills Supper Club and MGM Grand Hotel fires both originated in combustible concealed spaces.[29,30] Fires in horizontal concealed spaces, such as cock lofts, attics, interstitial spaces, and soffits, can spread undetected until they either burn through the floor or roof above or cause parts of the ceiling below to drop. At that time, a fresh air supply, preheated combustible materials, and hot pyrolysis products can combine to produce a rapidly developing fire, which may break out of the concealed space over a wide area. Vertical fire spread inside walls and chases can spread fire between floors and into attic spaces where it mushrooms out horizontally. The rapid vertical spread of fire was quantitatively demonstrated during several full-scale fire tests in wood-frame housing in the Bushwick section of Brooklyn, New York. In one test, temperatures in excess of 1500°F (816°C) were recorded at the top of a 32 ft (9.75 m) shaft 1 minute after a fire was started at the bottom.[31]

Flame spread through horizontal noncombustible concealed spaces is rarely a hazard unless the space contains a significant amount of combustible materials, such as communications or electrical cable trays, plastic pipe, cellular foam insulation, and insulation with a combustible vapor barrier. Isolated combustible items are not likely to propagate fire horizontally; however, they may when grouped together. For example, grouped electrical cables in trays may spread a fire, although any fire spread will be slow and not likely to extend very far from the ignition source; one exception is foam-insulated coaxial cable.[32] This does not mean that such combustibles will not assist in fire spread when they are preheated by hot fire gases from another source. Movement of flame through a noncombustible ceiling plenum space was reported as contributing to the horizontal spread of fire in One New York Plaza.[33] The interstitial space contained a number of electrical communications cables and exposed foam plastic insulation on the inside of the exterior walls. Insulation installed with a combustible vapor barrier exposed can spread fire even if its fuel contribution is very small.

Electrical cables that are difficult to ignite are available and being used in nuclear power plants. New materials have been

developed to meet stringent fire resistance requirements for use in life safety applications. One such application is fire-resistant cables for emergency power supply lines. In tests, fire-resistant cables did not propagate fire horizontally, except in a multiple-stacked tray configuration.[34] Tests have also shown that use of fire-retardant coatings can be effective in inhibiting horizontal fire spread; however, there were major performance differences among the products tested.[35] Although some combustibles do not pose a serious threat of horizontal fire spread in noncombustible concealed spaces, they are likely to pose a serious threat of spread in vertical concealed spaces.

Vertical Openings

Unprotected vertical openings have been responsible for many large loss-of-life fires. These openings can act as a chimney—smoke, hot gases, and burning pyrolysis products flow up under the stack effect and then mushroom out horizontally. Because of their function, openings such as elevator shafts, stairways, laundry chutes, and air shafts cannot be cut off at floor levels. Vertical openings are enclosed with fire-rated walls to prevent fire spread and, in the case of vertical exitways, to provide a safe path of egress for occupants and access for fire department personnel. Vertical interior exitways are often the only avenue of escape to the outside or to adjacent floors for building occupants. NFPA *101*®, *Life Safety Code*®, provides a comprehensive treatment of exits in general and for various types of occupancies involving both new and existing buildings. Detailed requirements are given for enclosing walls, doors, stairs, ramps, escalators, and other components of an exit system.

Shafts containing power, communications cable, combustible ducts or pipes, and other combustible materials should normally be enclosed and often firestopped at each floor. The reliability of the protection of combustible material penetrations through enclosure walls will normally be lower than for noncombustibles. If fire enters a vertical shaft containing combustible materials, it can spread rapidly upward, generate considerable smoke, and possibly spread to other floors.

Room or Suite Compartmentation

The goals of compartmentation in confining a fire to the room or suite of rooms of origin are generally the following:

1. Segregate a space that has a higher fire hazard than the surrounding area. This is commonly found around rooms or suites used for storage, trash, flammable liquids, furnaces, laboratories, maintenance, and shops such as woodworking or painting.
2. Compartmentation is also used to protect locations of high value or critical operations from a fire in the surrounding area. Computer rooms, control rooms, vaults, record rooms, and high-value storage areas are often protected from a fire involving the rest of the building.
3. Minimize risk of loss of an occupant of one space as a result of a fire in space controlled by another. This is common in apartments, office suites, motel/hotel rooms, row houses, and other multitenant buildings.

An added benefit is that compartmentation limits the size of the fire, which limits the amount of smoke that will be generated and facilitates fire suppression.

Properly designed and installed compartmentation has been successful in limiting many fires to the unit of origin. In a number of high-rise fires, occupants who were unable to escape safely through corridors were able to "sit out" a major fire in an apartment adjacent to theirs.[36] A common cause of "failure" of this level of compartmentation has been a door that did not have a closer or was left open.

When a single room is compartmented, there may be insufficient ventilation for a fire to develop fully unless a window is open or happens to break. Occasionally such fires will completely self-extinguish.

Protection of Corridors

Fire-resistive corridor partitions may be required to (1) protect the means of access to an exit for sufficient time to permit occupant evacuation or (2) provide a protected means of access to the fire department personnel. In addition, when used in conjunction with room-to-room or suite-to-suite fire-resistive separation, the corridor wall forms an element in preventing fire spread.

Corridor partitions in nonsprinklered buildings typically are required to have a 1-hour fire resistance rating, and codes may require the partition to extend from the floor to the underside of the floor above. Either automatic or self-closers are generally required on doors opening into the corridor. Since smoke entering the corridor is a significant problem, as the corridor provides access to the exits, automatic door closers, if used, are generally actuated by smoke detectors. Additional information on corridor doors can be found later in this chapter where protection for openings is discussed. Corridor walls that resist the passage of smoke have become common applications in some occupancies that are fully or completely sprinkler protected. These walls generally do not have a specified fire resistance rating. Their intent is strictly to restrict movement of smoke beyond the barrier.

Building Separation

Walls separating two buildings or dividing a building into separate fire areas limit the maximum probable property loss and also can divide one building into what is legally two or more buildings to comply with the height and area limits of building codes. Stability becomes a very important consideration in this class of wall. Although all fire separation walls must maintain their stability under fire exposure for their rated duration, walls separating buildings or dividing a building into two fire areas must maintain stability during a complete burnout on either side, which is often accompanied by structural collapse of the burned-out side.

If at least one of the buildings has a fire-resistive frame—such as reinforced concrete or protected steel—panel walls built in along a column line can provide fire separation. The frame must have sufficient resistance to withstand a fire of the maximum expected severity for that building. Care must be taken so that the floor construction will not adversely affect stability of the wall under fire exposure. In buildings of Type V (wood

frame), Type IV (heavy timber), or Type III (ordinary) construction, the combustible framing members can be tied into the fire wall so that they are self-releasing in case of collapse. The wall then remains supported by the framing on the unexposed side. The use of self-releasing framing is considered to have been generally successful in combustible construction but has questionable reliability in steel-framed buildings. Caution must be exercised in the design of these fire walls because some methods of framing combustible members into the wall will lower its fire resistance.

Freestanding fire walls are most commonly used in one- or two-story industrial and storage buildings of unprotected steel-frame construction. The maximum height is generally limited by economic considerations. A freestanding fire wall is entirely self-supporting under vertical loads and is not directly connected to the building framing. The adjacent building framing can provide support under horizontal loading. During a fire, the wall must be capable of acting as a cantilever to withstand all horizontal forces directed toward the fire side. Freestanding fire walls should be designed to withstand at least a 5 lb/ft^2 (24.5 kg/m^2) uniform lateral loading without any support from the framing on either side.[37]

Tension stress in mortar joints limits the height of unreinforced 12 in. (0.3 m) concrete block walls to 15 ft (4.6 m). Higher walls either require massive construction, which is rarely practical, or reinforcement. A common reinforcement technique is installation of vertical steel bars, anchored to the foundation, within hollow masonry units that are then filled with concrete. Reinforced pilasters can also be built into the wall at periodic points along the perimeter. A typical freestanding fire wall is illustrated in Figure 18.1.7.

Freestanding fire walls have very definite limitations under horizontal forces, which may preclude or restrict their use. They are particularly vulnerable to collapse under seismic loads and wind forces received by exterior walls. Additional support must be provided if the walls are temporarily used as an exterior wall or become an exterior wall as a result of a fire. Piping, conveyors, and similar items whose collapse in a fire will exert a horizontal pull should not pass through freestanding fire walls. Where they must, means should be provided to allow the penetrating items to break away without impacting the wall.

Fire walls in steel-frame buildings may be tied into the building structure so the forces of collapse on one side are resisted by the framing on the other side. The wall may be built along a column line and the columns and horizontal framing tied into the wall. The columns and framing in the wall line must be protected so that they have the same fire resistance as the wall. The walls have to be located in the framing so that the strength of framing on one side will be capable of withstanding the pull of collapsing framing on the other side. The construction of a typical tied fire wall is shown in Figure 18.1.8.

Fire separation between buildings can also be provided by two blank exterior walls of adequate fire resistance and located very close together. Each wall is tied to the frame in its building; collapse of the frame pulls the wall in, leaving the other wall to resist the fire.

Pipes, conveyors, cable trays, and similar through-penetrations of fire walls can present special problems in seismic areas. The need for mobility may conflict with opening protection

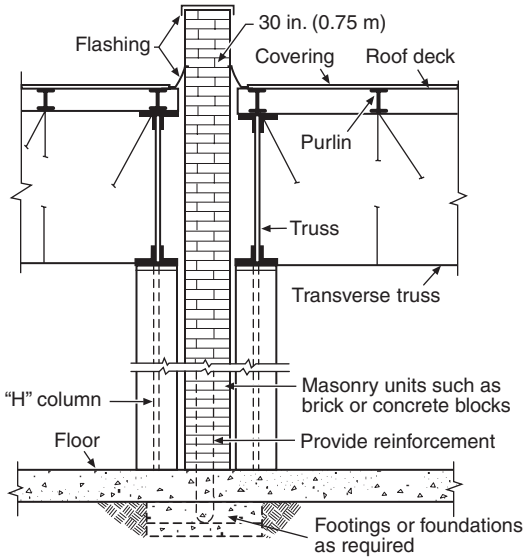

FIGURE 18.1.7 Typical Freestanding Fire Wall, Used at Expansion Joints or at Joints Between Buildings

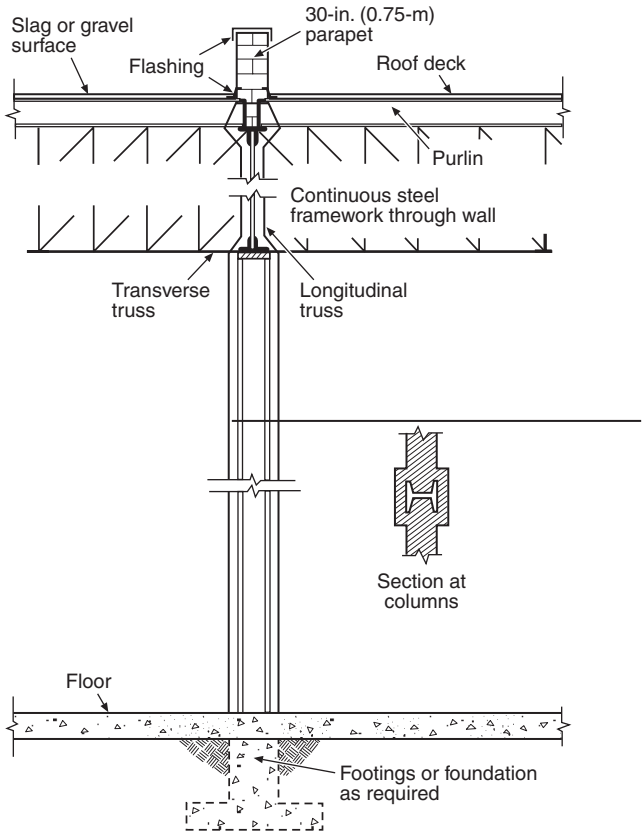

FIGURE 18.1.8 Typical Tied Fire Wall, Used with Continuous Building Framework

criteria. The complexity of the problem depends on whether the systems are to be designed to protect against one hazard at a time (fire or earthquake) or whether the simultaneous or consecutive occurrence of earthquake and fire should be considered in protection. See NFPA 221, *Standard for High Challenge Fire Walls, Fire Walls, and Fire Barrier Walls,* for minimum requirements for walls that separate buildings or subdivide buildings and prevent the spread of fire.

Fire Plumes Above Roofs

Fire walls must extend through and above a combustible roof to reduce the risk of fire spread over the top of the wall. Codes and standards typically call for fire walls to have a parapet 18 to 36 in. (0.46 to 0.9 m) above a combustible roof. The parapet minimizes the risk of direct flame spread over the fire wall and reduces the risk of fire spread by radiant heat from flames above the roof. The risk of direct flame spread over an 18 to 36 in. (0.46 to 0.9 m) high parapet is very low. However, risk of fire spread by radiant heat depends on the ease of combustibility of the roof surface, the height of the parapet, the dimensions of the fire plume through the roof of the fire zone, the wind velocity, and, if the roof covering is resistive to ignition by radiant heat, its insulating properties and the duration of the exposing fire. If a roof surface is combustible, the risk of fire spread by radiant heat past a parapet can be quite high.

The threat of fire spread by radiant heat over a parapet can be calculated using the thermal radiation values identified in Annex A of NFPA 80A, *Recommended Practice for Protection of Buildings from Exterior Fire Exposures,* and the plume dimensions.[38] Standard heat-transfer procedures can then be applied, using the formula:

$$I = I_o \Phi$$

where

I_o = Radiating intensity of the fire plume

Φ = Configuration factor or view factor

I = Unit incident radiation on the exposed surface

Instead of using the referenced radiant intensities, the average temperature of the plume flames can be estimated and the radiation calculated using the following relation:

$$I = \sigma T^4 \Phi$$

where

σ = Stefan-Boltzman constant

T = Absolute temperature

This assumes the flame plume is sufficiently thick so that it radiates as a black body.

The configuration factor for plume-roof relationships can be calculated using the formula found in a cited reference.[39] The effect of wind velocity, which deflects the fire plume, must be accounted for in calculation of the configuration factor. At high winds, a fire plume can be deflected such that it is almost horizontal above a burning roof. However, in high winds, a fire plume also tends to break up and is expected to be cooled by excess air. The angle of the fire plume selected is a matter of professional judgment; use of 45 degrees is considered reasonable by some engineers.

If the roof surface is combustible, the value of the incident thermal radiation calculated will indicate whether ignition of the roof is expected. If the surface is noncombustible or resistive to ignition by radiant heat, it is then necessary to calculate the temperature of the combustible subsurface material to which heat will be transferred from the surface. This is an unsteady-state heat transfer problem readily solved by standard numerical procedures.

A simple example of the calculation of incident thermal radiation can be used to illustrate the method of analysis. For the example, consider a 12 ft (3.7 m) high and 60 ft (18.3 m) wide frame building with a wood-surfaced roof. The building is subdivided by a masonry fire wall with a 3 ft (0.9 m) parapet (Figure 18.1.9).

The expected height of flames above the roof would be about 1.4 times the height of the building, or approximately 17 ft (5.2 m).[39] Assuming a flame temperature of 1400°F (760°C), the thermal radiation from the fire plume would be about 5.8 Btu/ft^2/sec (66 kW/m^2). In a moderate wind, a fire plume deflection of 45 degrees is possible. The maximum configuration factor would be about 0.3 and the incident radiation on the wood roof surface about 1.75 Btu/ft^2/sec (20 kW/m^2).

At an incident radiation of 1.1 Btu/ft^2/sec (12.5 kW/m^2), a wood roof can be sufficiently heated so that a small burning brand will ignite it;[40] this is referred to as pilot ignition. Since in the example the incident thermal radiation is well above that required for pilot ignition, flame spread over this fire wall is to be expected if the wind deflects the fire plume toward the exposed roof.

Fire-Resistive Wall Requirements for Structural Stability

Fire-rated wall requirements may be intended to ensure structural stability rather than to provide a fire barrier. In many cases,

FIGURE 18.1.9 Fire Plume Exposing a Wood Roof over a Parapeted Fire Wall

for example, hourly rated exterior bearing walls are permitted to have unlimited unprotected window areas; it is obvious that the rating refers to structural stability rather than provision of a fire barrier. Required fire ratings of interior bearing walls may or may not be intended to provide a fire barrier. Interior bearing walls with an hourly rating for fire separation do require protection of all openings; however, interior bearing walls that have an hourly rating only for structural stability purposes would not need opening protection. Caution must be exercised in selecting the proper hourly rating for interior bearing walls intended for structural stability only. A barrier separation wall is exposed to fire on only one side, where an interior bearing wall that would be providing only structural stability could be exposed to fire on both sides. The same hourly rating wall will not provide the same protection in both cases.

Fire-resistive walls of a high hourly rating are occasionally improperly specified to separate areas for protection against an explosion hazard rather than a long-duration fire. The fire resistance of a wall has no relationship to its ability to withstand explosion forces. A wall with a 1 hour rating may withstand explosion overpressures better than a wall with a 4 hour rating; no conventional wall will remain in place unless the explosion pressure is limited by venting or suppression.

PROTECTION OF OPENINGS

The protection for openings in a fire-rated wall generally has less resistance to fire spread than is provided by the wall. This is allowable because (1) easily ignited combustibles are not normally found against doors and other opening protection constructions, and (2) fire suppression forces can usually extinguish small localized fires that may spread past the wall. However, because openings do reduce the effectiveness of a fire barrier, fire doors generally cannot occupy more than 25 percent of the linear length of any fire separation wall. Clearances may be required in front of and to the sides of the opening to compensate for the differences between a wall rating and door rating.

Factors that reduce the fire resistance of opening protection as compared to resistance of walls include the following:

1. There is no maximum temperature-rise limitation on the unexposed sides of most types of fire doors. The unexposed side of steel doors may actually glow red during fire testing. When there is a limit to, or listing of, a temperature rise on a fire door, it applies only to the temperature rise during the initial 30 minutes of the fire test. (Temperature-rise limits are often specified in building codes for doors on exit stair enclosures.) Fire doors also buckle during the fire tests and are permitted to move out of their frames in a direction perpendicular to the plane of the door as much as 2.88 in. (73 mm). Some flaming is also permitted on unexposed sides of fire doors during the test procedures.

2. Requirements for the protection of duct penetrations place no limit on the temperature rise on the duct itself on the unexposed side of the wall.

3. Piping, cable trays, and conduit can penetrate fire walls and, although the opening must be firestopped, the temperature rise on the metal penetration itself would normally be above the 250°F (121°C) average or 325°F (161°C) single-point temperature-rise limit required of the wall. However, some codes require use of through-penetration firestopping systems that have a temperature-rise limitation on the penetrating item also.

4. The standard fire test furnace is operated at a pressure rating so that a neutral plane is established with the tested assembly. As a result of research studies, ASTM modified the test standards for fire doors and fire windows to require positive pressure testing of some elements. The neutral plane is established based on the assembly being tested. For example, within the first 5 minutes of the window test, the neutral plane is established so that at least the upper two-thirds of the window assembly is under positive pressure.

5. Vision panels and fire windows may transmit heat by both conduction and radiation.

6. Doors can become large radiators during early fire tests.

Thermally induced distortions of between 4 and 5 in. (102 and 127 mm) were observed on some foreign tests of swinging steel fire doors.[41] Considerably smaller distortions were noted with wood and insulated metal swinging doors. However, wood doors were noted as being more likely to fail by localized carbonation at hinges, locks, and knobs. Rolling steel fire doors generally do not deform appreciably during a fire. Large distortions of some rated fire doors, both wood and metal, were also reported in "Project Corridor," a series of fire tests conducted by the California State Fire Marshal in a simulated light-hazard occupancy.[42] In some countries, extensible bolts and latches are added to swinging steel fire doors so that the door is held in the frame at five or six points. Distortions of this type of door were reported to be under 1 in. (2.54 mm) during a standard fire test.[39]

However, the most common failure mode of fire doors observed in actual fires is not closing. This has occurred because of lack of maintenance; physical damage to the closer, door, guides, or tracks; blockage in the doorway; and other faults. Reliable fire door performance cannot be ensured unless doorways are kept clean and doors maintained in operating condition, as specified in NFPA 80, *Standard for Fire Doors and Other Opening Protectives,* and the manufacturer's instructions. Some common faults often observed on swinging fire doors include inoperative latches and improperly adjusted closing devices. Overhead and sliding doors that are not used regularly are particularly susceptible to track and guide damage. The closing mechanism on overhead doors is a more complicated and less visible mechanism than the closing mechanism on most other fire doors. Inspection, testing, and proper preventive maintenance are always essential.

Fire doors, windows, and shutters are the most widely used and accepted means of protecting openings in fire-resistive walls. Suitability of these closures is determined through tests by recognized testing laboratories, and untested doors cannot be relied on for effective protection. Fire door assemblies for the protection of openings depend on the use of labeled fire doors and frames (where frames are required) and listed or labeled hardware. Hardware for fire doors is referred to as "builder's hardware," which includes fire exit hardware and fire door hardware.

Doors must be installed in a properly constructed wall and floor so that fire cannot spread below, around, or above the door. Special noncombustible sills are required for door openings in buildings with combustible floors, except for openings protected by 20 or 30 minute doors. However, combustible floor coverings may extend through openings protected by fire doors rated at 1½ hours or less if the cover has a critical radiant flux of 0.22 W/cm^2 or greater. Critical radiant flux is to be determined per NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source.* In general, the critical radiant flux for vinyl sheet and flooring, wool carpet, and some synthetic carpets will exceed 0.22 W/cm$^{2.}$ Combustible floor coverings may not extend through openings required to be protected by 3-hour or higher-rated doors.

Classification of Openings, Doors, and Windows

Fire doors are now rated according to the duration of fire exposure and, optionally, the temperature rise on the unexposed surface after 30 minutes, when tested as per NFPA 252, *Standard Methods of Fire Tests of Door Assemblies.* Doors are rated as 4 hour, 3 hour, 1½ hour, 45 minute, 30 minute, and 20 minute. Temperature rises are listed at 250, 450, and 650°F (121, 232, and 343°C); absence of a temperature rating indicates a rise of over 650°F (343°C) on the unexposed surface of the door after 30 minutes of testing. There is no temperature rise limitation for most types of fire doors. Fire doors tested under NFPA 252 are exposed to a standard temperature-time curve and a hose stream test. The hose stream test is not always required by the authority having jurisdiction for 20 and 30 minute doors. Those doors that are fire tested without a hose stream test indicate this fact on the label. The categories in which fire doors are classified are also identified on the label; these include access, bullet-resisting, chute, curtain, dumbwaiter, freight elevator, rolling steel, service counter, sliding, special-purpose, and swinging-type doors.

Existing fire doors and windows may be classified by an hourly rating designation, an alphabetical letter designation, or a combination of these. At one time the alphabetical letter designation was one method commonly employed to classify the opening for which the fire door is considered suitable. Traditionally, the relationship between the alphabetical designation and its use was as follows (from NFPA 80, Appendix E):

1. Class A—Openings in fire walls and in walls that divide a single building into fire areas
2. Class B—Openings in enclosures of vertical communications through buildings and in 2 hour rated partitions providing horizontal fire separations
3. Class C—Openings in walls or partitions between rooms and corridors having a fire resistance rating of 1 hour or less
4. Class D—Openings in exterior walls subject to severe fire exposure from outside the building
5. Class E—Openings in exterior walls subject to moderate or light fire exposure from outside the building

The alphabetical classification of the opening does not apply to the closure; however, in actual practice, the distinction between opening classification and door classification was rarely maintained. A 3 hour door for use in a Class A opening was commonly called a Class A door.

Building codes and NFPA 80 commonly specify a door by its fire-protection rating instead of by the classification of opening to be protected. Fire doors are now available with ½ hour and ⅓ hour ratings, which do not fall within the specified protection criteria for the classes of opening. The following paragraphs summarize current application of doors, windows, and shutters for openings in fire-resistive walls.

Four and Three Hour Fire Doors. Openings in walls separating buildings or dividing a building into different fire areas are generally protected by 4 or 3 hour fire doors. Many codes only require 3 hour fire doors in separation walls required to have a fire resistance of 3 hour or more. However, some authorities require two 3 hour fire doors, one on each side of the opening, whenever a wall is required to have a fire resistance of 4 hours. Four-hour fire door listings are relatively recent, and their availability may not be reflected in all codes.

One-and-One-Half Hour Fire Doors. Openings in 2 hour enclosures of vertical openings in buildings are protected by 1½ hour fire doors. Many codes also permit the use of 1½ hour fire doors to protect openings in walls separating buildings or dividing buildings into different fire areas when the wall is only required to have a fire resistance of 2 hours. One-and-one-half hour fire doors are used in walls required to have a 2 hour fire resistance to enclose hazardous areas.

One-and-One-Half Hour Fire Doors and Shutters. Openings in exterior walls that can be subjected to severe fire exposure from outside the building are protected by 1½ hour fire doors and shutters.

One Hour Fire Doors. Openings in 1 hour enclosures of vertical openings in buildings, such as stairs, shafts, and exit enclosures, are protected by 1 hour fire doors.

Three-Quarter Hour Fire Doors. Openings in room partitions and walls around some hazardous areas are protected by ¾ hour fire doors. Sometimes they are also permitted in partitions that subdivide floors of a building. Although ¾ hour fire-rated doors are for use in 1 hour corridor partitions, many codes permit installation of other types of doors, such as ½ or ⅓ hour fire-rated or 1¾ in. (45 mm) solid-bonded wood-core doors. Either automatic closers or self-closers are generally required on corridor doors. Since control of smoke is also necessary to protect a corridor as an access to an exit, automatic closers are generally actuated by smoke detectors.

Three-Quarter Hour Fire Doors and Shutters. Openings in exterior walls subject to a moderate or light fire exposure from outside the building are protected by ¾ hour fire doors and shutters.

Three-Quarter Hour Fire Windows. Openings in corridor or room partitions or in exterior walls subject to a moderate or light external fire exposure can be protected by ¾ hour fire windows.

One-Half Hour and One-Third Hour Fire Doors. Doors with these ratings are for use where control of smoke is a primary consideration. They are also used for the protection of openings in partitions between a habitable room and a corridor when the wall is constructed to have a fire-resistance rating of not more than 1 hour or across corridors where a smoke partition is required. Some codes permit the use of 1¾ in. (45 mm) solid-bonded wood-core doors in corridor, room, and smoke-stop partitions that are required to have a fire resistance of not more than 1 hour. These doors cannot be used for corridor doors to hazardous areas or to protect openings in enclosures of vertical openings in buildings.

Types of Doors

There are several types of construction for fire doors, which are described in the following paragraphs.

Composite Doors. These are of the flush design and consist of a manufactured core material with chemically impregnated wood-edge banding and untreated wood-face veneers or laminated plastic faces or are surrounded by and encased in steel.

Hollow Metal Doors. These are of formed steel of the flush and paneled designs of 20 gauge or heavier steel. These doors may include a honeycomb core.

Metal-Clad Doors. These are of flush and paneled design consisting of metal-covered wood cores or stiles and rails and insulated panels covered with steel of 24 gauge or lighter.

Sheet-Metal Doors. These are of formed 22 gauge or lighter steel and of the corrugated, flush, and paneled designs.

Rolling Steel Doors. These are of the interlocking steel-slat design or plate-steel construction.

Tin-Clad Doors. These are of two- or three-ply wood-core construction, covered with 30 gauge galvanized steel or terneplate (maximum size 14–20 in. [0.36–0.51 m]) or 24 gauge galvanized steel sheets not more than 48 in. (1.2 m) wide.

Curtain-Type Doors. These consist of interlocking steel blades or a continuous formed-spring steel curtain in a steel frame.

Wood-Core Doors. These doors consist of wood, hardboard, or plastic-faced sheets bonded to a wood block or wood particleboard core material with untreated wood edges.

Unrated Door Protection

The fire resistance of existing doors can be improved by coating the doors with an intumescent paint, although no formal fire resistance rating for such a door has been established. This method is not commonly accepted in the United States, although it has been used in England. Intumescent paint is listed for reducing flame spread, not for improving fire resistance. However, tests conducted by NBS showed that a single layer of intumescent paint, 7 to 8 mil (0.18 to 0.20 mm) thick, significantly delayed char penetration into a soft wood joist.[43] Ordinary wood-panel doors, in which both door and frame were coated with two layers of intumescent paint, withstood fully developed room fires similarly to 1¾ in. (44.5 mm) thick solid-core wood doors in simulated nursing home room fires.[19] In another test, a wood-panel door was protected with gypsumboard on the thin panel and intumescent paint on the remainder of the wood. This upgraded door withstood a standard fire test, modified to simulate the positive pressure of a room fire, longer than a 20 minute rated fire door.[44] However, there is no fire protection rating assigned to any upgraded fire doors; it is entirely up to the authority having jurisdiction whether or not this upgraded door is acceptable for improving the fire safety in existing buildings.

Glazing for Fire Doors, Windows, and Walls

Glazing materials are available for use in fire-rated doors, windows, and walls; they are used as vision panels in fire doors and as windows in fire-rated corridor walls. In addition, they are frequently used in smoke-stop barriers and to enclose open stairways in older buildings.

Wired glass was historically the only transparent material that could be used in fire-rated doors and windows. It is a glass sheet containing an imbedded net of steel that helps distribute heat, lowers thermal stresses, and increases the strength of the assembly. When exposed to a fire, the glass starts cracking after a minute or two but does not open up. The glass begins to weaken when heated to about 1470°F (799°C) and gradually starts to soften. At about 1600°F (871°C) it deforms so badly that it will drop out.[39] Its normal 45 minute fire resistance rating corresponds to 1638°F (892°C) on the standard temperature-time curve. In actual fires, the endurance of wired glass is temperature dependent; if it is never heated above the temperature at which it weakens, it could remain in place for an extended period of time. Wired glass has been the most economical fire protection–rated glazing material.

Clear fire protection–rated glazing has been developed as an alternative to wired glass and to provide a higher hourly fire rating than had been possible with wired glass. These products include fire protection–rated glass and transparent ceramics as well as fire resistance–rated glass. The clear glazing provides more architectural freedom to achieve openness while still meeting building codes' often increased compartmentation requirements. Clear fire protection–rated glazing materials that also can provide security protection are available.

Glazing materials for use in fire-rated windows, doors, frames, and sidelights are tested in accordance with NFPA 257, *Standard on Fire Test for Window and Glass Block Assemblies.* This test includes exposure to a standard temperature-time curve fire on one side for the rated period of time, plus the hose stream test. There also are fire-resistant glazing materials that are suitable for use in specific wall and partition assemblies. These are

tested in accordance with NFPA 271, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter.* This test includes the same temperature-rise limitation on the unexposed surface of the glazing material as on the wall.

Vision panels are permitted in fire doors rated at 3 hours or less. However, vision panels in 3 hour fire doors and fire doors with a 1½ hour rating used in protecting severe exterior exposures must be tested as a component of the door assembly in accordance with NFPA 252. These vision panels are limited to 100 in.^{2} (0.065 m^2) or less. Wired glass may not be used in 3 hour fire doors or 1½ hour doors used for severe exposure protection. Vision panels used in 1½ hour and 1 hour fire-rated doors is limited to the maximum area tested. In ¾ hour rated doors and windows and 20 and 30 minute doors, wired glass is limited to 1296 in.^{2} (0.84 m^2) per light with a maximum dimension of 54 in. (1.37 m). In all applications, the maximum exposed area and area per light for glazing material other than wired glass are listed individually for each product.

Glazing materials used in fire doors, windows, sidelights, and commercial lights must also meet applicable safety standards if these are subject to human impact. These current standards include the U.S. Consumer Product Safety Commission (CPSC) *Safety Standard for Architectural Glazing* and the less stringent, in terms of impact resistance, ANSI Z79.1, *Safety Performance Specifications and Methods of Test for Safety Glazing Materials Used in Buildings.* Wired glass is specifically exempt from the CPSC standard but not the ANSI standard.

Glazing materials in fire doors, windows, and frames are commonly installed on the job site and not provided by the manufacturer of the fire door. The door manufacturer provides grooves in the door for the glazing, and the glazing manufacturer or distributor supplies the glazing in the necessary light sizes. NFPA 80 requires each light to have a visible listing mark when installed. This mark may be the only way to identify whether the glazing installed is clear fire protection–rated material or ordinary commercial glass. Installation and caulking requirements are very specific and specified in the individual listings. Grooves and installation methods and materials used for wired glass will generally not be suitable for use with other glazing materials.

Vision panels and windows differ from a solid wall primarily in the transmission of radiant heat. Conductive heat transmission is also increased, but high conductive heat transmission is also found in doors, door and window hardware, and frames. The intensity of radiant heat, I, to which a combustible or person would be exposed through a wired-glass panel from a fully developed room fire, is given by the following formula:

$$I = k\Phi I_0$$

where k is the transmissivity of the window, Φ is the configuration factor, and I_o is the radiant intensity of the exposing fire. This equation may be used for U.S. customary or SI units, as long as their use is consistent.

A radiant intensity of 5 Btu/ft^2/sec (57 kW/m^2) has been measured for a room fire involving ordinary residential furnishings with average ventilation, such as an open door.[45] Measurements of well-ventilated fires in light-hazard occupancies indicate a peak radiant intensity of 7.4 Btu/ft^2/sec (84 kW/m^2).[30] Transmissivity of glass windows is reported to range from 0.4 to 0.6.[40] These values of transmissivity are reasonable for the early period of fire exposure; as the glazing is exposed to the fire for a period of time, its transmissivity will be reduced. The configuration factor can be determined from any specific situation for graphs found in most heat-transfer texts.

If wood on the unexposed side of the wired glass is exposed to a radiant intensity above 3 Btu/ft^2/sec (34 kW/m^2), autoignition may occur. Most synthetic materials will require a higher level of radiant heat intensity for autoignition.

When wired-glass panels are installed in walls on a dead-end corridor or other location in which building occupants have no alternative escape path, the heat radiated through the glass may prevent escape. If persons moving past the glass absorb sufficient heat to cause severe pain, their ability to escape could be impaired. The human threshold of severe pain for exposure to radiant heat depends on both the intensity and the time over which it is received. Experimental data that have defined this limit[46] can be approximated by the following equation:

$$Q_{max} = 2.3t^{0.25} \leq 45 \text{ sec}$$

where Q_{max} is the total heat absorbed by the skin in Btu/ft^2 (W/m^2) over t seconds at the threshold of severe pain. As a person moves past the wired-glass panel, the view factor, Φ, will change. The absorbed heat can be calculated by determining Φ for a number of points along the person's path and using a stepwise integration over the time required to move past each point. The normal walking speed used in exit calculations is 3.5 ft/sec (1.07 m/sec).[9] If the total heat absorbed exceeds the limits in the equation, the escape of occupants past the wired-glass panels may be impaired.

Fire Blocking and Firestop Protection

The term *fire blocking* is used to describe both barriers to restrict the spread of fire in concealed spaces. Materials used to fill gaps around penetrations in walls and ceilings are called firestop devices or systems.

In wood-frame construction, the normal fire block inside walls and ceiling spaces is a 2 in. (50.8 mm) thick (nominal) piece of lumber. However, for other applications, fire blocking should normally be noncombustible and have a sufficiently high melting point so that it will remain in place under fire exposure. Gypsum board, sheet metal, plaster, brick, cement grout, mineral fiber insulation, fire blocking, and ceramic fiberboards are all examples of commonly used fire blocking. Firestop systems protect penetrations of fire-rated walls and floors by noncombustible pipe or tube, and conduit has commonly been provided by filling the annular space around the penetrant with a noncombustible material, such as cement grout, mineral wool, cement plaster, and so forth. This type of firestop system is regarded as having performed effectively in actual fires. However, lack of firestop systems[29,30] or improperly protected openings, such as the combustible foam plastic used at Brown's Ferry Nuclear Plant,[47] have been responsible for a number of serious fire losses.

Considerable attention and research have been directed toward wall and floor penetrations by plastic drain, waste, and vent

(DWV) pipes.[48–51] Full-scale tests have shown that the integrity of a 2 hour fire-resistive chase enclosure could be maintained by encasing the pipe in an 18 in. (0.46 m) steel sleeve and penetrating the chase at a 45 degree downward angle. These results were applicable to 3 in. (76 mm) laterals of both PVC and ABS DWV pipe. Unless otherwise tested and approved, chases should be firestop protected at each floor. In many buildings, much of the plumbing is installed in wall cavities. Use of plastic DWV pipe inside fire-resistive wall assemblies has been extensively tested, and a number of methods of protection that will not compromise the fire resistance or create a risk of vertical fire spread have been identified.

Cable-tray penetrations present another challenge; the size of the penetrant is large and contains a mixture of combustible and noncombustible material. Research and development programs were sponsored by the Nuclear Regulatory Commission (NRC) on firestops for use in nuclear power plants. The results of these programs, plus work by suppliers, led to new firestop products.

Building codes require approved and tested firestops wherever conduit, pipe, cables, or other utilities pass through fire-rated—and sometimes non-fire-rated—walls, floors, and ceilings. These firestop products can be qualified under either ASTM E814, *Standard Test Method for Fire Tests of Through-Penetration Fire Stops,* or under a fire exposure corresponding to ASTM E119, *Standard Test Method for Fire Tests of Building Construction and Materials.* The test furnace must be operated at a specified positive pressure, such as 0.01 or 0.03 in. of water column (2.5 or 7.5 pascal). Currently, neither of these tests evaluates smoke spread.

There are two types of tested firestop protection: (1) through-penetration firestop devices and (2) through-penetration firestop systems. The firestop devices are manufactured products used primarily for protecting cable and poke-through penetrations. Through-penetration firestop systems are field-installed constrictions for protecting penetrations of floors or walls by conduit, pipe, duct, cable, cable trays, and so forth. The basic standard used to investigate these firestops is UL 1479, *Standard for Safety Fire Tests of Through-Penetration Firestops,* which is based on ASTM E814.

ASTM E814 was developed for evaluating firestops that are installed to prevent spread of fire through an opening where cable trays, pipe, conduits, ducts, and so on, pass through a wall or floor. This standard was first published in 1981. The ASTM E814 test has many similarities to ASTM E119, but it can be conducted on a much smaller scale and at a documented positive pressure. In addition, all test items are subject to a hose stream test similar to that required for some constructions tested under ASTM E119. ASTM E119 requires testing of at least a 100 ft^2 (9.3 m^2) sample of a wall and a 180 ft^2 (16.2 m^2) sample of a floor. A wall or floor sample less than 9 ft^2 (0.83 m^2) can be used in ASTM E814. The ASTM E814 furnace is heated to follow the temperature history of ASTM E119. There is no standard "aging" test for the new firestop materials; one proprietary product recently was recalled because its reliability apparently deteriorated with age.

Two types of hourly time ratings are established for a tested firestop: F and T. The conditions for these ratings are broader. The F rating is a measure of the ability of the firestop system to maintain its physical integrity under the fire exposure and hose stream tests and to prevent occurrence or passage of flame on the unexposed surface. The T rating is intended to measure whether combustible materials on the unexposed side of a fire barrier would be ignited by conduction of heat through the firestop material or along the penetrating conduit or pipe. The same maximum temperature limit is used in the ASTM E814 test as in the ASTM E119 test. The hourly F or T rating is the duration of the fire test that the through-penetration firestop system passed.

The T rating achieved can be less than the F rating; there is nothing similar to this in the ASTM E119 test. If the temperature limit is reached before the completion of a successful test for an F rating, the T rating will be based on the time at which the temperature limit was reached. However, the F rating assigned would be the total hourly duration of the successful test. Building codes that require firestop systems tested under ASTM E814 differ as to if and when a T rating is necessary.

There are many types of listed through-penetration firestop system constructions, ranging from relatively simple to complex arrangements. A typical through-penetration firestop system requires installation of both a form and a fill material. The form material is generally a ceramic fiber mat; a hole the size of the penetrating conduit (or pipe) is cut in it and the form is slipped over the conduit into the opening in the wall or floor. The form material serves to place and restrain the fill material that is installed in the annular space around the conduit to a specified thickness. Fill materials include one- and two-part foams, silicone elastomers, proprietary caulking and grouting materials, and specific proprietary cementitious mixtures.

Some through-penetration firestop systems also require use of an additional filling material, such as ceramic fibers, and some only require a single material, such as a proprietary caulk or grout. There are a number of through-penetration firestop systems that are much more complex and require additional features, such as sleeves, special supports to retain the system in the opening, and insulation on the conduit or pipe extending out from the surface of the floor or wall.

Some of these systems permit penetrating items to be easily removed or replaced. This facilitates future additions of pipe, tube, or cable through the penetration opening. However, restoration of the integrity of the original firestop may or may not be possible under the conditions of the system's listing by a testing laboratory. Any additions or changes that require removal and restoration of a through-penetration firestop system have to be tightly controlled so that (1) the restoration is performed in an approved manner, (2) the allowable number of penetrating items is not exceeded, (3) only permitted penetrants are installed, and (4) adequate clearances are maintained among penetrating items and between penetrating items and the sides of the opening.

Some designs for curtain walls, particularly in high-rise buildings, offer the danger of vertical spread of fire behind the curtain walls for the entire height of the building. This can occur when the panels of a curtain wall do not rest tightly for their full length on a floor slab. Rather, there is a continuous relieving angle attachment between the panels and the floor slab, creating vertical flue spaces between the panels and the end of the

floor slab. Where fire blocking is not inherent in the design, it is necessary to fill this space with appropriate fire block materials. This arrangement is generally less satisfactory because of the tendency for both expansion and contraction of the exterior wall and the likelihood of maintenance operations causing unplanned openings through and around the firestopping.

Atria

Atria, which are common in many new buildings, depart from the traditional compartmentation concept of fire containment by enclosing all vertical openings. Alternative arrangements must be provided in atrium buildings to achieve the same level of protection found in buildings using the traditional compartmentation concept. The occupancy should be one in which a rapidly spreading fire would not be encountered, and all occupants should be expected to be aware of any hazards before they are endangered, and in time to move to a place of safety if necessary.

Fire protection in atrium buildings is generally provided by a combination of methods, such as compartmentation, ventilation, automatic suppression, and contents and material control. NFPA *101* requires atria in new construction to be separated from adjacent spaces by fire barriers having at least a 1 hour fire resistance rating. However, as many as three levels of a building may open directly to the atrium without the need for a fire-resistive barrier. As an alternative where 1 hour barriers are normally required, glass walls may be used, provided there are sprinklers spaced 6 ft (1.8 m) apart and not more than 1 ft (0.3 m) from the glass along both sides of the glass wall. The sprinklers must be located to ensure that the glass surface is wet when the sprinklers operate. Sprinklers are not required on the atrium side of the glass wall if there is no walkway or other floor area on that side above the main floor level.

Large-volume atria will dilute fire gases and, with proper ventilation, direct their flow safely to the outside. Small atria may not have the capacity to dilute fire gases, although if they are properly designed and ventilated, fire gases can be channeled to the outside and the risk of horizontal fire spread minimized.

SUMMARY

Barriers can protect people and property by confining a fire to its area of origin until it either is extinguished or burns itself out. Fire resistance ratings of barriers are based on fire endurance tests and are measured in hours or fractions thereof. The basis for almost all fire-resistive testing is the standard temperature-time curve.

The concepts of fire severity and fire load, although technically obsolete, are still used to make conservative estimates of the maximum severity of a fire. Fire load is a measure of the maximum heat that would be released if all the combustibles in a given area burned. Fire modeling is based on mathematical models that calculate the temperature history of room fires as a function of ventilation, fuel, and the walls and ceiling of the room. The most widely used models in the United States are zone models, exemplified by the CFAST component of HAZARD.

Several aspects of a building can affect fire spread, among them concealed spaces, vertical openings, compartmentation, fire-resistive corridor partitions, fire walls, and the protection of openings in the fire walls.

Chapter 2

Interior Finish

Revised by

Marcelo M. Hirschler

Chapter Contents

Interior Finish and Trim Concepts
Fire Tests for Interior Wall and Ceiling Finish Materials
Fire Tests for Interior Floor Finish Materials
Types of Interior Finish
Role of Interior Finish in Fires
Methods of Application
Full-Scale Tests

Key Terms

cone calorimeter, critical radiant flux test, flame spread index, flashover, flooring radiant panel test, full-scale test, interior finish material, interior lining material, lateral ignition and flame spread test (LIFT), methenamine pill test, room corner test, smoke density chamber test, smoke developed index, Steiner tunnel test, trim material

The best fire protection strategy for buildings is one that limits fires to a small size. In instances where fires eventually do become large, the fire growth rate must be slow enough to give occupants time to react or to give emergency responders enough time to respond and combat the fire manually and to rescue trapped victims while the fire is still limited in size.

Fires need to be limited in size because fire hazard is related to fire size. A material's burning rate—measured by its heat release rate—is the single most important parameter affecting fire hazard, because burning rates determine fire size. Burning rates directly affect temperature rise and the mass loss rate. Furthermore, mass loss and heat release also control the amount of smoke (and soot) released into a given volume, which determines visibility and thus the ease of escape or rescue of fire victims. Moreover, in a given volume, heat release and mass loss rates also affect the amounts of toxic products generated, which determines toxic hazard.

Large fires in buildings always represent an acute threat to occupants, irrespective of what is burning; and the faster a fire grows to a large size, the greater the threat. Any building material, furnishing, or content will have undesirable fire properties if its presence could cause a fire that would otherwise stay small to become large. For that reason, the use of furnishings and contents, especially including interior finish, with superior fire performance is a way to passively protect building occupants from the dangers of fire. Once a room fire has progressed so that the upper layer temperature approaches 1112°F (600°C) and that layer becomes thick, descending toward the lower portion of the room, all combustible furnishings and combustible room contents may be ignited, leading to flashover or full room fire involvement. Although some fires involve extended periods of slow, undetected fire development, fires that cause large life loss or high property loss nearly always grow rapidly to large size. Such fires typically reach flashover, or full room involvement, within minutes of having been small and easy to control. Therefore, prevention of flashover is a key strategy for lowering fire hazard. NFPA 555, *Guide on Methods for Evaluating Potential for Room Flashover,* is a guide for considering ways to prevent flashover.

Building interior finishes, principally wall and ceiling linings, can have a major impact on both fire growth and ultimate fire size. Interior wall and ceiling linings may act like fuses, spreading flames away from fire origin to involve other objects, causing the fire to grow to large size. Interior finishes may also provide a large, unbroken surface over which flame spreads. As the flame spreads to involve greater surface area, a fire's rate of heat release, and, therefore, the fire size increases. If the interior finish exhibits poor fire performance, the flames from the interior finish may release sufficient energy to cause the formation of a hot gas layer. Combustible interior finishes, such as low-density fiberboard ceilings, wood paneling, textile wall coverings, and combustible floor coverings, have been found in the past to be significant factors in many major fires, including some that became multiple death fires.[1–11] In recent years there have been fewer cases where interior finish has led to fire fatalities, but interior finish is still a major fire problem. The NFPA Fire Analysis and Research Division publishes yearly reports on fire loss statistics and the 2005 report[12] shows that interior finish was responsible for being the item first ignited in 22,900 fires in homes annually between 1999 and 2002 (just over 6% of the total) , which resulted in 261 civilian annual fire fatalities (just under 9% of the total). Worldwide, relatively recently there have been two major nightclub fires with multiple fatalities that were primarily associated with the use of inadequate interior finish materials, which were the items first ignited: the West Warwick, Rhode Island, fire on February 20, 2003, caused 100 fatalities [13,14] and the Buenos Aires, Argentina, fire on December 30, 2004,

Dr. Marcelo M. Hirschler is a consultant with GBH International in Mill Valley, California.

caused 193 fatalities.[15] In both fires, there were multiple code violations and other issues.

Interior finishes are regulated by codes, including NFPA *101*®, *Life Safety Code*®, and by *NFPA 5000*®, *Building Construction and Safety Code*®, to slow initial fire growth and to reduce the likelihood of fire growing to a large size. In fact, the sections addressing interior finish in NFPA *101* and in *NFPA 5000* (Chapter 10 in both codes) are correlated, and both are under the jurisdiction of the same NFPA technical committee, the Technical Committee on Furnishings and Contents.

This chapter reviews the effect of interior finish materials on fire growth. In order to properly evaluate the fire performance of interior finish materials, the fire tests to be used must be suitable for that use. Thus, after broadly looking at what interior finish and interior floor finish entails, the fire tests that can be used for evaluation of interior wall, ceiling, and floor finish materials will be addressed. This chapter then examines ways in which fire behavior requirements can be amended for certain specific interior finish materials to ensure that each type of material can be used safely. This chapter examines the method of application of interior finishes and the effect this can have on fire behavior. This chapter also contains some discussion of decorative materials, mainly by contrast to interior finish materials, and with an indication of the unique issues associated with them.

See also Section 3, Chapter 5, "Introduction to Fire Modeling"; Section 6, Chapter 1, "Fire Hazards of Materials"; and Section 6, Chapter 3, "Concepts and Protocols of Fire Testing."

INTERIOR FINISH AND TRIM CONCEPTS

Most codes, such as NFPA *101* or *NFPA 5000,* define interior wall and ceiling finishes as "the exposed surfaces of walls, ceilings, and floors within buildings" with the following explanation: "Interior finish is not intended to apply to surfaces within spaces, such as those that are concealed or inaccessible. Furnishings that, in some cases, might be secured in place for functional reasons should not be considered as interior finish." Thus, interior finish are those materials or assemblies of materials that form the exposed interior surfaces of walls and ceilings in a building. Interior wall finishes also include the interior finish of columns, fixed or movable walls, and fixed or movable partitions. Interior finish materials include materials such as wood, plaster, wallboard, acoustical tile, wall and ceiling coverings, plastics (including light-transmitting plastics), and insulating materials. Interior finish materials also include interior floor finishes, which tend to be a less severe fire problem, because heat and smoke rise in a fire. Interior floor finishes are the exposed floor surfaces of buildings (floors, ramps, stair treads and risers, and other walking surfaces) and include floor coverings, such as carpets and floor tiles, that may be applied over, or in lieu of, a finished floor. The term *interior lining* or *lining material* is used by the international fire community to define interior finish and the role of interior surfaces in the growth of fire in the room of origin. The term *interior lining* is not gaining very wide acceptance in North America and is unlikely to replace the term *interior finish,* at least in the near future.

There is some variability in the way interior finish regulations are applied. For example, some regulatory officials consider countertops and building cabinets as interior finish, and they are explicitly regulated as such in many transportation environments. It is sometimes difficult to differentiate between interior finishes and furnishings. Furnishings, although in some cases fastened in place, are not normally considered interior finish. For example, fixed plastic-covered restaurant "booth" seating and permanently mounted work counters and cabinets at a nursing station in a health care facility are not usually classified as interior finish.

Interior trim represents the picture moldings, baseboards, handrails, door and window frames, and similar decorative or protective materials used in fixed applications. Interior trim is ordinarily regulated as an interior finish. However, the requirements for trim and other incidental finish materials (like doors) are more lenient than those for the remainder of the wall and ceiling interior finish, when the trim or incidental finish is less than 10 percent of the aggregate wall and ceiling area. The "10 percent rule" is intended to be based on the trim or incidental finish being uniformly distributed and lacking sufficient continuity to allow flames to spread over any significant surface area. Concentration of the trim in one area, so that the trim forms one "fuel package," would violate the principle underlying the "10 percent rule."

Movable walls, folding partitions, and flexible or folding door assemblies are all normally treated as interior finishes. Movable partitions, used for example as a portion of office furnishings or work stations, are regulated as interior finish. Office cubicle partitions and work stations are sometimes formed of textile materials mounted over various substrates. Full-scale tests at the National Institute of Standards and Technology (NIST) involving office work stations consisting of computer terminals, 5 ft (1.5 m) high partitions of textile covering over fiberglass on metal frames, wood desks, and typical office contents revealed that fires involving such work stations may reach large sizes in 300 to 600 seconds.[16,17]

FIRE TESTS FOR INTERIOR WALL AND CEILING FINISH MATERIALS

The nature of interior finish materials and the fire environment to which they may be exposed vary so widely that development of a fire test becomes highly complex. The following three factors must be taken into account:

1. The start and growth of fire in a building is affected by the ignition source, space geometry, ventilation, and by the nature, amount, and location of other processes and materials in the building.
2. There are many time-varying events associated with fires, such as oxygen concentration, rate of heat release, and effects caused by protection systems.
3. Materials vary in form, composition, density, and application.

With these variables in mind, the difficulty in designing a test that will provide a basis for predicting performance under a specific fire exposure becomes obvious. Equally obvious is the impracticality of designing tests to represent all fire conditions. A test designed to represent a "typical" fire or to expose materials to one set of "standard test" conditions may not provide a reliable basis for predicting real-life performance of all materials tested. Thus, there is a constant search for improved test methods that will provide a range of results for a variety of fire conditions.

However, the traditional test for interior finish fire performance, which is NFPA 255, *Standard Method of Test of Surface*

Burning Characteristics of Building Materials (Steiner tunnel test, which also has equivalent designations ASTM E84 and UL 723), is still being widely used in the United States. In recent versions of codes alternative testing of interior finish materials is permitted by the use of a room-corner test: NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth.* The major reason for using the room-corner test is that it assesses interior finish in a realistic room scenario and measures the key fire property, heat release,[18] and therefore results of room-corner tests are more reliable than results of tunnel tests. The Steiner tunnel test has been found to be an adequate fire test for traditional building materials and for materials that are not very thin and that remain in place during the test. However, many modern interior finish materials and systems are more complex than that and may not be suitably assessed by the Steiner tunnel fire test. A discussion on fire testing of interior finish was published recently.[19]

The use of bench-scale test data to predict product behavior through the use of models has been under study for many years, but there is no agreement yet in the United States on using such tests for regulatory purposes. Use of data from bench-scale tests, such as the cone calorimeter and the lateral ignition and flame spread test (LIFT apparatus),[20,21] to predict product behavior under a variety of circumstances may result in improved regulation of interior finish materials in the future. The models are fairly adequate in linking the actual fire hazard associated with the use of a product in a specific situation to regulatory limits.[22–26] This future form of regulation must be contrasted with the current regulation of interior finishes using the traditional standardized procedure (NFPA 255) or the more modern heat release tests (such as NFPA 286) in which the behavior of one product is simply compared with another. At present, this is still a practical approach for building regulation; however, one should understand that good behavior in a standardized test (such as NFPA 255) does not necessarily ensure good behavior in an actual fire, particularly when dealing with nontraditional materials and with complex systems. For example, it has been industry practice to evaluate movable partitions as an assembly in the Steiner tunnel test. There is concern that the NFPA 255 flame spread indices may not be suitable to predict the performance of certain movable or fixed partitions in fires without the benefit of adding supplemental restrictions such as the presence of sprinklers or limiting the height of the partition. Similarly, products such as foam plastic insulation have been identified, in building and fire codes, as materials for which NFPA 255 test protocol is not appropriate.

Steiner Tunnel Test

The 25 ft (7.62 m) Steiner tunnel test, also known as NFPA 255, ASTM E84, and UL 723, was developed by A. J. Steiner at Underwriters Laboratories Inc.[27–30] After a series of fatal fires, the need for a method of controlling interior finishes was recognized and the use of the tunnel test proposed. The method was adopted by the American Society for Testing and Materials (ASTM, now ASTM International) as a tentative standard in 1950 and as an official standard in 1958 (as ASTM E84). NFPA adopted the test method tentatively in 1953 and officially in 1958 as NFPA 255. In both organizations it has been revised periodically.

Figures 18.2.1 and 18.2.2 show the general appearance and basic layout of the tunnel test apparatus. A detailed description can be found in NFPA 255. In summary, a 20- to 24-in. (508- to 610-mm) wide by 24-ft (7.3-m) long test specimen (normally up to 0.15 m thick) is placed face down on a ledge at the top of the furnace to form the ceiling of the test chamber. A gas burner projects a 4½-ft (1.4-m) long flame (89 kW intensity) onto the underside of the test specimen while air flows through the tunnel at a controlled linear air velocity of 240 ft/min (approximately

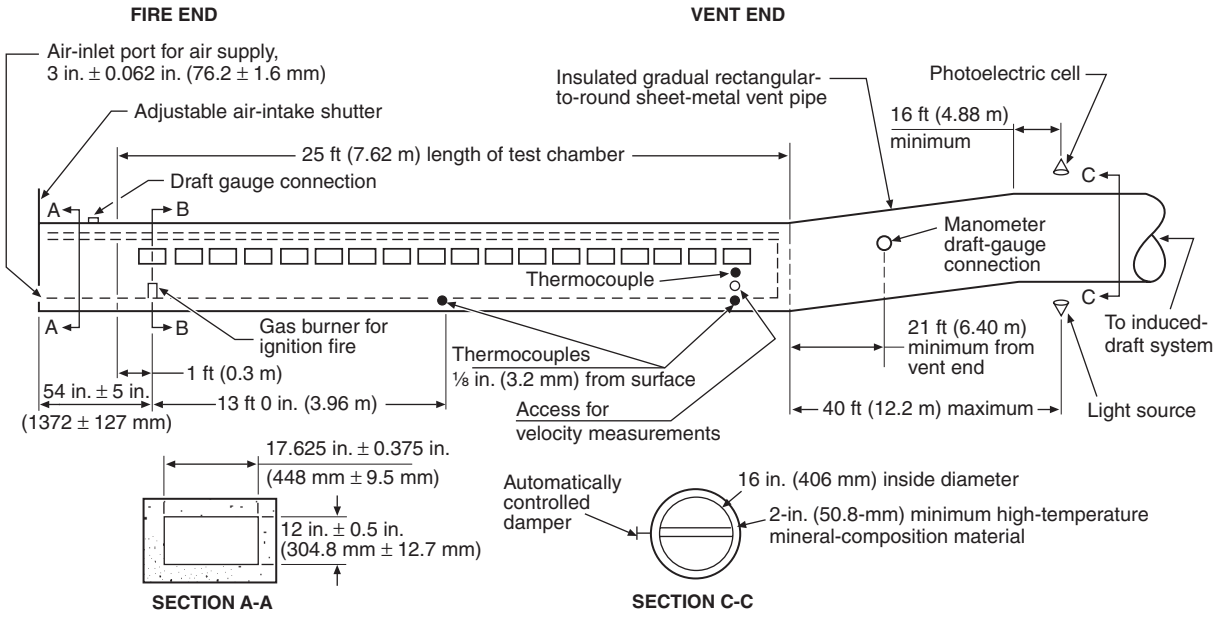

FIGURE 18.2.1 Steiner Tunnel Test Apparatus Used for the Fire Hazard Classification of Building Materials

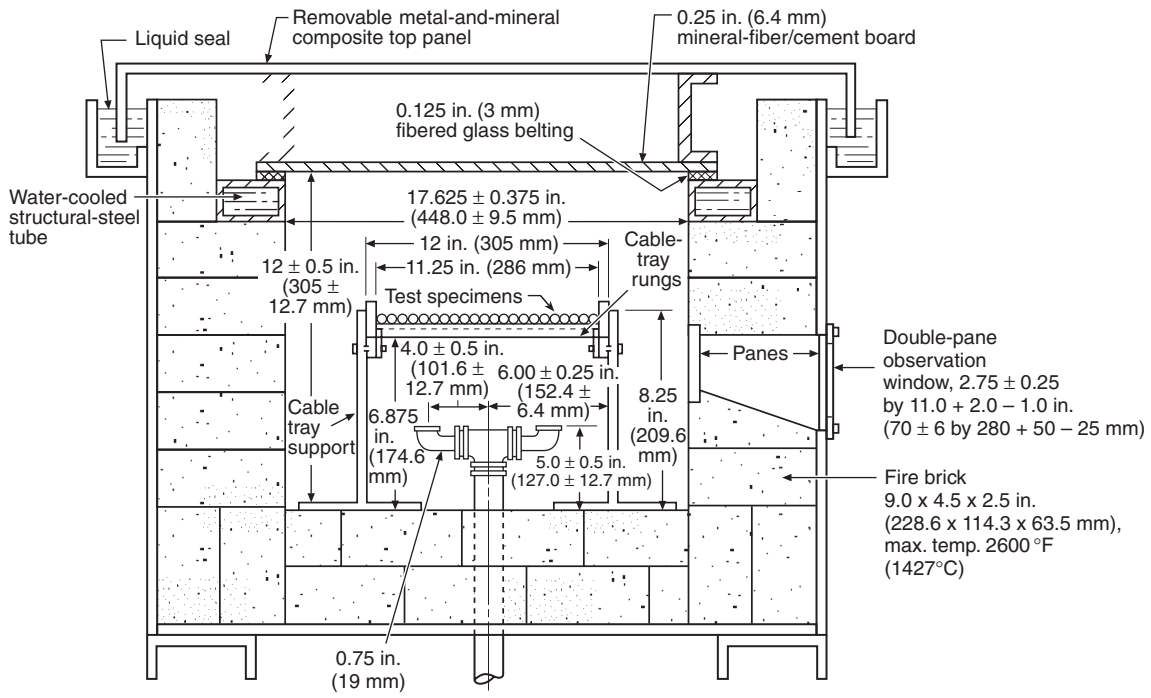

FIGURE 18.2.2 Cross-Sectional View of the Steiner Tunnel Test Apparatus

73 m/min). Flame spread over the face of the test specimen is observed through windows in the side of the "tunnel." Flame propagation is recorded as a function of time over the 10 minute test duration. The record of flame propagation versus time is used to calculate a flame spread index, by comparison with two standard reference materials. Red oak flooring is arbitrarily assigned a flame spread index of 100 and a cementitious board material is assigned a flame spread index of 0. According to the test standard, red oak flooring spreads flame 24 ft (7.3 m) to the end of the test specimen in 5½ minutes ± 15 seconds. The flame spread indices of products are calculated on the basis of a graph of flame spread versus time. The lower the flame spread index, the better the presumed performance. However, as stated above, there is not necessarily a correlation between the measured flame spread index and product behavior in actual fires. NFPA 255 simply provides a basis for comparing one product with another under a standardized set of test conditions.

The reduction in light across the tunnel exhaust caused by smoke generated during the test is measured by a photometer system consisting of a lamp and photo cell. The attenuation of light by the passing smoke and particulate is used to compute a smoke developed index. The smoke developed index for a test specimen is determined by comparing the reduction in light caused by the smoke from red oak flooring to the reduction of light by smoke from a test specimen. Red oak flooring is arbitrarily assigned a value of 100 and the cementitious board material is assigned a smoke developed index of 0. Therefore, a product achieving a 450 smoke developed index produces a curve of light attenuation versus time which has 4.5 times the area of the curve produced by red oak flooring (in comparison with the results for the cementitious board). In simplistic terms, one may think of a product having a 450 smoke developed index as one that produces 4.5 times the amount of smoke that red oak flooring generates during a 10 minute tunnel test.

Factors Affecting Test Results. Products should be tested as proposed for use. For example, the use of high-temperature mortar cement to mount a thin wall covering to an inorganic reinforced cement board substrate may result in artificially good test performance, but such an assembly is not likely to simulate actual installation practices. A product installed in a manner different from that used in testing may perform differently and, in some cases, unsatisfactorily. To illustrate, products that are to be installed over gypsum board with adhesives, such as vinyl wall covering, must be tested over gypsum board, because the paper facing on the gypsum board and the adhesives used can affect fire behavior. ASTM has issued two standard practices which address mounting and testing some materials: pipe and duct insulation materials (ASTM E2231[31]) and vinyl and paper wall and ceiling covering materials (ASTM E2404[32]) and is in the process of developing other practices.

The significance of adhesives has been briefly addressed in the previous paragraph: its fire performance can significantly affect the flame spread index and the smoke developed index measured in the tunnel test. Products should be tested with fastening details that represent conditions of actual use. NFPA *101* and *NFPA 5000* require that interior finish materials be tested as they are to be installed. For example, Paragraph 10.2.1.1 of NFPA *101* (2006) states, "Classification of interior finish materials shall be in accordance with tests made under conditions simulating actual installations, provided that the authority having jurisdiction shall be permitted to establish the classification of any material on which a rating by standard test is not available, unless otherwise provided." This idea is reinforced in the

test method itself. For another example, Paragraph 4.2.1.3 of NFPA 255 (2006) states, "The specimen shall be representative of the material for which test results are desired."

Specimen thickness can also affect flame spread. Thinner sections of the same material often will spread flame more rapidly than thicker sections. For example, data show that the flame spread rate remains constant for an acrylic sheet (polymethyl methacrylate or PMMA) with a thickness greater than approximately ⅜ in. (9.5 mm).[33] Decreasing thickness increases the rate of flame spread for that acrylic sheet. These findings indicate that products to be used in varying thicknesses must be tested at the thickness at which they are to be used. Similarly, products that are offered in different densities should be tested in a range of densities.

Other mounting details can be important too. Thermally thin products, such as wood paneling with thickness of ¼ in. (6.4 mm) or less, that are tested when directly applied to an inorganic-reinforced cement board (as noted earlier) may behave differently if they were installed over furring strips with air space. The installation of paneling with air space will likely result in a greater tendency for surface flame spread. Similarly, where a product is to be applied in multiple layers, it should be tested in the maximum thickness intended for use. For example, a wall covering tested by itself may perform satisfactorily, but multiple layers of the same product applied to a wall covering may spread flame and, in recent years, multiple layers of wall coverings applied to gypsum board have contributed to flame propagation in a number of fires where multiple lives were lost.

As discussed throughout this section, the tunnel test is not able to adequately evaluate certain types of materials. Some materials, such as foam plastic insulation, can achieve a low flame spread index and still spread flames readily in actual fires. A research program involving textile wall coverings demonstrated that NFPA 255 is often unable to evaluate textile wall coverings properly.[34]

One should be suspicious of tunnel results for lightweight materials with low thermal inertia and for thermoplastic materials that drip to the floor of the tunnel during testing. When questions arise about the fire performance of a material or product, the product should be evaluated on a full-scale basis, using an ignition source simulating the type of fire likely to be encountered in actual use. Products should be mounted in a manner that is representative of the conditions of actual use, as it has been shown that often each layer of a system may "pass" a certain set of fire test criteria, but the entire system will perform much worse.

Application of Tunnel Test Results. NFPA *101* and *NFPA 5000* classify interior finish materials using flame spread and smoke developed indices. It is recognized that considerable variability exists in tunnel data, and precise values are not likely to be obtained in replicate tests. Further, small differences in indices (10 to 20 points, for example) are not likely to be discernible in terms of actual fire behavior. Accordingly, flame spread indices are usually rounded to the nearest whole number divisible by 5.

Classification	*Flame Spread Index*	*Smoke Developed Index*
A	0–25	0–450
B	26–75	0–450
C	76–200	0–450

Interior wall and ceiling finish classifications are based mainly on flame spread index with a single smoke developed index limit value of 450, which is common to all classifications.

Flame spread indices are used to provide information on the rate of flame spread across the surface of a material. Heat transfer would be the principal hazard associated with flame spread and would only affect a person who was in close proximity to the fire. As a consequence, different classes of interior finish materials are specified within a building, depending on location. For example, exit enclosures in which travel paths are severely restricted have the most severe flame spread index limitations, since individuals in such a location would be restricted in their travel paths and, therefore, might not be able to avoid the heat from the flame.

A smoke developed index of 450 is used for all interior finish classifications. The smoke developed indices assess product behavior in terms of obscuration of exit paths and loss of visibility by smoke. Smoke interferes with visibility on the basis of the accumulated soot and other particles within a given volume. The smoke level will depend on both time and rate of smoke production. A product that has a low smoke developed index would be expected to maintain visibility in egress paths for a longer period of time than a material with a high smoke developed index. The same smoke developed index criterion is used for all three classifications (i.e., classes A, B, and C). The recommended 450 limit acknowledges that smoke affects visibility both in the immediate vicinity of the fire and in remote areas as well. Large buildings can be quickly filled with smoke as the result of a fire. An upper limit has been established that is applicable to interior finishes, regardless of where the materials are installed.

The smoke developed index limit of 450 was originally developed from research conducted by Underwriters Laboratories Inc. (UL).[35] In this research, products were burned in the NFPA 255 "tunnel test" and the smoke discharged into a 5000 ft^3 (141.5 m^3) room. The room was equipped with illuminated exit signs. The time required for exit signs to be obscured was recorded and compared to the smoke developed index for the different materials tested. The UL report stated that materials with smoke developed index values above 325 showed "good" to "marginal" visibility in a few cases, whereas other materials produced conditions of "marginal" to "obscuration" in the 6-minute period. The 450 limit has been used for many years and has long been thought to set a "reasonable" limit for smoke developed index values in rooms. The 450 smoke developed index limit takes into account both the time required to produce the smoke and the effect of the smoke on vision distance.

There is no direct relationship between flame spread index and smoke developed index. In the UL report referenced above,[35] for example, one material had a flame spread index of 490 and a smoke developed index of 57, whereas another had a flame spread index of 44 and a smoke developed index of 1387.

The smoke developed index from NFPA 255 is determined solely on the basis of obscuration of light. It should be recognized that, in some cases, smoke may also act as an irritant, further affecting visibility, and the smoke may, in addition, have a debilitating effect on persons attempting to escape. The irritability and other physiological effects are not evaluated by the 450 smoke developed index limit.

Different classes of interior finish materials are specified, depending on location within a building and on the occupancy involved. Interior finish restrictions are less stringent for a general office area, for example, than would be the case for an exit stair enclosure or exit access corridor. Similarly, occupancies having less capable occupants have stricter interior finish requirements than occupancies used by mobile and alert occupants. For example, the interior finish restrictions for health care facilities are quite restrictive, due to the inability of hospital patients to take action for their own self-preservation.

The limits on interior finish are set forth in the 2006 editions of NFPA *101* and *NFPA 5000*. The limits for interior wall

Notes:
1. Class A interior wall and ceiling finish—flame spread index 0–25, (new applications) smoke developed index 0–450.
2. Class B interior wall and ceiling finish—flame spread index 26–75, (new applications) smoke developed index 0–450.
3. Class C interior wall and ceiling finish—flame spread index 76–200, (new applications) smoke developed index 0–450.
4. Automatic sprinklers: The annex of NFPA *101* states that where a complete standard system of automatic sprinklers is installed, interior wall and ceiling finish with a flame spread rating not exceeding Class C is permitted to be used in any location where Class B is required and with a rating of Class B in any location where Class A is required. These provisions do not apply to new detention and correctional occupancies.
5. Exposed portions of structural members complying with the requirements for heavy timber construction are permitted.

[a]*Life Safety Code* requirements for interior wall and ceiling finish materials apply as shown in this table where specified elsewhere in the *Life Safety Code* for specific occupancies (see Chapter 7 and Chapters 11 through 42), unless otherwise specified in the sections addressing individual materials.

[b]Note that everywhere that a Class A, Class B, or Class C interior wall or ceiling finish material is required, a material that has been tested by NFPA 286 and complies with the appropriate criteria is also permitted.

[c]See corresponding chapters for details.

and ceiling finish are summarized in Table 18.2.1 and those for interior floor finish are summarized in Table 18.2.2. As noted in footnotes to the tables, automatic fire suppression, such as automatic sprinklers, will significantly mitigate the hazard associated with a fire, including one associated with interior finish materials. Accordingly, codes often allow materials, including interior finish materials, to comply with a less severe fire performance classification when the area is fully provided with protection from automatic sprinkler systems, in accordance with the appropriate system, namely either NFPA 13, *Standard for the Installation of Sprinkler Systems,* NFPA 13D, *Standard for the Installation of Sprinkler Systems in One- and Two-Family Dwellings and Manufactured Homes,* or NFPA 13R, *Standard for the Installation of Sprinkler Systems in Residential Occupancies up to and Including Four Stories in Height.* The code will explicitly discuss these trade-offs. Accordingly, the informational annexes of NFPA *101* and *NFPA 5000* talk about allowing interior finish materials to drop one classification when automatic sprinkler systems are provided. For example, if the code normally requires a Class A interior finish and automatic sprinklers are installed, then a Class B interior finish is normally allowed. This trade-off is not written in code language and is different from the one incorporated into the International Building Code, for example.

Room-Corner Test

Seeking a more realistic assessment of the hazard of interior finishes, several laboratories started conducting room-corner tests around 1970. These originally comprised an 8 ft (2.44 m) high corner construction with 2 to 4 ft (0.1 to 1.22 m) long wing walls. A simulated ceiling of the same material was provided. A wood crib placed in the corner at floor level was used for ignition. The degree of flame spread and the rate and amount of smoke developed were the primary observations. Interest in the rapidity of flame spread across the surface of what was considered low-flame-spread cellular plastics in actual fires reinforced the use of the corner test. Large-scale corner tests conducted by Factory Mutual Research (now FM Global) and UL (Underwriters Laboratories) have used corners up to 25-ft (7.6-m) high with wing walls up to 50-ft (15.4-m) long to determine the burning characteristics of cellular plastics and the effectiveness of protective measures such as automatic sprinkler protection or thermal barriers.[36] Results have reinforced the premise that fire hazard cannot be fully judged on the basis of a traditional fire test method.[37]

Building codes and NFPA *101* now specify the use of room-corner tests for judging the flammability behavior of certain interior finishes. NFPA *101* and *NFPA 5000,* for example, use NFPA 265, *Standard Methods of Fire Tests for Evaluating Room Fire Growth Contribution of Textile Coverings on Full Height Panels and Walls,* to evaluate the performance of textile and expanded vinyl wall coverings. In the 1980s, researchers at the University of California–Berkeley Fire Research Laboratory showed that wall coverings with NFPA 255 (ASTM E84) ratings as low as 15 sometimes performed poorly, producing flashover in room-corner tests.[34–38] It was determined that room-corner tests (such as NFPA 265) provide a better indication of the hazard presented by these particular wall coverings than do the

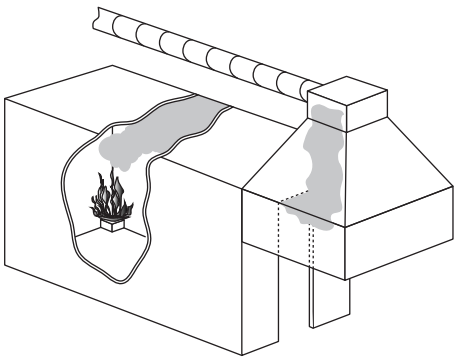

FIGURE 18.2.3 Schematic of Modern Room-Corner Test Apparatus

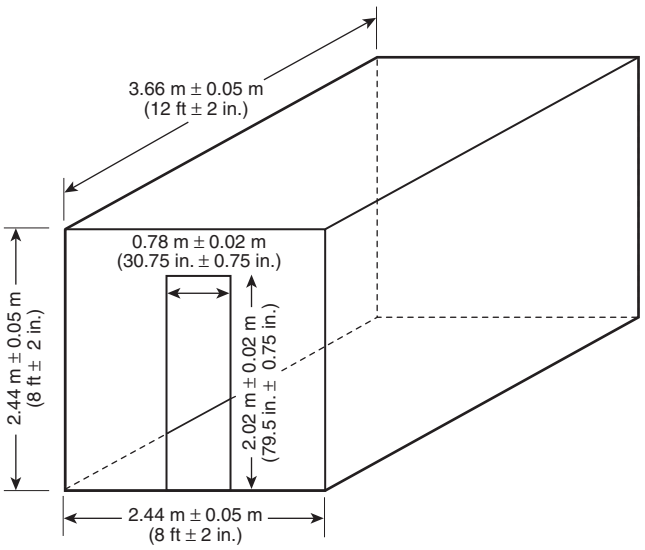

FIGURE 18.2.4 Interior Fire Test Room Dimensions and Interior Doorway Dimensions (Source: Figure 4.2.1, NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth,* 2006 ed.)

NFPA 255 flame spread indices. The general layout of modern room corner tests is shown in Figure 18.2.3.

The NFPA 265 test method consists of an 8-ft (2.44-m) wide by 12-ft (3.66-m) long by 8-ft (2.44-m) high room with a single door opening (Figures 18.2.4 through 18.2.6). Products are mounted on three walls, opposite the room door. A diffusion burner is positioned near the corner of the room and provides the required fire exposure. The smoke from the room is collected in a hood and duct exhaust system where instrumentation is used to determine heat release rate (through oxygen depletion) and smoke release (as optical density). Heat flux and temperature measurements are also, optionally, made within the room. Key visual observations are the extent of flame spread and the occurrence of flashover. In NFPA 265, the burner (placed 2 in. [51 mm] away from each wall, near a corner) provides 5 minute, 40 kW fire exposure (which simulates a "waste basket"–sized fire exposure) followed by a 10 minute, 150 kW exposure. A key issue is the fact that the 150 kW burner flame does not reach the

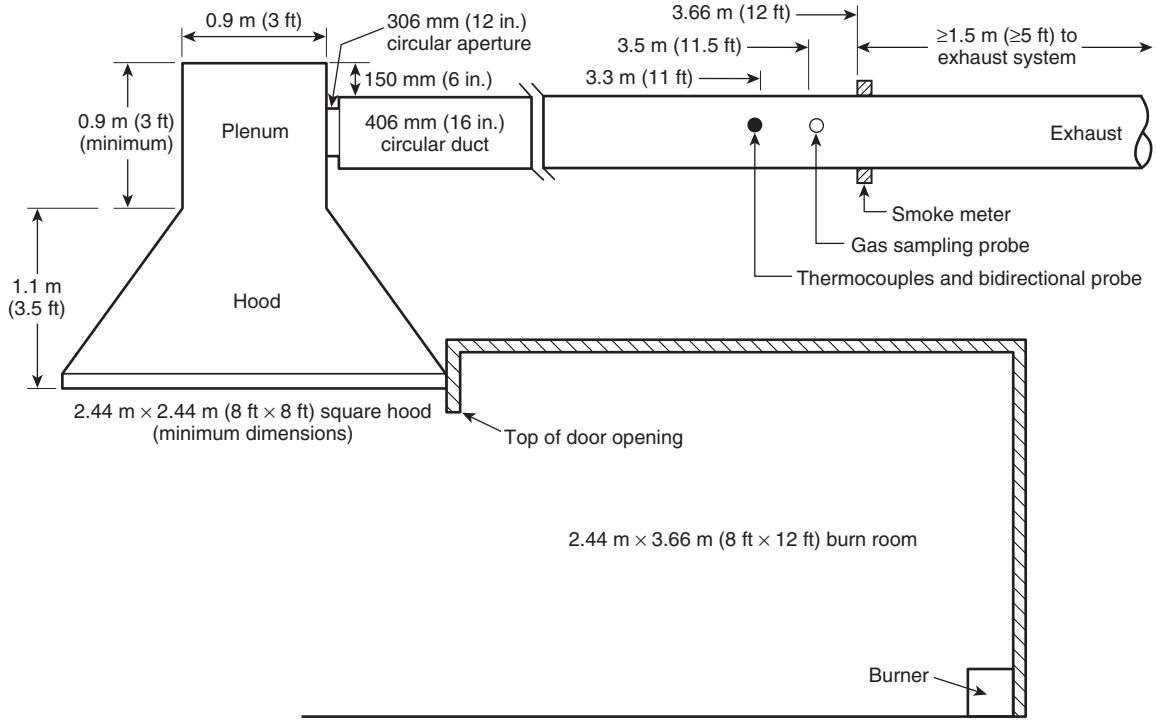

FIGURE 18.2.5 Canopy Hood and Exhaust Duct (Source: Figure 7.2.1, NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth,* 2006 ed.)

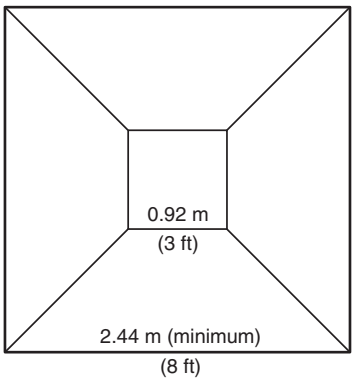

FIGURE 18.2.6 Plan View of Canopy Hood (Source: Figure 7.2.1.3, NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth,* 2006 ed.)

ceiling, and the test method is, therefore, not applicable to ceiling coverings. Thus, although the fire exposure specified within NFPA 265 is believed to be appropriate for wall coverings, ceiling coverings are not adequately evaluated by this procedure since the burner placement and 150 kW output (assuming no involvement of a wall test specimen) produces a flame that does not reach the ceiling. The codes set limits for products tested in accordance with NFPA 265, which is for textile and expanded vinyl wall coverings only. The 2006 editions of the codes require that materials tested using the complete NFPA 265 test (also known as Protocol B, namely not the screening test) must meet the following test criteria:

1. Flame shall not spread to the ceiling during the 40 kW exposure.
2. During the 150 kW exposure, flame shall not spread to the outer extremities of the sample on the 8 ft × 12 ft (2.44 m × 3.66 m) wall and flashover shall not occur.

For ceiling coverings and for other interior finish materials, the codes use a different burner placement and output, as detailed in NFPA 286. The NFPA 286 test places the test specimen on the three walls of the room (just like the NFPA 265 test) but also covering the entire ceiling. The test uses a 5 minute, 40 kW initial exposure, followed by a 10 minute, 160 kW exposure, with the burner flush against both walls in the corner. The 160 kW exposure (even absent any contribution by the products undergoing test) will result in burner flames hitting the ceiling and turning to expose the underside of the ceiling for 18 to 24 in. (457 to 610 mm). The direct flame exposure to the ceiling is considered necessary to adequately evaluate ceiling finish. The codes also set limits for products tested in accordance with NFPA 286 (all interior finish materials). Interior finish materials tested by NFPA 286 must meet the following test criteria:

1. Flames shall not spread to the ceiling during the 40 kW exposure.
2. During the 160 kW exposure, flame shall not spread to the outer extremities of the sample on the 8 ft × 12 ft (2.44 m × 3.66 m) wall and flashover shall not occur.
3. The peak heat release rate throughout the test shall not exceed 800 kW.
4. For new installations, the total smoke released throughout the test shall not exceed 1000 m^2.

Clearly the room-corner test is a much more suitable way of assessing fire performance than the NFPA 255 tunnel test. However, the codes admit the NFPA 286 room-corner test results based on the premise that materials that don't cause flashover (or high smoke release) in the room-corner test are known to also have flame spread indices of less than 200 and smoke developed indices of less than 450 in the Steiner tunnel test. This is excellent as far as it goes, but needs refinement. The Steiner tunnel test is very likely to give falsely favorable results (in fact, that happens often with materials that melt and drip and with materials that are thin films) but it rarely gives falsely unfavorable results (meaning that a high flame spread index, or FSI, is almost always indicative of a material with mediocre or poor fire performance). The room-corner test results are potentially much more suitable to classification of materials, because the heat release rate history is obtained in the test. However, the fact that the heat release rate history is not used for code classification purposes results in some inconsistencies occurring when comparing results from both tests. Therefore, it would be important to use the heat release rate history in the room-corner test and not just whether flashover does or does not occur, and the codes have started in that direction by requiring a peak heat release rate not exceeding 800 kW and not just the absence of flashover. Work based on a survey of published data[19] analyzed the comparative fire performance of 25 materials tested in the Steiner tunnel and in the room-corner test, the following points illustrate the problem:

- Five materials had an FSI of 200 or less (i.e., Class A, B, or C) in the Steiner tunnel and yet led to flashover in the room-corner test. The Steiner tunnel test classifies them as acceptable and the room-corner test as unacceptable.
- Fourteen materials had an FSI of 25 or less (i.e., Class A) in the Steiner tunnel and released less than 400 kW in the room-corner test. Both tests consider them satisfactory materials.
- Two materials had an FSI of greater than 25 but not exceeding 75 (i.e., Class B) in the Steiner tunnel and also released less than 400 kW in the room-corner test. The Steiner tunnel test classifies them as Class B and yet the codes would allow such materials to be used instead of Class A materials.
- Two materials had an FSI of 25 or less (i.e., Class A) in the Steiner tunnel and released more than 400 kW but less than flashover in the room-corner test. The codes classify the materials as Class A but these materials are clearly less fire safe than those that release less than 400 kW.
- Two materials had an FSI of 200 or less (i.e., Class C) in the Steiner tunnel and heat release very close to but less than flashover in the room-corner test. The Steiner tunnel test classifies them as Class C and the codes consider them equivalent to Class A materials.

In terms of smoke release by interior wall and ceiling finish, the question has been posed whether it is necessary to test for smoke release if a material shows excellent fire performance in the room-corner test, or is it enough to just develop low heat

release products? Recent work[19] shows that of five series of tests conducted in room-corner tests (two in Europe and three in the United States), with a total of 84 materials tested, systematically some 10 percent of the materials (in fact 10 of the 84) give low heat release but very high smoke release. Therefore, it is important to also assess smoke release of interior wall and ceiling finish in a large-scale test. Thus, a smoke release criterion is included in the codes for use with the NFPA 286 room-corner test. The code requirements, total smoke release (TSR) of 1000 m^2 in the NFPA 286 room-corner test, is roughly equivalent to the 450 smoke developed index (SDI) criterion used for the Steiner tunnel test.

A different version of the room-corner test procedure was developed as the result of a research project sponsored by the National Association of Garage Door Manufacturers.[39,40] It is referenced in the 2006 editions of building codes such as *NFPA 5000®*, *Building Construction and Safety Code®*, for the regulation of foam plastic–insulated garage doors in commercial applications. This room-corner test method and associated regulatory limits are particularly notable in that heat release and smoke release limits have been developed that are linked to the actual fire hazard. The heat release rate and smoke limits eliminate the need for subjective judgments of product behavior required by the older editions of room-corner tests.

If foam or cellular plastics are to be used exposed within a building, the application should be substantiated on the basis of tests that are representative of the conditions of actual use. Room-corner tests, such as NFPA 265, NFPA 286, and ISO 9705[41] or ASTM E2257,[42] have been used to evaluate foam plastic insulation materials. They all use a gas diffusion burner as the fire source, with ISO 9705 or ASTM E2257 being the most severe one (the ignition source is 100 kW for the first 10 minutes and 300 kW for the next 10 minutes).

Full-scale test procedures, like room-corner tests, allow products to be evaluated because they will be installed using an ignition source representative of those likely to be encountered during actual use. Accordingly, results of room-corner fire tests are more indicative of product behavior during actual fires than are traditional tests, such as NFPA 255. Codes exempt materials tested in accordance with an appropriate room-corner test from classification in accordance with NFPA 255. In other words, the codes allow products shown to perform acceptably by a room-corner fire test to be used as interior finish in those locations otherwise requiring Class A, B, or C materials. Furthermore, the data from room-corner fire tests is also suitable for use as input into fire models for performance-based design.

Other Flame Spread Tests

Attempts have been made to develop a smaller scale test that could be used in place of the nominally 25 ft (7.6 m) long "tunnel" test. The advantages of such a method are obvious: less space required for the equipment, smaller specimens needed, and lower costs. The Forest Products Laboratory developed a reduced-scale version of the tunnel. The reduced-scale tunnel was 8 ft (2.4 m) long and used flame spread observations as a function of time to determine flame spread ratings. The 8 ft (2.4 m) tunnel test was adopted by ASTM in 1968 as ASTM E286[43] and withdrawn by ASTM in 1991.

A radiant panel apparatus was developed at the National Bureau of Standards (NBS), now NIST. The radiant panel apparatus uses a much smaller test specimen of 6 in. by 18 in. (152 mm by 457 mm) and measures hazard in terms of both flame spread and, potentially, heat release rate after ignition. The test method was adopted as a standard by ASTM in 1967 as ASTM E162.[44] In the radiant panel test, *Standard Test Method for Surface Flammability of Materials Using a Radiant Heat Energy Source,* the specimen is positioned at an angle of 30° to vertical in front of a gas-fired, porous, refractory, vertical panel. The specimen slants toward the radiant panel at the top and a small pilot flame at that location ignites flammable gases released from the surface of the specimen. Air is drawn over the surface of the specimen at a controlled rate by a fan in the hood under which the equipment is located. The rate of flame travel from the top of the specimen to the bottom is noted, as are temperatures that develop in the stack. The amount of smoke generated can be measured by weighing deposits on a filter located in the stack. The test is continued for 15 minutes or until surface flaming reaches the lower edge of the specimen. This radiant panel apparatus is available commercially and is used in many research, commercial, and industrial laboratories. The results of tests are expressed on a scale and reported as the "radiant panel index." In the radiant panel, the air flow is against or across the direction of flame travel. This provides a clear definition of the interfacial burning. With the Steiner tunnel test (NFPA 255), the flame travel and airflow coincide, and, with some materials, the flame front may be several feet in front of the interfacial burning (see Figure 18.2.3).

ASTM E162 was not originally intended for regulatory use and is not used in codes (building code, fire code, or life safety code) as a substitute for evaluating products in accordance with the Steiner tunnel test, such as NFPA 255. It is, however, used for some transportation vehicles and for manufactured housing. In the case of rail transportation vehicles, both the Federal Railroad Administration[45,46] and NFPA 130, *Standard for Fixed Guideway Transit and Passenger Rail Systems,* require that lining materials pass the ASTM E162 test, with radiant panel indices ranging from 25 to 100, depending on the application. ASTM E162 is also used in NFPA 1192, *Standard on Recreational Vehicles,* for assessing the flame spread performance of cabinet door and drawer faces, exposed cabinet bottoms and end panels, and tub/shower walls in recreational vehicles, and in NFPA 501, *Standard on Manufactured Housing,* as an alternative to the Steiner tunnel test to assess flame spread performance of interior finish materials in manufactured housing; for both applications a radiant panel index of 200 is required.

Smoke Density Chamber Test

A "bench test" for measuring smoke generation, the smoke density chamber, has been available for many years. Described in ASTM E662,[47] it measures the specific optical density of smoke generated in a chamber from test specimens up to 1 in. (25.4 mm) thick. Despite the existence of a clause in ASTM E662 that intends to limit the test procedure for use as a research and development tool, it is actually widely used for regulatory purposes (including its use for lining materials in trains by the Federal Railroad Administration[45,46] and in airplanes by the

Federal Aviation Administration[48]) but not normally for interior finish in codes. A variation of the test (ASTM E1995,[49] also known as NFPA 270, *Standard Test Method for Measurement of Smoke Obscuration Using a Conical Radiant Source in a Single Closed Chamber,* and ISO 5659-2[50]) is used for regulating interior finish in ships by the International Maritime Organization (IMO), the U.S. Coast Guard, and NFPA 301, *Code for Safety to Life from Fire on Merchant Vessels.* ASTM E1995 differs from ASTM E662 mainly in that the burner is a conical heater and the sample is tested horizontally. The smoke density chamber test is known to have numerous shortcomings. The method involves a closed, static chamber, whereas smoke transfer in actual fires is dynamic. The chamber is closed, and oxygen-deficient atmospheres can develop that may artificially affect the burning behavior of the products being tested. Deposits of soot on wall surfaces and optics can affect measurements. In summary, numerous questions exist as to the relevance of data from ASTM E662 to the behavior of products in actual fires.

FIRE TESTS FOR INTERIOR FLOOR FINISH MATERIALS

Fire tests for interior finishes were developed primarily with wall and ceiling finishes in mind, long before carpeting became popular as an interior floor finish. Official attention was directed toward a possible hazard with soft floor coverings in 1960 and 1961 as a result of a series of small fires in the Washington, D.C., area.[51] A well-publicized dwelling fire on the West Coast in 1967, followed by the Harmer House Nursing Home fire in Ohio in 1970, focused attention on carpet floor coverings, although carpets were a contributing, rather than a causative, factor in these incidents.[52,53]

In 1965, the Public Health Service of the U.S. Department of Health, Education, and Welfare issued a directive setting flame spread limits on floor coverings in federally funded hospitals, citing the Steiner tunnel test as the test method. In the Steiner tunnel test, a floor covering would be mounted upside down and on the ceiling of the apparatus. Since neither the mounting nor location correctly simulated an actual installation, it is not surprising that the tunnel test was ultimately judged to be inadequate for floor coverings. Moreover, the Steiner tunnel cannot assess ignitability and its fuel source is not appropriate to assess slow flame spread. It was also found to be inadequate for carpets made with synthetic fibers of the type that melt, drip, or delaminate when exposed to elevated temperatures. As a further deficiency, carpets with separate underlayments could not be effectively tested in the tunnel. Thus, the need for a test specifically designed for interior floor finishes was clearly identified.

In 1969, UL started work on a new test for floor coverings with the test specimens mounted in a floor position.[54] The program was sponsored by the U.S. Public Health Service and resulted in what became known as UL Subject 992, the floor covering chamber test. In essence, UL Subject 992 is an 8 ft (2.44 m) version of the Steiner tunnel, with the test specimen mounted on the floor of the tunnel and with appropriate modifications in heat input, burner design, airflow, and other test specifications. This test never gained widespread acceptance and is no longer used.

Methenamine Pill Test

NIST (formerly NBS) developed the methenamine pill test as a means of preventing the use of highly flammable carpet floor coverings. The pill test was adopted by the federal government in 1970 as DOC FF-1-70 (Federal Register 1970a) for carpets and DOC FF-2-70 for rugs[55–57] and was also adopted by ASTM as ASTM D2859.[58] In this test, eight 9 in. (229 mm) square sections of a carpet are conditioned to drive off excess moisture, brought to room temperature in a desiccator, and tested. Each specimen, in turn, is placed on the bottom of a 1 ft (0.3 m) enclosed cube, which is open at the top. The specimen is held in place by a 9 in. (229 mm) square metal plate having an 8 in. (203 mm) circular cutout. A methenamine tablet is placed at the center of the circle and lighted. The pill produces a candlelike flame for about 100 seconds. A specimen fails if the flame advances to within 1 in. (25.4 mm) of the metal ring in the holddown plate. At least seven of the eight specimens must pass the test to meet the established criteria. All carpet manufactured for sale in the United States has been required, since April 1971, to pass this test (Figure 18.2.7).

Although the pill test is a small-scale test, the results have large implications in terms of floor covering performance. It has been shown that the pill test provides adequate "first to ignite" protection for carpet located in rooms.[59,60] Experiments conducted at NIST[61,62] revealed that carpet and floor coverings were unlikely to be involved in a fire or propagate flame in rooms until room fires approach or exceed flashover unless the fire started at the floor level. As a consequence, little additional safety is to be gained by regulating floor coverings within rooms beyond the pill test. These findings were used, in part, to establish the current code restrictions for floor coverings.

Experience has shown that many flooring materials (traditional floor finishes such as wood flooring or resilient materials) will not ignite unless exposed to an ignition source of well over 1 kW/m^2, but that some carpetlike or loose-fill materials may ignite at lower heat fluxes. A study of precision of the flooring radiant panel test method (ASTM E648,[63] NFPA 253, *Standard Method*

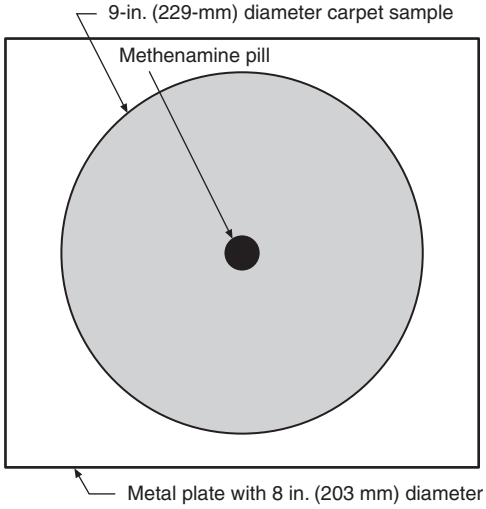

FIGURE 18.2.7 Methenamine Pill Test

of Test for Critical Rdiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source) found carpets with critical radiant heat fluxes well under 2 kW/m^2.[64] The minimum critical radiant flux of a product that will still pass the pill test has been determined to be 0.4 kW/m^2.[61] Therefore, as stated above, all carpets sold in the United States must meet the "methenamine pill" test, which ensures that flame spread will be minimal.

Flooring Radiant Panel Test or Critical Radiant Flux Test

Floor coverings having modest resistance to flame spread are unlikely to become involved in the early growth of a fire within a room. Thus, regulation of floor coverings is generally where specified by the code or where a need is indicated by some unusual product. It has been shown that floor coverings will tend to propagate flame only under the influence of a sizable exposure fire (often after flashover). Corridor floor coverings, for example, may spread flame when subjected to radiant heat from the hot gases discharging from the doorway of a fully fire-involved room.[65,66] The fire discharges flame and hot gases into the upper level of the corridor, which results in radiant heat energy transfer to the floor. The level of energy radiating onto the floor is a significant factor in determining whether progressive flaming will occur. Corridors with combustible wall and ceiling finishes would be expected to produce a potentially greater fire hazard. Experimental results suggest that floor coverings would contribute much less to fire spread than wall or ceiling finish in the initial growth of fires.[67]

Codes specify the use of the flooring radiant panel test for floor coverings in exits and corridors of certain occupancies. The flooring radiant panel test consists of a closed chamber having a radiant panel inclined at a 30° angle from a 39 in. (1000 mm) long test specimen. The test specimen is exposed to radiant heat that ranges from approximately 11 kW/m^2 to 1 kW/m^2. Flame spread over the face of the floor covering specimen is initiated by flames from a gas burner (Figure 18.2.8). The test determines the minimum energy required for a floor covering to spread flame. The flooring radiant panel test simulates conditions that have been observed and defined in large-scale corridor experiments, particularly when there is little or no combustible wall or ceiling finish. The test method assesses the critical incident flux required for continued flame propagation. It does so by determining the distance between the igniter and the point where flame propagation stops, and obtaining the heat flux from a calibration curve of heat flux versus distance. The flooring radiant panel measures the minimum energy required to be impinged on floor coverings to sustain flame propagation. The minimum value required to

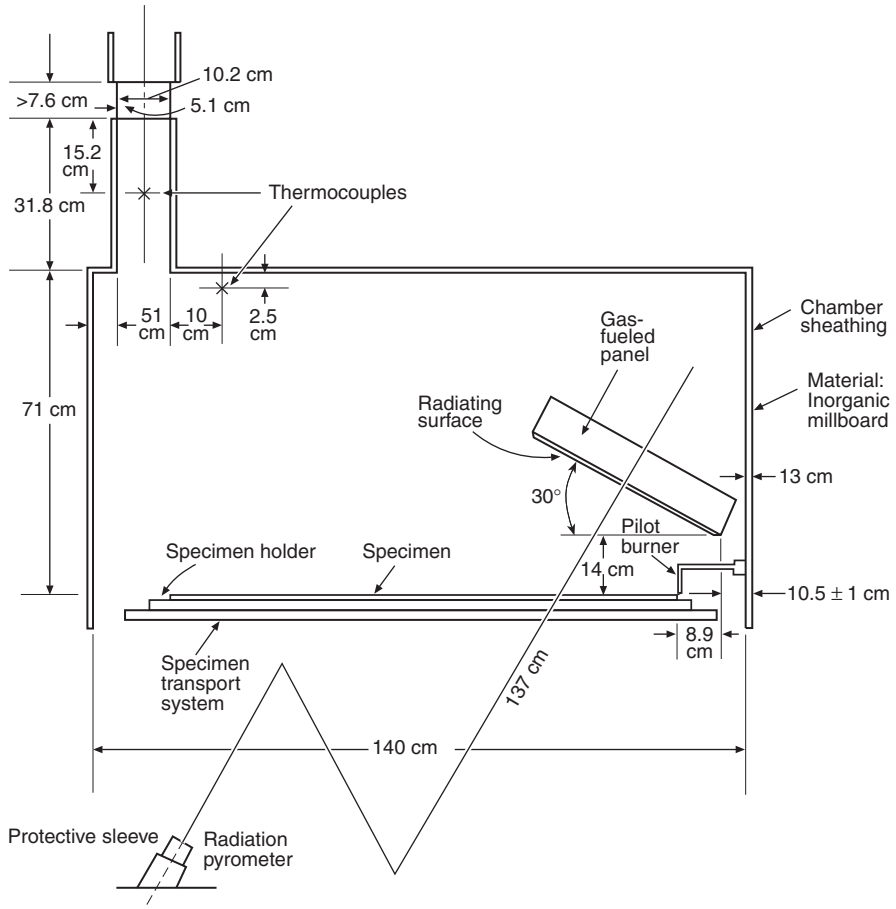

FIGURE 18.2.8 Flooring Radiant Panel Test Schematic (Size Elevation).
Note: in. = cm × 0.3937.

sustain flame propagation is termed *critical radiant flux*. The higher the critical radiant flux, the better the performance. In summary, the flooring radiant panel test is used for evaluating the fire performance of a floor covering in a building in areas where risks need to be especially minimized. Floor coverings in open building spaces and in rooms within buildings generally merit no further regulation, provided the floor covering is at least as resistant to flame spread as a material that will meet the federal flammability standard FF-1-70/ASTM D2859 methenamine pill test. Therefore, most codes regulate interior floor finish to be tested with the flooring radiant panel (ASTM E648, NFPA 253).

The codes classify interior floor finishes on the basis of critical radiant flux and group them into the following two classes:

- *Class I.* A minimum critical radiant flux of 0.43 Btu per ft^2 per second (0.45 W/cm^2)
- *Class II.* A minimum critical radiant flux of 0.19 Btu per ft^2 per second (0.22 W/cm^2)

See Table 18.2.2 for assignment of the two classes of floor finishes to the various occupancies identified in NFPA *101*.

The flooring radiant panel test requires test specimens to be representative of the product to be installed. Where carpet is to be loose-laid over concrete, for example, it should be tested over a thick, high-density inorganic reinforced cement board that simulates concrete. Where carpet, with or without integral pad, is to be bonded to concrete, an adhesive should be used, following the manufacturer's directions as to the type and application rate. The use of a separate underlayment (pad) will normally lower the critical radiant flux of a test specimen and, therefore, increase the tendency for flame spread. Research at NIST[68] has shown that underlayment lowers the critical radiant flux of a test specimen due to the insulative effect of the underlayment. The flooring radiant panel test formerly allowed a manufacturer of carpet to test over a "standard" pad or the actual underlayment proposed for use. Research at NIST has shown that using what was formerly considered the standard pad—a rubber-coated jute and animal hair or fiber pad a minimum of ⅜ in. (9.5 mm) thick and weighing 50 oz/yd^2 (1.86 kg/m^2)—is likely to yield lower critical radiant flux values than those associated with other underlayments in use.[68,69] If the manufacturer tests a carpet over the "standard pad," NFPA 253 allows the results to be applied to any carpet/underlayment combination. Alternatively, if the manufacturer chooses to test using the actual pad proposed for use, the results would be valid only for the actual combination tested.

Floor coverings are not generally regulated on the basis of smoke generation in codes. Regulation of floor coverings on the basis of smoke is usually not considered necessary. Floor coverings will not normally spread flame until after a fire grows to large size and most fires will be so large and the smoke production so great when floor coverings become involved that the minimal benefits achieved by imposing smoke limits on floor coverings would not generally warrant such regulation. Nevertheless, some jurisdictions and many transport environments (including trains and ships) establish criteria for floor finishes based on a test for smoke generation. In such instances, the ASTM E662 test method has been used for trains (and for some building regulations) and the ISO 5659-2 test method has been used for ships. These test methods provide procedures for measuring the specific optical density of smoke generated in a closed chamber, as discussed previously.

TYPES OF INTERIOR FINISH

The types of interior finish materials are numerous and include such commonly used materials as plaster, gypsum wallboard, wood, plywood paneling, fibrous ceiling tiles, several different plastic products, and a variety of wall coverings. Collectively, these finishes serve several functions: aesthetic, acoustical, and insulating, as well as protecting against wear and abrasion.

Wall and ceiling finish classification needs to be based on test specimens that are representative of actual installations (particularly in terms of the various layers involved and of components such as adhesives). Building, fire, and life safety codes single out certain specific interior finish materials. The interior finish materials singled out are very thin materials, structural members, textile wall and ceiling coverings, expanded vinyl wall and ceiling coverings, foam plastic insulation, interior trim (foam plastic or otherwise), light-transmitting plastics, wall base, metal panels, and fire retardant coatings (not discussed in building codes). NFPA *101* also has a specific reference to the fact that decorations and furnishings not meeting the definition of interior finish should not be tested by the test methods for interior finish. Electrical nonmetallic raceways are normally considered a subset of interior trim.

Very Thin Materials

Codes exempt very thin materials applied directly to the surface of walls and ceilings in a total thickness of less than 1/28 in. (0.9 mm) from testing as interior finish "if they meet the requirements of Class A interior wall or ceiling finish when tested in accordance with the Steiner tunnel test, using fiber cement board as the substrate material." This exemption for 1/28 in. thin materials that attain a flame spread index of 25 or less applies to products such as gypsum wallboard, single layers of paints, and thin paper, vinyl, or textile wall coverings. The exception for thin materials is based on the understanding that thin coverings secured to a substrate will tend to behave like the substrate. Thin coverings, such as paint on steel and paper over gypsum, will not generally spread flames or contribute to fire growth during the developing stage of a fire. However, thicker coverings, such as multiple layers of a wall covering or paint, can contribute to rapid fire growth.

Structural Members

Exposed portions of structural members complying with the requirements for Type IV(2HH) construction are exempt from testing and classification as interior finish in codes.

Textile Wall and Ceiling Coverings

Some textile wall and ceiling coverings are able to achieve good flame spread indices (less than 25) when tested in accordance with NFPA 255, and yet these same textile wall coverings in room-corner tests sometimes propagate flame and cause fires to grow to full-room size, that is, flashover, within minutes.[34] The codes mandate three options for textile wall coverings: (a) automatic suppression (sprinklers) as well as a Class A

performance in the Steiner tunnel test, (b) satisfactory behavior in the NFPA 265 room-corner test, or (c) satisfactory behavior in the NFPA 286 room-corner test. Since the ignition source of the NFPA 265 room-corner test does not reach the ceiling, textile ceiling coverings are allowed only options (a) or (c) and not (b). Satisfactory performance in accordance with NFPA 265 requires (a) no flame spread to the ceiling during the initial exposure, (b) no flame spread to the extremities of the sample, and (c) no flashover. Satisfactory performance in accordance with NFPA 286 is more difficult to achieve, because it requires two additional criteria: heat release rate not exceeding 800 kW and total smoke release not exceeding 1000 m^2. Since NFPA *101* applies to existing buildings, textile wall or ceiling coverings are not allowed to be tested by NFPA 286.

Expanded Vinyl Wall and Ceiling Coverings

Expanded vinyl wall or ceiling coverings are another example of products that may attain good flame spread indices in the Steiner tunnel test and yet perform unsatisfactorily in an actual fire. The codes establish special criteria for the use of expanded vinyl wall and ceiling coverings, similar to the requirements for textile coverings. The code also allows the use of expanded vinyl wall coverings for walls (but not ceilings) if the wall covering has been tested to the less severe room-corner test in NFPA 265.

Foam Plastic Insulation

The development of certain types of cellular plastics in board, poured-in-place, and sprayed-on foam has yielded lightweight materials with exceptional thermal insulation. The incorporation of fire retardants into some cellular plastic products makes it possible for them to meet the NFPA 255–related requirements for interior finishes. As a result, cellular plastics, particularly the sprayed-on type, have been used as exposed insulation. Rapid fire spread in several widely publicized fires (including the two nightclub fires described earlier[13–15]) involving exposed cellular polyurethane and polystyrene materials resulted in recommendations for protection of such surfaces against ignition and fire spread by the use of 15-minute thermal barriers.[70,71] NFPA *101* and *NFPA 5000* state that cellular or foam plastic materials are not allowed for use as interior finish unless actual fire tests substantiate, on a reasonable basis, their combustibility characteristics for the intended use.

Interior Trim

Codes also state that interior trim (for example around doors or windows or as chair rails) materials (other than cellular or foam plastics) must comply with an NFPA 255 flame spread index classification of Class C, without smoke developed index limitation, provided they do not exceed 10 percent of the aggregate wall or ceiling area. The rationale for this requirement is that typical wood products exhibit a Class C flame spread index classification. On the other hand, cellular or foam plastics may be used as interior trim only if they meet three criteria: (1) they do not exceed 10 percent of the aggregate wall or ceiling area, (2) the density is not less than 20 lb/ft^3 (320 kg/m^3) and they are no more than ½ in. (12.7 mm) thick and 4 in. (102 mm) wide, and (3) they comply with a NFPA 255 Class B flame spread index without the smoke developed index limitation. The exception for "plastic trim" is based on the assumption that the fire performance of the foam plastic trim will be comparable or better than that of traditional wood products. The required Class B flame spread index is better than the flame spread index achieved by most wood materials. A minimum density of 20 lb/ft^3 (320.4 kg/m^3) is set to prohibit the use of lightweight foam plastics, which typically have densities of 1 to 3 lb/ft^3 (16 to 48 kg/m^3). The width and thickness limits are to restrict the combustible mass. The concept of the "10 percent rule," which applies the same way for foam plastic as for other trim, has already been discussed in the section on concepts.

Electrical Nonmetallic Raceways. Electrical nonmetallic raceways are a special case of interior trim. Raceways are not normally regulated as interior finish. However, concerns have been expressed about the potential contribution of a sizable number of raceways mounted along a wall or ceiling. If the raceways collectively form a substantial surface area over which fire may spread, they could behave like combustible interior finish. Where the authority having jurisdiction judges that a potential hazard exists because of the number, area exposed, or type of material involved, NFPA *101* and *NFPA 5000* currently require nonmetallic raceways to attain a flame spread index of 25 or less when tested "in the form in which they are used." Similar to foam plastic trim, when the raceway constitutes less than 10 percent of the wall area, the smoke index is not limited.

Light-Transmitting Plastics

Light-transmitting plastics are permitted for use if they meet several small-scale fire test criteria and meet other severe area limitations.

Wall Base

Interior floor trim material used at the junction of the wall and the floor to provide a functional or decorative border, and not exceeding 6 in. (150 mm) in height, is permitted for use by NFPA *101* and *NFPA* 5000 if it meets the interior wall finish requirements for its location or the requirements for Class II interior floor finish.

Metal Panels

Listed factory-finished NFPA 255 Class A metal ceiling and wall panels are permitted by NFPA *101* and *NFPA 5000* to be finished with one additional application of paint and to be used in areas where Class A interior finishes are required. The total paint thickness is not allowed to exceed 1/28 in. (0.90 mm).

Fire-Retardant Coatings

Fire-retardant coatings are permitted by NFPA *101* if they are maintained to retain the effectiveness of the treatment under service conditions encountered in actual use.

Decorations and Furnishings

Free-hanging draperies that cover most or all of a wall surface have, on occasion, been subject to the requirements for interior

finish but are considered decorations by NFPA *101* and fire codes and are not addressed by building codes such as *NFPA 5000.* The traditional test for interior finish combustibility, NFPA 255, does not adequately assess the fire behavior of such products. Free-hanging drapery materials are more properly evaluated by NFPA 701*, Standard Methods of Fire Tests for Flame Propagation of Textiles and Films,* although the test is less severe than NFPA 255. When applied to a solid backing, such as gypsum wallboard, a drapery material needs to be considered as a textile wall covering and would be evaluated as interior finish (textile wall or ceiling covering, as appropriate). Other decorations and furnishings are often also required to meet the fire performance of NFPA 701, for example in NFPA *101*. However, when these are stand-alone decorations, they are no longer associated with interior finish and are often not regulated.

ROLE OF INTERIOR FINISH IN FIRES

Most building fires begin when decorative materials, furnishings, or waste accumulations ignite. Interior finishes are less often the first items ignited. For example, in 1999–2002 home fires, interior finish on walls, floors, or ceilings was cited as the first item ignited in only about 6 percent of fires, about 9 percent of civilian fire deaths, about 6 percent of civilian fire injuries, and about 10 percent of direct property damage from fires.[15] When interior finish is ignited, typical heat sources are equipment installed adjacent to interior finish (e.g., wiring, switches, receptacles, outlets, cords and plugs, fireplaces, chimneys or flues), equipment placed near interior finish (e.g., stoves, space heaters, water heaters, dryers, furnaces), equipment used near interior finish (e.g., torches), and open flame sources (e.g., matches, lighters, candles) used by adults or children to intentionally or unintentionally start a fire. Once a fire has started and intensified, however, the interior finish can become involved and contribute extensively to the spread and growth of fire. For example, multiple layers of wall coverings contributed to fire growth in the multideath fires at the Holiday Inn in Cambridge, Ohio, in 1979,[72] and at an office building in Atlanta, Georgia, in 1989.[7] Similarly, the use of non-fire-retarded wood paneling as interior finish in corridors, stairways, or exits (which does not comply with code requirements) often leads to an enhancement of the heat release in the fire; 0.25 inch luan paneling, 0.125 inch plywood paneling, and heart pine boards mounted on furring strips contributed to the severity of fires in a fraternity dormitory in Berkeley, California, in 1990; in a board-and-care facility fire in Detroit, Michigan, in 1992; and in a fraternity house fire in Chapel Hill, North Carolina, in 1996, respectively.[10,11,73,74]

Mechanisms

Interior finish affects fire hazard in four ways: (1) affecting the rate of fire buildup to flashover conditions, (2) contributing to fire extension by flame spread over its surface, (3) adding to the intensity of a fire by contributing additional fuel, and (4) producing smoke and toxic gases that can contribute to life hazard and property damage.[75] From a fire safety standpoint, the most desirable interior finish is one made of a relatively dense and noncombustible material that is a good conductor of heat, does not speed up flashover, does not add fuel to the fire, provides no path for surface flame spread, and produces little or no smoke or toxic gases. Materials that exhibit high rates of flame spread, contribute substantial quantities of fuel to a fire, or produce hazardous quantities of smoke or toxic gases are undesirable.

Interior Finish Materials and Flashover

Combustible interior finish in an enclosure can reduce the heat release rate necessary for flashover and can reduce the time to flashover. Flashover is caused by thermal radiation feedback from the ceiling and upper walls, which have been heated by the fire. This radiation feedback gradually heats the contents of the fire area. When all the combustibles in the space have become heated to their ignition temperatures, simultaneous ignition occurs. Interior finish plays an important role in the occurrence of flashover; that is, an insulating interior finish that lowers heat transfer to upper walls or ceilings can reduce both the time and the rate of heat release required to reach flashover. Any interior finish material that is combustible will contribute fuel to an existing fire, but those with better fire performance are likely to have minimal effects. Considering the nature of thermal radiation, the size and shape of the space in which the fire occurs becomes a critical factor.[76] In some corridor tests conducted by NIST, rapid spread of flame over one or more surfaces was found,[77] an obviously undesirable feature unlikely to be found with materials that meet the NFPA 286 room-corner test.

Once a room fire reaches full involvement, or flashover, heat, smoke, and combustion gases escape through openings to adjoining spaces. In those cases, the ignition of combustible interior finish may become a significant factor in the spread of fire to other areas. Several full-scale fire tests have demonstrated that heat, smoke, and combustion gases from burning furnishings are often sufficient to create a threat to the life safety of persons unable to evacuate the room of fire origin, without any contribution from combustible interior finishes if the interior finish materials have adequate fire performance.[78,79] However, even in such a case, the life safety of occupants remote from the fire and, in addition, potential property damage may be affected by the nature of the interior finishes. It is critical, therefore, to ensure proper fire performance of interior finish.

METHODS OF APPLICATION

The method of applying an interior finish both in actual practice and during the fire test can have a large effect on its fire behavior. For this reason, the manufacturer's specifications for material application should be strictly followed. Special attention must be paid to fastening details, including the type and application of adhesives and the number of coats and the application rate of any fire-retardant coatings. Application details are equally important in repair or replacement of interior finishes. Any new material used in retrofit must meet the code requirements in effect at the time of the retrofit.

The substrate material to which surface finishes are attached plays an important role in the flame spread behavior of thin products.[80] A thin combustible finish applied to a noncombustible substrate may sometimes present little hazard. The same finish material on a combustible backing could constitute a much more serious hazard. In the former situation, the substrate

will not ignite and, thus, will absorb heat during early fire development. In the latter case, both the surface finish and the backing material may ignite and the system will spread flames much more rapidly than either material would alone.

A particularly important case is that of paints. Testing[81] has shown that adding up to two layers of paint with a dry film thickness of about 0.007 in. (0.18 mm) will not change the fire properties of surface-covering systems. Testing has also shown that the fire properties of the surface-covering systems are highly substrate-dependent and that thin coatings generally take on the characteristics of the substrate. When exposed to fire, the potential for partial delamination, bubbling, and blistering of paint has been shown to result in an accelerated rate of flame spread.

The adhesive used is also a crucial factor in the fire behavior of interior finishes. The best performance is likely when an intimate bond is maintained between the face product and the substrate. However, adhesives can, and often do, also contribute fuel to a fire, and too much adhesive or the use of a highly flammable or inappropriate adhesive may result in faster flame propagation. The failure in bond between a surface finish and a substrate can also result in poor performance. Adhesives that soften at moderate temperatures may allow wall and ceiling finishes to drop or partially peel away during the growth stage of a fire. Perhaps the "worst case" for an interior finish is where partial release or partial delamination occurs. In such a case, the material separates from the substrate but remains in position. This not only increases the susceptibility of the surface material to ignition but it also exposes the substrate material, which, if combustible, adds fuel to the fire.

Some interior finishes, such as polystyrene ceiling tiles, achieve acceptable performance in an entirely different manner. They are designed to fall away early in a fire, thereby avoiding fire exposure. Satisfactory performance for such products results from evading flame during the fire growth phase. However, if the products fall or delaminate too early in a fire, they may interfere with persons attempting to escape. Where interior finish materials may fall or delaminate at relatively low temperatures and where the products involved have a significant mass, the behavior of such products should be assessed in terms of their impact on occupants and their effect on potential evacuation. Some building codes specify that wall and ceiling finishes should not become detached when exposed to elevated temperatures of 175 to 300°F (79 to 149°C) for a specified time interval, usually 30 minutes.

Thermally thin products, such as wood paneling 0.25 in. (6.4 mm) thick or less, will tend to spread flame more rapidly when the paneling is installed over studs or furring strips with air space than would be the case if installed over a solid substrate, such as cement board or gypsum board. As a consequence, in such cases some codes require that Class B and C interior finish materials less than 0.25 in. (6.4 mm) thick be permitted for use only when applied over a substrate of noncombustible material. Concern also exists about the possibility of flame spread over concealed surfaces of combustible interior finish materials where air space exists behind the finish. Building codes have application sections that restrict the application of interior finishes over air space in noncombustible assemblies. Interior finishes installed over an air space are restricted to products having a Class A flame spread index on both faces. Building codes regulate concealed spaces created by furring strips by requiring either firestopping or that the space be filled with inorganic or Class A materials.

The use of sprayed-on materials for interior finishes has proliferated. Some of these materials are coatings that are inherently fire safe. Other materials, however, especially the sprayed-on cellular or foam plastics used for insulation or decorative effects, may readily spread flames. The use of such products should be permitted only if fire behavior can be substantiated by large-scale tests conducted under actual fire conditions.

FULL-SCALE TESTS

Many large-scale fire tests have been conducted using existing buildings slated for demolition or available for other reasons. When carefully planned, such tests can add significantly to knowledge about the growth and spread of fire in buildings.

One of the first of these tests was conducted in Great Britain in 1949, under the auspices of the Fire Research Station (now Building Research Establishment).[82] Two 2 story dwellings were used, one with cellulose fiber insulation board lining and the other with plasterboard over fiberboard. One test was conducted in each house, both with real or simulated furnishings, with the bedroom doors open. Another test was conducted in each house with the doors closed. With both types of lining, temperatures in the living room, which was the room where the fire was started, became intolerable within a few minutes. As in many other tests and actual fires, the value of the closed door also was clearly demonstrated in decreasing fire hazard in bedrooms.

In 1958, the Division of Building Research of the National Research Council of Canada (NRCC) conducted a series of full-scale tests, known as the "St. Lawrence Burns," in six dwellings and two larger buildings.[83] Again, the one objective was to study fire spread as it would affect the life safety of the occupants of the second-floor bedroom behind open and closed doors. All dwellings became "smoke logged" within 6 minutes of the ignition of the wood cribs, regardless of the type of interior finish. Temperatures and gaseous combustion products developed much faster in the dwellings with combustible finishes and in those tests in which the bedroom doors were open.

Many large buildings scheduled for demolition were partially burned under the auspices of the Illinois Institute of Technology (ITT) Research Institute. In those tests and in extensive room/corridor tests, much information was developed relative to fire spread, flashover phenomena, and factors affecting life safety in fires.

The Office of the State Fire Marshal in California sponsored a series of tests in unused buildings at Camp Parks in the early 1970s. The objective was to develop criteria for egress facilities, particularly corridors. The final report includes a discussion of the reaction and interaction of wall, ceiling, and floor finishes.[84] Precedent for the full-scale corridor burns was established earlier in 1959 and 1960 by the City of Los Angeles (CA) Fire Department. Final reports on the Los Angeles tests were published in two volumes by NFPA.[85,86]

Furnished room burnout and corridor tests conducted at the Forest Products Laboratory of the U.S. Department of Agriculture compared the relative importance of room furnishings

versus room finishes.[78] A conclusion was reached that lethal levels of combustion products usually developed from burning furnishings before the wall finishes were seriously involved; this was supported by later work at Southwest Research Institute.[79] These and other studies recognize that once a fire is well established, it is highly probable that all combustibles in the room will become involved. Thus, the attainment of flashover, which is often associated with full room involvement in fire statistics, is an indication that life is untenable in the room of fire origin. It is also recognized that early detection, containment, and extinguishment in the room of fire origin is important, not only for early evacuation from the fire area, but also for the safety of persons elsewhere in the building and for the protection of the building itself.

Full-scale experiments have also been conducted to determine how the location and area of a wall finish affects the spread of fire in a corridor.[87] A series of experiments were conducted in a 6-ft (1.83-m) wide by 8-ft (2.44-m) high by 55-ft (16.76-m) long corridor exposed to hot gases from a burner. The corridor ceiling and upper walls were exposed to temperatures of approximately 1450°F (788°C). Corridor ceiling finish materials had flame spread indices between 0 and 25, whereas the wall coverings had a flame spread index of 90. These experiments revealed that ceiling interior finish plays an important role in flame spread behavior of walls. It was determined that wall coverings with a flame spread index of 90 could be used safely with ceiling finish materials having a flame spread index of no more than 25 when the wall covering was limited to the lower 4 ft (1.2 m) of wall surface. Most test configurations using material with a flame spread index of 90 covering the full height of the corridor walls and with ceiling finish materials having a flame spread index of 25 resulted in rapid flame propagation and unsafe conditions. It was deduced that some Class A (FSI < 25) ceiling materials increased flame spread mainly due to the fact that they were better insulators than materials with a zero flame spread index. In other words, the ceiling finish material influenced flame spread over walls by its resistance to heat transfer. This was a unique and unusual situation. These full-scale experiments support the application of materials with flame spread indices greater than those normally allowed when such interior finishes, such as a wainscot, are located in the lower portion of a wall. Codes occasionally recognize this principle and allow Class C materials as a corridor wall finish where Class B is normally required, for example, in health care occupancies, as long as the interior finish does not exceed 4 ft in height and is restricted to the lower half of the wall.

From 1979 to 1980, the U.S. Fire Administration sponsored a series of 75 tests to evaluate the performance of residential sprinklers in single-family and mobile homes. These tests showed the rapid buildup of heat and toxic gases that was possible with ordinary-hazard furnishings, particularly when the fire was ignited in the corner of the room or near curtains. There was a significant difference in the levels of combustion products and the times to reach those levels between fires in noncombustible interior finish and combustible interior finish.[88]

Room fire tests were commonly used in the 1980s for research purposes to evaluate interior finishes, wall coverings, and room furnishings. To help make sense of the proliferation of testing procedures, ASTM E603, *Standard Guide for Room Fire Experiments,*[89] and ASTM E2067, *Standard Practice for Full-Scale Oxygen Consumption Calorimetry Fire Tests,*[90] were developed. The ASTM E603 guide provides information on how room fire tests can be implemented and what combustion parameters are measured. Testing instrumentation may include, but is not limited to, oxygen, carbon dioxide, carbon monoxide, and other gas measurements; rate of heat release; heat flux; flame spread; temperature; air velocity profiles; mass loss rates; and smoke optical densities. The subsequent ASTM E2067 practice goes into considerably more detail but addresses mainly the tests that are intended to make heat release measurements rather than demonstration-type tests; it is a companion to ASTM E603.

See also Section 6, Chapter 3, "Concepts and Protocols of Fire Testing."

SUMMARY

Building interior finish materials can have a significant effect on fire growth and, ultimately, fire size. Interior finish materials can affect the rate of fire buildup to full room involvement and flashover, contribute to fire extension, add to the intensity of a fire, and produce smoke and toxic gases.

Several tests have been developed to try to predict the behavior of interior finish products in a fire. The Steiner tunnel test (NFPA 255 or ASTM E84) is used to calculate the flame spread index and smoke developed index of an interior wall or ceiling finish material, based on flame spread over the face of the test specimen. Room-corner tests are used to determine the probability of flashover and the heat release rate (measured through oxygen depletion) and smoke release in a room in which finish products are mounted on three walls forming a corner (and usually also on the ceiling). Fire testing of interior finish as conducted today is probably adequate to eliminate the poorest performers (both in terms of heat release, or flame spread, and smoke release). However, the emphasis on the supremacy of the Steiner tunnel test for all interior wall and ceiling finish materials means that the full capabilities of the room-corner test, including the actual heat release rates measured, are not being used, and improvements in that area would be welcome.

Fire tests for interior floor finishes include the methenamine pill test, which is a required safety test for all carpet manufactured for sale in the United States, and the critical radiant flux test, which measures the minimum energy required to be impinged on a floor covering to sustain flame propagation.

In addition to controlled laboratory tests, many large-scale fire tests of interior finishes have been conducted by various research organizations on buildings slated for demolition. Such tests yield important data concerning the behavior of interior finishes and furnishings in a fire.

Chapter 3

Smoke Movement in Buildings

James A. Milke ❑ John H. Klote

Chapter Contents

Description of Smoke
Smoke Production
Hazard of Smoke
Principles of Smoke Movement
Smoke Management

Key Terms

atria, buoyancy, compartmentation, dilution, pressurization, smoke (cool), smoke (hot), smoke movement, smoke production, stack effect, wind effect

Smoke is inherent in all fires and contains dangerous products of combustion that have critical influences on life safety, property protection, and operations by fire fighters in buildings. In some fires, the volume of visible smoke is so great that it may fill an entire building and obscure visibility at street level to such an extent that it is difficult to identify the fire-involved building. In other incidents, the volume of visible smoke generated may be considerably less, although the danger to life is not necessarily diminished because of the presence of invisible airborne products of combustion.

This chapter gives information on the techniques used to evaluate the physical characteristics of smoke and assess its movement in both short and tall buildings. Information on smoke properties and the forces inducing movement are used as a basis for designing smoke-control systems. The approaches that can be used to limit the hazard of smoke in buildings are also covered.

This chapter provides a general background on the subject, including a discussion of relationships, and selected equations useful in understanding smoke movement and smoke management in buildings. Detailed design information is available from a number of sources. The book by Klote and Milke,[1] *Design of Smoke-Management Systems,* provides a consolidation and systematic presentation of data and calculations necessary for the design of systems to manage smoke movement. Specific design information is provided in that publication for pressurized stairwells, pressurized elevators, zoned smoke control, and smoke management in large spaces, including atria and shopping malls. Klote and Milke each have written chapters in the third edition of the *SFPE Handbook of Fire Protection Engineering,*[2] which summarize much of the general information from the book by those two authors. First published in 1988, NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences,* provides additional recommendations for stairwell pressurization systems and zoned smoke-control systems, including suggested levels of pressurization for such systems in sprinklered and unsprinklered buildings. NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces,* first published in 1991, is a technical guide for the design of smoke management systems in shopping malls, atria, and other large-volume spaces.

For related topics see, Section 3, Chapter 5, "Introduction to Fire Modeling"; Section 3, Chapter 6, "Applying Models to Fire Protection Engineering Problems and Fire Investigations"; Section 3, Chapter 9, "Closed Form Enclosure Fire Calculations"; Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems"; and Section 18, Chapter 4, "Venting Practices."

James A. Milke, Ph.D., P.E., is an associate professor in the department of fire protection engineering at the University of Maryland. He is a fellow of SFPE and is past chair of the NFPA Smoke Management Systems Committee.

John H. Klote, D.Sc., P.E., is a consultant specializing in smoke management and was the head of building fire physics at NIST. He is a fellow of SFPE and a fellow of ASHRAE. Dr. Klote is a member of the NFPA Smoke Management Committee.

DESCRIPTION OF SMOKE

As a fire burns, it generates heat and also generates products of combustion as a result of the chemical reactions associated with the combustion process. These products of combustion include the following:

1. Gases, such as carbon dioxide, carbon monoxide, water vapor, and possibly many others depending on the fuel
2. Solids, such as "soot," and liquids

A major portion of the heat generated by a fire remains in the mass of combustion products generated by the fire. This mass expands, is lighter than the surrounding air, and rises as a plume. The rising plume is turbulent and, because of this, entrains large quantities of air from the surrounding atmosphere into the rising gases, as indicated in Figure 18.3.1. This entrainment has the following effects:

1. Increases the total mass and volume of the plume
2. Cools the plume by mixing the cool entrained air with the rising hot gases; normally, the rising plume is hotter at its center and cooler toward the edges where cooler air is entrained
3. Dilutes the concentration of fire products in the plume

Smoke is defined in NFPA 92A and 92B as "The airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis or combustion, along with the quantity of air that is entrained or otherwise mixed into the mass."[1,2]

SMOKE PRODUCTION

The volume of combustion products contained in a rising plume is relatively small compared to the volume of air in the total mixture. Consequently, the volume of smoke produced by a fire approximates the volume of air drawn or entrained into the rising plume. Figure 18.3.1 illustrates the process.

In situations in which the height of the plume, measured from the top of the fire to the level of the smoke layer, is greater than the height of the solid body of flame, reasonably accurate estimates of the rate of smoke production can be obtained using empirical formulas.[3,4]

In general, the equations given in this chapter should be used where the fire is small compared to the height of the space involved. Alternatively, where this is not true, approaches such as those contained in Section 18, Chapter 4, "Venting Practices"; Section 3, Chapter 5, "Introduction to Fire Modeling"; and Section 3, Chapter 9, "Closed Form Enclosure Fire Calculations" are more appropriate.

The following equation is based on research conducted at Factory Mutual Research (FMR) and is the equation used for smoke production in NFPA 92B. The rate of smoke production (i.e., mass entrainment rate) can be estimated as[5]

$$\dot{m} = 0.071k^{2/3}Q_c^{1/3}z^{5/3} + 0.0018Q_c \qquad (1)$$

where

$\dot{m}$ = Mass flow in plume at height z (kg/sec)

k = Wall factor (Figure 18.3.2)

Q_c = Convective heat release rate of fire (kW)

z = Height above top of fuel (m)

Equation 1 is the same as the corresponding equation in NFPA 92B for the value of $k = 1$. Equation 1 includes a series of assumptions, the most important of which are the following:

1. The tip of the flame is a significant distance below the bottom of the smoke layer as is often the case in malls and atria. The formula is less accurate in spaces with a low ceiling relative to the height of the fire involved. In such cases, see NFPA 92B for the applicable equation.

2. The fire bed itself covers an area whose length and width are reasonably approximate to each other. The original formula is based on the assumption of a circular fire. The degree of error in the formula increases as the ratio of length to width increases.

3. The ceiling is sufficiently high so that a correction for the "virtual origin" of the fire is unnecessary (see Klote and Milke[1] for a description of virtual origin). This is true where the fire is small compared to the height of the space involved, as is the case for small fires in rooms or for design applications involving atria or other large-volume spaces.

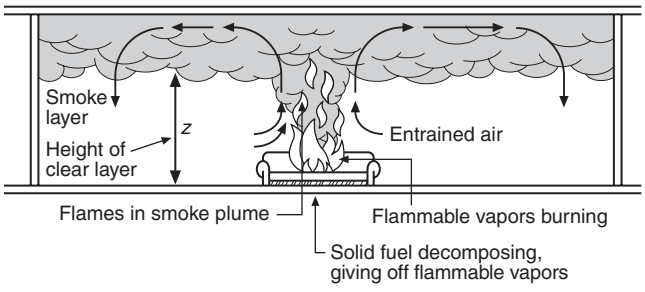

FIGURE 18.3.1 Production of Smoke from a Fire

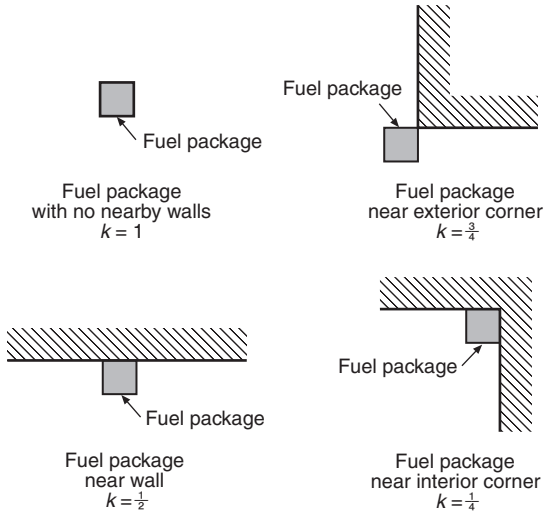

FIGURE 18.3.2 Wall Factors for Fuel Package Locations

Flame Height

A reasonable estimate of the visible flame height[6] can be obtained from the equation:

$$z_f = 0.166(Q/k)^{0.4} \quad (2)$$

where

z_f = Mean flame height (m)

Q = Heat release of the fire (kW)

k = Wall factor (see Figure 18.3.2).

Equation 2 is the same as the corresponding equation in NFPA 92B for the value of $k = 1$. The convective portion of the heat release rate, Q_c, can be expressed as

$$Q_c = \xi Q \quad (3)$$

where ξ is the convective fraction of heat release. The convective fraction depends on the heat conduction through the fuel and the radiative heat transfer of the flames, but a value of 0.7 is often used for ξ. The results of Equation 3 for a convective fraction of 0.7 are shown graphically in Figure 18.3.3.

Average Plume Temperature

Detailed engineering equations for fire plumes have been presented.[5,6] The average temperature of a fire plume is needed to express the rate of smoke production as a volumetric rate rather than as a mass rate (as in the previous section).

$$T_p = \frac{Q_c}{\dot{m} C_p} + T_o$$

where

T_p = Average plume temperature (°C)

$\dot{m}$ = Mass flow in plume at height z (kg/sec)

Q_c = Convective heat release rate of fire (kW)

C_p = Specific heat of plume gases, 1.00 kJ/kg°C

T_o = Ambient temperature (°C)

The average plume temperature decreases with increasing height above the fuel. This can be realized by recalling that the mass flow in the plume increases with the clear height, z.

The average plume temperature should not be confused with the centerline plume temperature. The plume centerline temperature is greater than the average plume temperature. Where the average plume temperature is approximately equal to the ambient temperature, the buoyancy of the plume is relatively weak. Because the mass entrainment equation (Equation 1) is for a strongly buoyant plume, the correlations may yield answers with significant errors in cases where the plume has low buoyancy. This topic needs further study, but in the absence of better data, it is recommended that the plume equations not be used when the average temperature increase is small—less than 4°F (2°C). The average temperature rise of a plume for a fuel package with no nearby walls is shown in Figure 18.3.4.

Volumetric Plume Flow

The volumetric flow rate of a plume is

$$\dot{V} = 1.1\dot{m}(T_p + 460)$$

where

$\dot{V}$ = Volumetric flow rate of plume at height z (ft^3/min)

$\dot{m}$ = Mass flow in plume at height z (lb/sec)

T_p = Average temperature of plume gases at height z (°F)

In SI units, this equation is

$$\dot{V} = \frac{\dot{m}(T_p + 273)}{353}$$

where

$\dot{V}$ = Volumetric flow rate of plume at height z (m^3/sec)

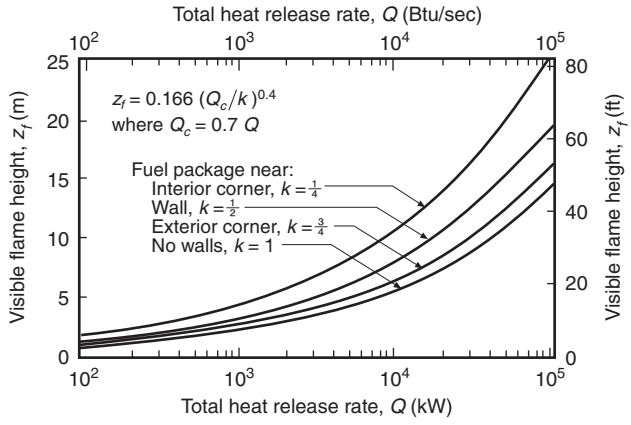

FIGURE 18.3.3 Flame Height Versus Fire Heat Release Rate

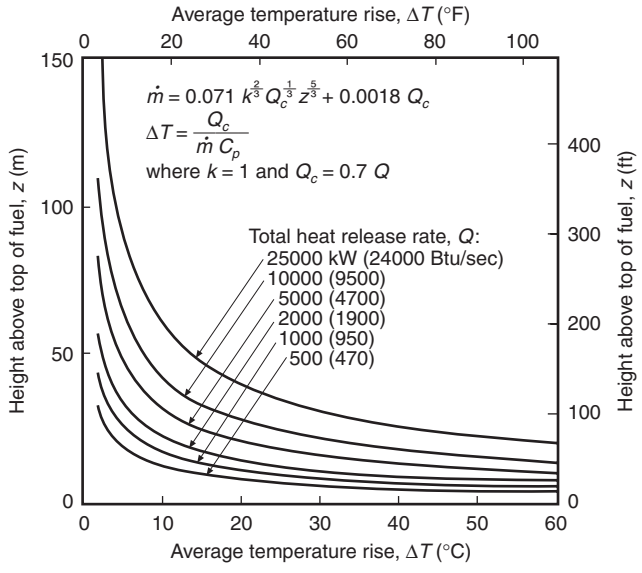

FIGURE 18.3.4 Average Plume Temperature Rise

$\dot{m}$ = Mass flow in plume at height z (kg/sec)

T_p = Average temperature of plume gases at height z (°C)

HAZARD OF SMOKE

Smoke can adversely affect people, property (including the building structure and contents), and mission continuity. The effect of exposure to smoke is dependent on the magnitude of the properties of the smoke (concentration of various gases, visibility reduction, temperature, and radiant flux) and the duration of the exposure.

People who are exposed to smoke may be harmed as a result of exposure to toxic gases, elevated temperature, or radiant energy. The toxic effects of the gases in smoke are described in Purser[7] and Klote and Milke.[1] For short duration exposures (on the order of 1 to 2 minutes), a carbon monoxide concentration of 0.1 to 0.8 percent may cause humans to become incapacitated while walking or being involved in a similar level of activity.

Exposure to radiant energy from a smoke layer at a temperature of at least 320°F (160°C) for a short duration (5 to 10 seconds) may be sufficient to inflict pain, considering the smoke to be a black body. Such a smoke layer temperature will provide a radiant heat flux of approximately 2 kW/m^2 (20 Btu/sft^2). Alternatively, people can typically tolerate being submerged in a smoke layer up to 212°F (100°C) for approximately 10 minutes.

A reduction of visibility by smoke may cause people evacuating to become disoriented or reduce their walking speed, thereby increasing the amount of time required for evacuation. Klote and Milke[1] describe the relationship between visibility and movement speed based on the work by Jin.[8] In addition, a reduction of visibility may increase the susceptibility of building occupants to trip over obstructions or fall over balcony railings.[9] A review of tenability analysis methods is provided by Purser as well as Milke, et al.[10]

Building contents can be affected by exposure to corrosive gases, particulate matter, and the elevated temperature of smoke. Electronic components may be damaged by temperatures and gas concentrations well below that needed to harm humans. Electronic equipment and data storage media are particularly sensitive to elevated temperature, being damaged at temperatures as low as 104°F (40°C) for diskettes and 176°F (80°C) for computer hardware. Smoke may contain several corrosive components, either as gases or absorbed into solid particles. Electronic equipment can be damaged by exposure to smoke containing only 0.01 percent of HCl or 0.1 percent of HF, especially if restoration activities are not initiated promptly after the incident. Contamination of food and pharmaceuticals is generally acknowledged, given exposure to smoke of virtually any concentration.

Mission continuity may be threatened following a fire, while a building or portion thereof is closed for restoration. This results in loss of revenue for the building owner, temporary unemployment of workers in the building, and loss of service of the facility to the community, among other effects.

PRINCIPLES OF SMOKE MOVEMENT

Smoke moves from an area of high pressure to one of low pressure. Pressure differences from one space to another may be caused by buoyancy from the fire, stack effect, wind, and forces from building heating, ventilating, and air-conditioning (HVAC) systems. Where multiple effects are present, smoke movement will depend on a combination of effects, one of which may be dominant.

Hot Smoke Versus Cool Smoke

The temperature of hot smoke results in the smoke being naturally buoyant. As such, the movement of hot smoke is directed toward the ceiling while clean (or at least less polluted) air is drawn in through the lower portion of the space. Hot smoke may be transported to adjacent rooms or corridors, depending on the level of energy produced by the fire and the size of connecting openings, such as open doors. Industrial and warehouse smoke and heat venting are effective smoke management methods because hot smoke is particularly buoyant.

As smoke is transmitted from the area of fire origin, it is cooled by the entrainment of air, heat transfer from the smoke body to surrounding walls and ceiling, and by radiant energy losses to all surroundings. When smoke from a fire flows through a relatively small crack, the entrainment of cool air on the unexposed side tends to cool the smoke very quickly. When the leakage is through larger openings, there may be less entrainment relative to the mass of smoke movement at such junctures and, therefore, cooling will be slower.

Where mixing and other forms of heat transfer have significantly reduced the temperature of the smoke, the effect of the buoyancy force is moderated. In such cases, stack effect, wind, and the mechanical HVAC or other air-movement systems become the primary controlling forces affecting smoke movement. Consequently, the movement of cool smoke is essentially the same as the movement of any other pollutant.

When hot smoke is transported from one area of a building to another through a confined passageway, such as a duct, shaft, or stairwell, there will be little or no cooling due to entrainment. In such cases, cooling will be limited to heat lost by conduction from the moving smoke through the shaft material. Often, this loss is modest, and hot smoke can be transported significant distances with only minor cooling by such confined passageways.

Smoke Movement in Tall Buildings

Smoke can behave very differently in tall buildings than in low buildings. In low buildings, the influences of the fire, such as heat, convective movement, and fire pressures, are generally the major factors that cause smoke movement. Smoke removal and venting practices reflect this behavior. In tall buildings, these same factors are complicated by the stack effect, which is the vertical natural air movement through the building caused by the differences in temperatures and densities between the inside and outside air. Stack effect in tall buildings can become an important factor in smoke movement and in building design features used to combat that movement.

The predominant factors that cause smoke movement in tall buildings are stack effect, the influence of external wind forces, and the forced air movement within the building. The next two parts of this chapter describe theoretical natural air movement, which is affected by the stack effect and external wind forces. Forced air movement caused by the building air-handling equipment is presented in Section 18, Chapter 4, "Venting Practices," and Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems," and is not discussed here except to note that air movement can be influenced significantly by the mechanical systems of the building. Many smoke management systems use emergency operation of the mechanical systems.

Flow Through Openings

Where a pressure difference exists across a crack, gap, or other opening, a flow will result from the higher pressure side to the lower pressure side. The *orifice equation* is commonly used to describe such flow:

$$\dot{V} = CA\sqrt{\frac{2\Delta P}{\rho}}$$

where

$\dot{V}$ = Volumetric flow rate through the path (m^3/sec)

C = Dimensionless flow coefficient

A = Flow area (also called leakage area) (m^2)

ΔP = Pressure difference across path (Pa)

ρ = Density of gas in path (kg/m^3)

In the context of flows through gaps around doors and through construction cracks, the coefficient C is generally 0.6 to 0.7. For standard air density of $\rho = 0.075$ lb/ft^3 (1.20 kg/m^3) and for $C = 0.65$, the flow equation above can be expressed as

$$\dot{V} = 2610A\sqrt{\Delta P}$$

where

$\dot{V}$ = Volumetric flow rate through the path (ft^3/min)

A = Flow area (also called leakage area) (ft^2)

ΔP = Pressure difference across path (in. of water)

In SI units, this equation is

$$\dot{V} = 0.839A\sqrt{\Delta P}$$

where

$\dot{V}$ = Volumetric flow rate through the path (m^3/sec)

A = Flow area (also called leakage area) (m^2)

ΔP = Pressure difference across path (Pa)

Stack Effect

Under normal conditions, stack effect can account for a major part of the natural air movement in buildings. During a fire, stack effect is often responsible for the wide distribution of smoke and toxic gases in high-rise buildings. "Normal" stack effect, present when the indoor air temperature is greater than the outdoor air temperature, is characterized by a strong draft from the ground floor to the roof of a tall building. The magnitude of this stack effect is a function of the building height, the airtightness of the exterior walls, the air leakage between floors of the building, and the temperature difference between the inside and outside of the building.

To illustrate the principle of stack effect, consider the schematic of a box with a single opening near the bottom and another near the top, as shown in Figure 18.3.5. The theoretical natural draft between the two openings is caused by the difference in weight of the column of air within the box and that of a corresponding column of air of equal dimensions outside the box. The magnitude of the theoretical natural draft may be computed by using the following formula:

$$\Delta P = 2.96HB_o\rho\left(\frac{1}{T_o} - \frac{1}{T_i}\right)$$

where

ΔP = Theoretical pressure difference (in. of water)

H = Vertical distance between the inlet and the outlet (ft)

B_o = Barometric pressure (in. of mercury)

T_o = Temperature of outside air (°F)

T_i = Temperature of inside air (°F)

ρ = Density of air at 0°F and 1 atmosphere pressure (lb/ft^3)

Assuming values of $B_0 = 29.9$ in. and $\rho = 0.0862$ lb/ft^3, this expression reduces to

$$\Delta P = 7.63H\left(\frac{1}{T_o} - \frac{1}{T_i}\right)$$

Vertical air movement in a building is caused by this natural draft, or stack effect. The magnitude of the stack effect depends on the difference between the inside and outside temperatures

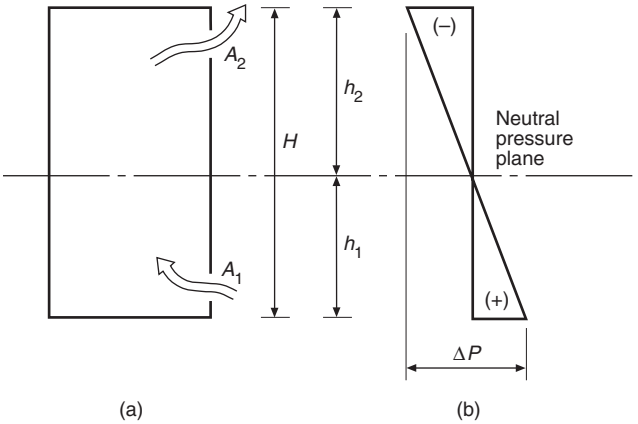

FIGURE 18.3.5 Air Movements Caused by (a) Pressure and (b) Location of Neutral Pressure Plane in a Structure Without Horizontal Barriers and With the Two Openings Shown

and on the vertical distance between openings. If the inside and outside temperatures are equal ($T_i = T_o$), no natural air movement takes place. When T_o is less than T_i, the air moves vertically upward, with the lower opening acting as the inlet and the upper opening as the outlet. A reverse stack effect occurs when T_o is greater than T_i. In this case, the upper opening is the inlet and the lower opening becomes the outlet.

Part (b) of Figure 18.3.5 illustrates the pressures that cause these movements. In this figure, if T_o is assumed to be equal to T_i, the exterior pressure will be greater than the interior pressure at the lower opening. Consequently, outside air is forced into the building at that location. Because the outside pressure at the upper opening is lower than the inside pressure, a negative pressure difference at that location is present, which forces the inside air to the outside. Based on basic engineering principles, the pressure distribution between these two locations is assumed to be linear.

If an opening were present in the exterior wall in a region of positive pressure, air would flow into the building. An opening in a region of negative pressure would cause air to flow out of the building. The neutral pressure plane indicates where inside and outside pressures are equal. If there were an opening at this level, air would move neither inward nor outward. The location of the neutral pressure plane in a structure without horizontal barriers and with the two openings shown in Figure 18.3.5 can be determined from the following relationship:

$$\frac{h_1}{h_2} = \frac{A_2^2 T_o}{A_1^2 T_i}$$

where

h_1 and h_2 = Distances from the neutral pressure plane to the lower and upper openings, respectively

A_1 and A_2 = Cross-sectional areas of the lower and upper openings, respectively

T_i and T_o = Absolute temperatures of the air inside and outside the building, respectively

The magnitude of the pressures created by stack effect are described by the equation

$$\Delta p = 7.63H\left(\frac{1}{T_o} - \frac{1}{T_i}\right)$$

where

Δp = Pressure difference (in. of water)

T_o = Temperature of outside air (°F)

T_i = Temperature of inside air (°F)

Examination of Figure 18.3.6 illustrates the significant differences between tall and short buildings with regard to air movement by stack effect. For example, assume that a fire develops a pressure of 0.06 in. of water (15 Pa) in a compartment, the outside temperature is 50°F (10°C) lower than the inside temperature, and the fire occurs at the same level as the lower opening. The curve $T_i \pm 50$°F (10°C) indicates that if the upper outlet were approximately 40 ft (12 m) above the fire, the inlet stack pressure would balance the pressure caused by the fire. A building taller than 40 ft (12 m) would create a greater stack pressure, and, theoretically, the outside air would move into the building.

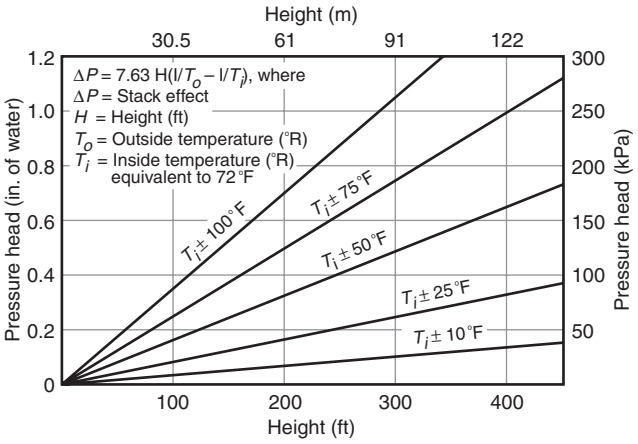

FIGURE 18.3.6 Stack Effect Due to Height and Temperature Difference (°C = [°F – 32] × 5/9)

Influence of Floors and Partitions

The theoretical draft described by Figure 18.3.5 and the net pressure difference present in real buildings is modified by the presence of floors and partitions. These barriers impede the free movement of air, although a significant flow can take place through openings in the assemblies.

The magnitude and location of the leakage areas in a building naturally vary with the building's function and type of construction. The National Research Council of Canada (NRCC) conducted studies of airtightness for major separations on four buildings ranging from 9 to 44 stories high. The measurements were used for computer modeling of the air movement for a simulated 20 story building with a floor plan dimension of 120 ft by 120 ft (36 m by 36 m) and a floor to floor height of 12 ft (3.6 m).[11] The data from the NRCC are given in Table 18.3.1 in the form of a ratio of the net leakage area to the surface area of the building component.

These leakage areas are sufficient to allow substantial air movement throughout the building. Most of the air will flow into vertical shafts, such as stairwells and elevator shafts. Some will flow vertically from floor to floor through the minor openings in the floor-ceiling assembly. This floor-to-floor movement is always caused by a pressure differential between the floors.

Part (a) of Figure 18.3.7 illustrates the pressure difference characteristics of a building in which stack effect causes air movement. The slopes of the pressure lines represent differences between any two regions at the same height. Airflow from one region to another is illustrated by the airflow directions represented by the arrows in Part (b) of Figure 18.3.7.

Wind Effects

Wind is another important factor influencing the movement of smoke. Again, tall and short buildings behave somewhat dif-

TABLE 18.3.1 Typical Leakage Areas for Walls and Floors of Commercial Buildings[a]

Construction Element	*Tightness*	*Area Ratio*[b]
		A/A_w

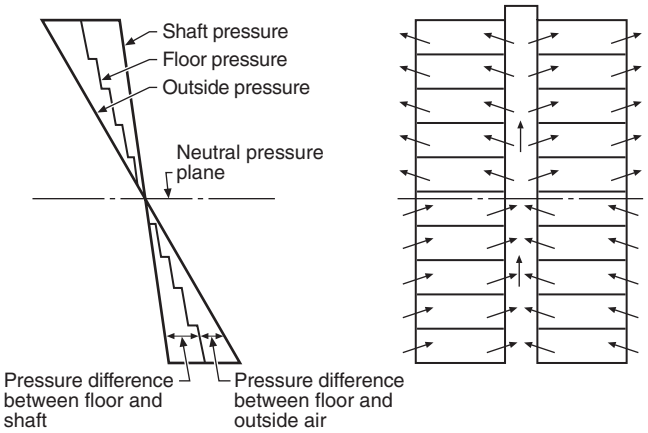

FIGURE 18.3.7 Pressure Difference Characteristics of a Building in Which Stack Action Causes Air Movement

ferently in this regard. Figure 18.3.8 illustrates the air pressure distribution along the four sides and the roof of a building. The plan view of the pressures shows that the windward wall is subjected to an inward pressure, whereas the leeward wall and the

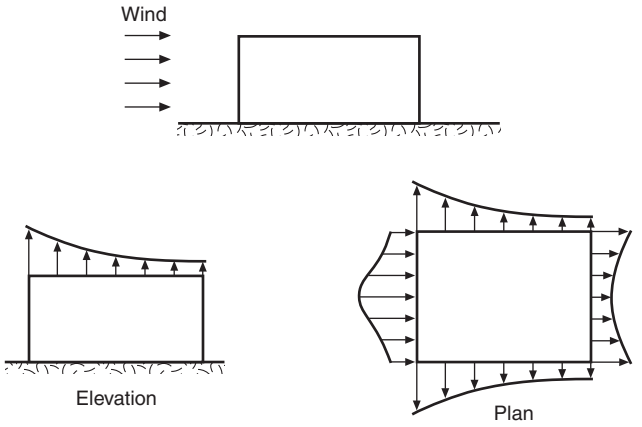

FIGURE 18.3.8 Air Pressure Distribution Along the Four Sides and Roof of a Building

two side walls have an outward pressure, or suction. The flat roof has an upward pressure, with the maximum amount occurring at the windward edge.

These pressures are caused by the movement of a mass of air over and around the structure. A short, wide building will cause the major volume of air to move over the roof, with correspondingly less air movement around the sides. A tall, narrow building, on the other hand, will cause the major volume of air to follow the path of least resistance around the building, with less movement over the top. The velocities of these movements are the primary cause of the amount and directions of the pressures on the building.

Wind velocities and direction vary over any face of a building. The following are the most important effects:

1. *Wind velocity.* The higher the wind velocity, the greater the effects of the following two influences.
2. *Ground effect.* Unless influenced by unusual arrangements of structures or terrain, the friction and turbulence that occur as air moves over the ground result in the lowest velocity at ground level, which increases with increasing height.
3. *Structures.* Buildings and other artificial or natural features, such as trees, can produce localized effects that can increase, decrease, or alter the direction of wind forces.

The effect of wind pressures and suctions modifies the natural air movement within a building. For example, the negative pressure on the roof of a tall building can have an aspirating effect on a vertical shaft opened at the roof level. This can cause the observed draft to exceed the theoretical draft shown in Figure 18.3.9. Note how the neutral pressure plane changes location throughout the building in the presence of significant wind.

Horizontal pressures and suctions cause the neutral planes in exterior walls to move. Positive wind pressure tends to raise the neutral pressure plane, whereas negative pressure lowers it. Figure 18.3.9 illustrates the influence of wind action on air movement in a building.

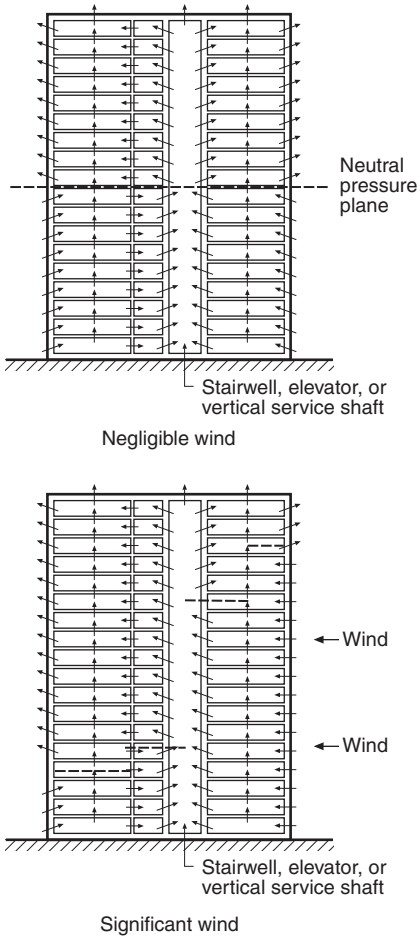

FIGURE 18.3.9 Influence of Wind Action on Air Movement in a Building

SMOKE MANAGEMENT

The term *smoke management,* as used in this section, includes all methods that can be used alone or in combination to modify smoke movement for the benefit of occupants or fire fighters or to reduce property damage. Compartmentation, dilution, airflow, pressurization, and buoyancy of the smoke itself can be used alone or in combination to manage the hazard of smoke in fires.

Compartmentation

Barriers such as walls, partitions, floors, and doors with sufficient fire resistance to remain effective throughout a fire exposure have a long history of providing protection against fire spread. These same barriers provide some level of smoke protection to spaces remote from the fire. Many codes, such as NFPA *101®*, *Life Safety Code®*, and NFPA 105, *Standard for the Installation of Smoke Door Assemblies and Other Opening Protectives,* provide specific criteria for the construction of smoke barriers, including doors and smoke dampers in these barriers. The amount of smoke leakage through such barriers depends on the size and shape of the leakage paths in a barrier and on the pressure difference across the leakage path.

There is no formalized analytical method for determining the rate of smoke leakage through barriers and the resulting levels of hazard in areas to be protected. A first-order approximation of the leakage can be made using the equation for flow through an opening. Typical leakage areas for barriers are listed in Table 18.3.1. Estimates of the leakage areas for gaps around doors can be obtained by considering the dimensions of paths around doors. Where multiple leakage paths are present, an effective leakage area can be determined following the methods in Klote and Milke.[1] In lieu of using the simple algebraic equation, fire and smoke transport models can address the smoke leakage through barriers (though these still require information to be provided concerning the size of the leakage paths). Full appraisal of the impact of such leakage requires knowledge of the smoke toxicity or an assumed design value of the acceptable smoke concentration in protected spaces. More effort is needed to increase the understanding of the capabilities and reliability of passive barriers in order to maximize the usefulness of this oldest and most fundamental method of smoke management.

Dilution

Dilution of smoke is sometimes referred to as smoke purging, smoke removal, smoke exhaust, or smoke extraction. Dilution can be used to maintain an acceptable smoke concentration in a compartment subject to smoke infiltration from an adjacent space. This can be effective if the rate of smoke leakage is small compared to either the total volume of the safeguarded space or the rate of purging air supplied to and removed from the space. Dilution also can be beneficial to the fire service for removing smoke after a fire has been extinguished. Sometimes, when doors are opened, smoke will flow into areas intended to be protected. Ideally, doors will be open only for short periods during evacuation. Smoke that has entered spaces remote from the fire can be purged by supplying outside air to dilute the smoke.

Some expectations may be unrealistic regarding what dilution can accomplish in the fire space. There is no theoretical or experimental evidence that using a building's HVAC system for smoke dilution will result in any significant improvement in tenable conditions within the fire space. Even though HVAC systems promote a considerable degree of air mixing within the spaces they serve, building fires produce very large quantities of smoke. As such, dilution of smoke by an HVAC system in the fire space does not usually result in any practical improvement in the tenable conditions of that space. Thus, smoke-purging systems intended to improve hazard conditions should not be used within a fire space or in spaces connected to a fire space by large openings.

The following is a simple analysis of smoke dilution for spaces in which there is no fire. At time zero ($t = 0$) a compartment is contaminated with some concentration of smoke, and no further smoke flows into or is generated within the compartment. In addition, the contaminant is considered uniformly distributed throughout the space. The concentration of contaminant in the space can be expressed as

$$a = \frac{1}{t} \log_e \left(\frac{C_o}{C} \right)$$

where

C_o = Initial concentration of contaminant

C = Concentration of contaminant at time t

a = Dilution rate in number of air changes per minute

t = Time after smoke stops entering space or time after which smoke production has stopped (minutes)

e = Constant, approximately 2.178

The concentrations C_o and C must be expressed in the same units, and they can be any units appropriate for the particular contaminant being considered. McGuire, Tamura, and Wilson[17] evaluated the maximum levels of smoke obscuration from a number of fire tests and a number of proposed criteria for tolerable levels of smoke obscuration. Based on this evaluation, they stated that the maximum levels of smoke obscuration are greater by a factor of 100 than those relating to the limit of tolerance. According to their observation, an area can be considered "reasonably safe" with respect to smoke obscuration if its atmosphere will not be contaminated to an extent greater than 1 percent by the atmosphere prevailing in the immediate fire area. Because a toxicity analysis can be somewhat involved and dilution will reduce concentrations of toxic smoke components as well as improve visibility, a first-order analysis can be done on a basis of smoke obscuration.

EXAMPLES: Smoke purging after the fire is extinguished.

1. After the fire department puts out a fire, the smoke must be cleared quickly so that an inspection can be made to determine if the fire is completely out. If the smoke HVAC system is capable of a dilution rate of six air changes per hour, how long will it take to reduce the smoke concentration to 1 percent of the initial value? The dilution rate, a, is 0.1 change per minute, and C_o/C is 100. $t = \frac{1}{0.1} \log_e(100) = 46$ minutes to purge smoke to 1 percent of initial value.

2. Considering the fire department's desire to inspect the area quickly, such a long purging time will probably be excessive. If the fire department wants the space to be purged in 10 minutes, what dilution rate is needed? The dilution time, t, is 10 minutes, and C_o/C is 100. $a = \frac{1}{10} \log_e(100) = 46$ change per minute (28 changes per hour).

In reality, it is impossible to ensure that the concentration of the contaminant is uniform throughout the compartment. Because of buoyancy, it is likely that higher concentrations would tend to be near the ceiling. Therefore, an exhaust inlet located near the ceiling and a supply outlet located near the floor would probably dilute smoke even faster than indicated by the preceding equations. Caution should be exercised in locating the supply and exhaust points to prevent the supply air from blowing into the exhaust inlet and thus short-circuiting the dilution operation.

Pressurization

Systems using pressurization produced by mechanical fans are referred to as smoke-control systems in NFPA 92A. Pressurization results in airflows of high velocity in the small gaps around closed doors and in construction cracks, thereby preventing smoke backflow through these openings. The pressurization systems most commonly used are pressurized stairwells and zoned smoke control. Elevator smoke control is rarely used, though interest in elevator smoke control may rise with the increasing interest in using the elevators as part of the means of egress for all or part of the building population. A public domain computer program, CONTAM,[18] may be applied to assess the pressure differences provided by a smoke-control system.

Many pressurized stairwells are provided with the goal of maintaining a tenable environment within the escape route in the event of a building fire. As such, a pressurized stairwell is designed to limit the amount of smoke migration into the stairwell, though not necessarily to keep the stairwell perfectly smoke-free. The following are the three major design concerns with pressurized stairwells:

1. Varying pressure differences that occur over the stairwell height
2. Large pressure fluctuations caused by doors being opened and closed
3. Location of supply air inlets and fans

Intuitively, it might appear that the pressure differences from the stairwell to the building would be approximately the same over the height of the stairwell. Unfortunately, this is not the case. For a building without vertical leakage through floors or shafts other than the stairwell, the pressure profile is linear. Of course, actual buildings have other shafts (elevators, pipe chases, etc.) and also have floor assemblies that are not airtight. However, this case is useful because it represents the most challenging situation to formulate a design. Its minimum pressure difference is less than that for buildings with more realistic leakage configurations and its maximum pressure difference is greater than that for other leakage configurations. A solution in the form of an algebraic equation exists to determine the pressure differences in a pressurized stairwell, neglecting vertical air movement in the building. In contrast, computer analyses are required to include the effects of more complicated building leakage arrangements.

When a door is opened in a pressurized stairwell, the pressure difference across the remaining closed doors can drop substantially. The two classes of design concepts that have been used to deal with this problem are overpressure relief and feedback control. An overpressure relief system that has gained attention as being simple and cost-effective is the "Canadian system." The essential features of this system are that air is supplied by one or more fans at relatively constant flow rates, and the ground-floor exterior stairwell door opens automatically when the system activates. This system eliminates the source of the most severe pressure fluctuations—the opening and closing of the exterior door.

There is concern about locating supply air inlets near the exterior ground-floor doors of the stairwell. If a supply inlet is located near this door, it is possible that much of the supply air will flow directly through the exterior doorway when it is opened, thus compromising the stairwell pressurization system. It is believed that locating inlets only one floor away from exterior doors eliminates this potential.

In the late 1960s, the concept of the "pressure sandwich" or "zoned smoke control" evolved. This consisted of exhausting the fire floor and pressurizing surrounding floors to limit

smoke movement to the fire floor by creating pressure differences between floor levels. According to the concept of zoned smoke control, a building can be divided into a number of smoke zones, each separated from the others by partitions and floors. A smoke-control zone can consist of one floor, more than one floor, or part of a floor. In the event of fire, pressure differences and airflows produced by mechanical fans can be used to restrict smoke spread to the zone in which the fire began, or the smoke zone. One of the factors affecting successful performance of a zoned smoke control system is accurate identification of the zone of fire origin. As such, fire alarm initiating devices used to actuate a zoned smoke control system need to be carefully selected. Failure to identify the correct fire zone, such as a case where a manual pull station is activated outside the fire zone, may result in a positive pressurization of the fire zone, which may encourage smoke spread to other zones.

When using zoned smoke control, careful integration of smoke zones, barriers, and the initiating devices is required. Physical barriers (walls or floors) must coincide with the spatial definition of the smoke control zone. Where HVAC equipment is used to supply and exhaust air, the HVAC zones must agree with the smoke zones. If fire alarm initiating devices or sprinkler waterflow alarms are used to actuate the zoned smoke-control system, the zones for these systems must coincide with the smoke-control zones.

As a caution, the design of zoned smoke-control systems is not intended to improve conditions in the fire zone. The concentration of smoke in this zone may render it untenable. Accordingly, in zoned smoke-control systems, building occupants should evacuate the zone in which the fire occurs as soon as possible after the fire has been detected.

Airflow

Airflow has been used extensively to manage smoke from fires in subway, railroad, and highway tunnels. Large flow rates of air are needed to control smoke flow, and these flow rates can supply additional oxygen to the fire. Because of the need for complex controls and large airflows, airflow is not used as extensively in buildings. The control problem consists of having very small flows when a door is closed, and then having those flows increase significantly when that door opens.

Thomas[19] determined that airflow in a corridor in which there is a fire can almost totally prevent smoke from flowing upstream of the fire. As illustrated in Figure 18.3.8, the smoke forms a surface that slopes into the direction of the oncoming airflow. Molecular diffusion is believed to result in the transfer of trace amounts of smoke, producing only an odor of smoke, but no hazard upstream. There is a minimum velocity below which smoke will flow upstream, and Thomas[19] developed the following empirical relation for this critical velocity. This relation, evaluated at an air density of 0.081 lb/ft^3 (1.3 kg/m^3) and temperature of 81°F (27°C), is

$$V_k = 5.68\left(\frac{E}{W}\right)^{1/3}$$

where

V_k = Critical air velocity to prevent smoke backflow (ft/min)

E = Energy release rate into corridor (Btu/hr)

W = Corridor width (ft)

This relation can be used when the fire is located in the corridor or when the smoke enters the corridor through an open doorway, an air transfer grille, or some other opening. Although the critical velocities calculated from the above equation are approximate, these critical velocities are indicative of the kind of velocities required to prevent smoke backflow from fires of different sizes.

EXAMPLES: Rough estimates of airflow for a doorway.

1. Thomas[19] indicated that his relationship for critical velocity can be used to obtain a rough estimate for doorways. A room fully involved in fire could have an energy release rate on the order of 8×10^6 Btu/hr. What estimate of critical velocity is obtained from the Thomas equation for a door 3 ft (0.9 m) wide?

$$V_k = 5.68\ (8 \times 10^6/3)^{1/3} = 800 \text{ ft/min}$$

If the door has an area of 20 ft^2 (1.9 m^2), this would amount to a flow of 1600 ft^3/min (0.76 m^3/sec).

2. Consideration of a smaller fire, such as a wastebasket fire, may be appropriate for many situations. What flow rate does the Thomas relation indicate is needed to prevent backflow for the door in Example 1? A wastebasket fire has a peak energy release rate near 0.5×10^6 Btu/hr (146 kW).

$$V_k = 5.68\ (0.5 \times 10^6/3)^{1/3} = 300 \text{ ft/min (1.5 m/sec)}$$

For a door area of 20 ft^2 (1.9 m^2), this would amount to a flow of 6000 ft^3/min (2.8 m^3/sec).

In any smoke management design with airflow, the effect of providing a significant quantity of fresh air to the fire needs to be considered. Also, the airflow must be exhausted at some point downstream.

Buoyancy in Large Spaces

Buoyancy of hot combustion gases is employed in both fan-powered and nonpowered smoke management systems for large-volume spaces. The spaces where such systems are employed include atria, arcades, covered shopping malls, sports arenas, and exhibition halls. In general, these buoyancy systems are used for spaces with floor to ceiling heights of at least 33 ft (10 m) and may be much greater. The following approaches can be used to manage smoke in large spaces.[20,21]

Smoke Filling. This approach consists of allowing smoke to fill the large-volume space while occupants evacuate the atrium. This approach applies only to spaces where the smoke-filling time is sufficient for both decision making and evacuation. Evacuation time can be estimated by people movement analysis.[22,23] Smoke-filling time can be estimated by computer fire models or by the filling time equations in NFPA 92B.

Unsteady Clear Height with Upper Layer Exhaust. This approach consists of providing a sufficient exhaust rate of smoke from the top of the atrium to delay the descent of the smoke layer to permit occupants to have sufficient time for decision making and

evacuation. This approach requires an analysis of people movement and analysis of the smoke-filling process with a fire model.

Steady Clear Height with Upper Layer Exhaust. This approach consists of exhausting smoke from the top of the atrium in order to achieve a steady clear height for a steady fire (Figure 18.3.10). Design analysis of this system is based on the fact that the mass flow of smoke entering the upper smoke layer equals that of the exhaust. For a fuel package away from walls, the exhaust airflow rates are shown in Figure 18.3.11.

Design Considerations

The design of exhaust systems for large-volume spaces includes more than the overall exhaust rate needed. Additional items include makeup air supply, stratification, and plugholing.

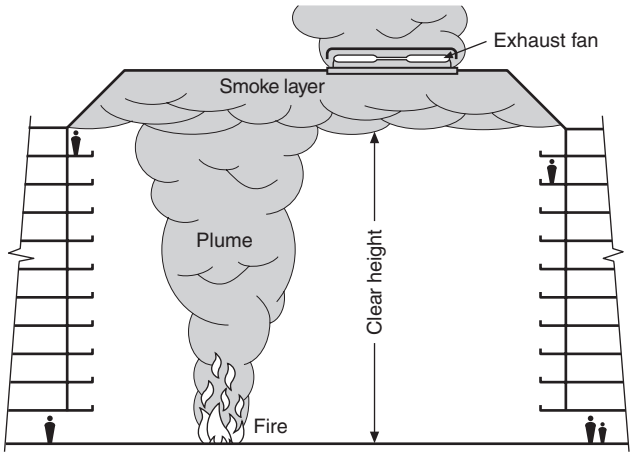

FIGURE 18.3.10 Atrium Smoke Exhaust to Maintain a Smoke-Free Clear Height

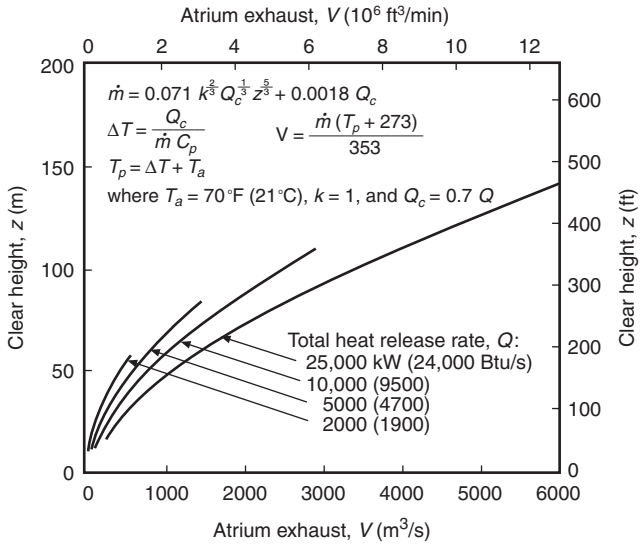

FIGURE 18.3.11 Atrium Exhaust Needed to Maintain a Clear Height for Various Heat Release Rates

The makeup air supply needs to be provided at a relatively low velocity (200 fpm [1 m/sec] or less at the fire) to avoid disrupting the plume and increasing entrainment of air in the plume. In addition, the makeup air supply should be distributed around the entire perimeter of the design fire to avoid tilting the flames or increasing the turbulence of the plume. If the makeup air velocity is provided at too great a speed or from one side only, the exhaust capacity may not be sufficient for the system to perform as intended.

Stratification of the smoke layer below the ceiling will delay or prevent actuation of ceiling-mounted smoke detectors and sprinklers. The solar load on an atrium often results in the formation of a layer of hot air under the ceiling. Stratification is expected if the temperature of the rising smoke plume is less than the surrounding air. If stratification of the smoke occurs at an intermediate height, smoke will not be able to reach ceiling-mounted smoke detectors, delaying or preventing smoke detection. This problem can be overcome by using projected beam detectors, as discussed in NFPA 92B.

Plugholing relates to the situation where a hole is "punched" through the smoke layer by a relatively high-velocity exhaust fan. The condition necessary for plugholing can be identified using calculations in NFPA 92B. If plugholing occurs, some of the exhaust capacity of the fan will be utilized to exhaust the "clean" air from below the smoke layer that is pulled through the hole in the smoke. As such, the efficiency of the exhaust system will decrease and the smoke layer will descend, perhaps to unacceptable levels.

Computational Tools for Design

NFPA 92B recognizes the following types of computational tools that can be used for analysis of smoke management systems in large-volume spaces: (1) scale modeling, (2) algebraic equations, and (3) compartment fire models. These tools can be used singularly or in combination. In scale modeling, a scale model of a building is made, and the design fire and results of the modeling are scaled in accordance with established scaling laws. Chapter 6 of NFPA 92B lists the algebraic equations that can be used for analysis of smoke management systems in large-volume spaces. Compartment fire models consist of zone fire models and computational fluid dynamics (CFD).

The algebraic equations and the zone fire models are based on the following assumptions: (1) a smoke plume rises from the fire, (2) the plume entrains air from the surroundings as it rises, (3) a smoke layer forms under the ceiling, (4) the concentration of contaminants is uniform throughout the smoke layer, (5) the smoke temperature is uniform throughout the smoke layer, and (6) the transition between the smoke layer and the room air is a plane. While the last three assumptions are not completely realistic, they are considered to be justified by the proven utility of the algebraic equations and the zone fire models.

If the algebraic equations are not applicable for a particular space of design fire, then computer fire models need to be applied to develop the design parameters of the system. When algebraic equations and the zone fire models are used for analysis of atrium smoke control, specific calculations need to be made concerning plugholing, and the makeup air velocity needs to be 200 fpm (1 m/sec) or less.

Computer fire models include the ASET,[24] ASET-B,[25] the BRI Model,[26] FIREFORM,[27] CCFM,[28] and CFAST.[29] The University of Maryland has made modifications to CCFM, specifically for atrium smoke management design.[30] Joglar-Billoch and Mowrer[31] have developed a model, FIRE-MD, to assess the impact of either mechanical or natural ventilation on the smoke layer position or properties. Descriptions of zone models are provided by Bukowski,[32] Friedman,[33] Jones,[34] Mitler and Rockett,[35] and Quintiere.[36] Klote[37] provides an overview of atrium smoke management and the public domain computer program, Atrium Smoke Management Engineering Tools (ASMET).

Zone fire models are best applied in cases where the changes in the geometry with respect to height are minimal. Further, because of the homogeneous smoke layer assumption that is part of the zone models, the zone models may not be appropriate for spaces with very large open areas or where horizontal spread needs to be modeled. In such cases, the computational fluid dynamics (CFD) models are more appropriate.

CFD models consist of dividing the large volume space into a large number of cells and solving the governing equations for each cell to obtain the flows and temperatures throughout the space. It is not unusual for atrium applications to consist of hundreds of thousands of cells. CFD models have the ability to realistically simulate smoke flow, and they can be used to evaluate tenability. There are a number of general purpose CFD models suitable for smoke management analysis. The fire dynamic simulator (FDS) model was developed at NIST specifically for fire application, and a number of projects have been conducted to verify FDS.[38] Because CFD models realistically simulate smoke flow, they can simulate plugholing without other algebraic equations, and CFD can simulate the consequences of exceeding the 200 fpm (1 m/sec) limit on makeup air.

SUMMARY

Smoke is defined as the "airborne solid and liquid particulates and gases" resulting from a fire, "along with the quantity of air that is . . . mixed into the mass." Smoke, whether or not it is highly visible, can contain dangerous products of combustion and pose a considerable threat to life and property.

Smoke moves from areas of high pressure to areas of lower pressure. Factors that affect smoke movement include the temperature of the smoke, the height of the building involved, the existence of openings in the building, stack effect, and wind. Smoke management methods use compartmentation, dilution, airflow, pressurization, and buoyancy of the smoke itself to control the smoke hazards of fires.

Chapter 4

Venting Practices

Gunnar Heskestad

Chapter Contents

Historical Background
Industrial Building Ventilation
Installed Vent Area
Elements of Venting Theory
Addendum: Automatic Heat and Smoke Venting in Sprinklered Buildings

Key Terms

curtain boards, curtained area, curtained compartment, General Motors fire, LAVENT, Livonia fire, unit vents, vent areas, venting

The importance of the buoyant properties of heat and smoke was realized at an early date, as evidenced by an NFPA standard adopted in 1903 that called for smoke vents over theater stages and in the ceilings of theater auditoriums. However, until the advent of effective artificial lighting, buildings were generally small enough so that windows provided adequate smoke venting, other than venting of fire through the roof.

The main body of this chapter covers venting practices as they would be applied to nonsprinklered buildings, based on NFPA 204, *Standard for Smoke and Heat Venting* (formerly 204M). An addendum to the chapter (in which the several different approaches are incorporated) discusses the current state of the technology involving the sprinkler/vent issue.

See also Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems"; and Section 18, Chapter 6, "Deflagration (Explosion) Venting."

HISTORICAL BACKGROUND

Large undivided floor areas present extremely difficult fire-fighting problems, since fire fighters must enter these areas to fight fires in central portions of the building. If fire fighters are unable to enter because of the accumulation of heat and smoke, fire-fighting efforts may be reduced to ineffective application of hose streams to perimeter areas while fire consumes the interior (Figure 18.4.1). Venting through roof openings can mitigate the accumulation of heat and smoke, enabling fire fighters to reach the origin or seat of the fire. In addition, venting provides occupants with the opportunity to travel to a safe area and, furthermore, can reduce damage to buildings and contents due to smoke and hot gases.

Great impetus to the subject of smoke and heat venting was provided by the General Motors fire at Livonia, Michigan, in 1953, when fire spread horizontally under an unvented metal roof, with 34 acres (137,600 m^2) of undivided area. Fire protection engineers were in general agreement that this fire could have been greatly reduced if there had been effective roof venting. The General Motors fire led to a new approach to the subject by the NFPA Committee on Building Construction, which prepared NFPA 204M, adopted by NFPA in May 1961. In 1968, the venting guide was expanded to include a new section on inspection and maintenance.

A reconfirmation action failed in 1975, as concerns had surfaced over use of NFPA 204M in conjunction with automatically sprinklered buildings. Because of this controversy, work on a revision of NFPA 204M continued at a slow pace but concluded with the 1982 edition.

The 1982 edition of NFPA 204M distinguished between unsprinklered and sprinklered buildings. The unsprinklered part was considered to represent a major advance in engineered smoke and heat venting. The sprinklered part, limited to a single chapter (Chapter 6), did not recognize that venting is necessarily desirable in a sprinklered building and did not offer a design basis, pending the resolution of some technical questions.

No changes were made for the 1985 edition of NFPA 204M, except for a limited revision of Chapter 6 dealing with venting of sprinklered buildings. Reference was made to new test data on deploying vents in a test building with automatic sprinklers. However, the new data did not permit conclusions to be developed whether sprinkler control was impaired or enhanced by the presence of automatic roof vents of typical spacing and area.

Gunnar Heskestad, Ph.D., retired from FM Global in 2004 as an assistant vice-president and consulting research scientist. He has specialized in fluid mechanics and heat transfer of fire with application to fire protection.

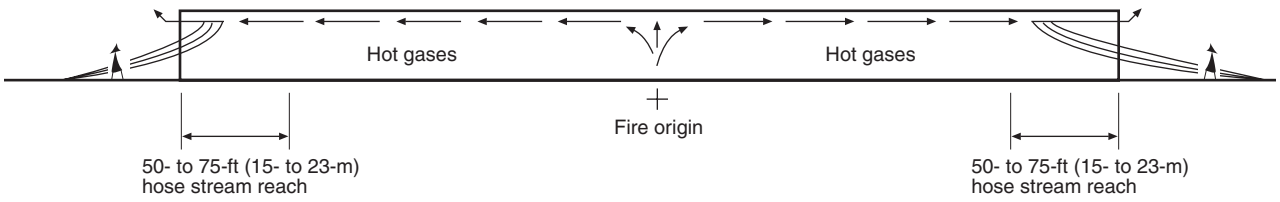

FIGURE 18.4.1 Behavior of Hot Gases in a Flat-Roofed Building

Changes for the 1991 edition of NFPA 204M again focused on Chapter 6. While the two previous editions had stated that a generalized design basis had not been developed and was not available for using sprinklers and vents together for hazard control, the 1991 edition stated that such a design basis "has not been universally recognized" and did not offer one. Furthermore, words were added to the effect that the concern for combining sprinklers and vents relates to "occupancies that present a high challenge to sprinkler systems." As in previous editions, "the designer is encouraged to use the available tools and data referenced in the document for solving problems peculiar to a particular type of hazard control."

The 1998 edition, designated NFPA 204, represented a significant revision. Tables in the previous editions that listed vent areas were deleted, and, instead, engineering equations and referenced computer models provided the designer with the tools to develop vent designs based on performance objectives. The engineering equations were updated based on new research and did not assume that the base of the fire and the so-called virtual origin coincided with the floor level, a simplifying assumption used in preceding editions (NFPA 204M). Additional data on heat release rate were presented, together with a new chapter dealing with techniques for estimating heat release rates of untested fuel arrays. As before, there was a single chapter devoted to sprinklered buildings (Chapter 8). The new chapter was little changed from Chapter 6 of the preceding edition, except for recognizing *curtain boards,* usually part of a venting system, as potentially detrimental to the outcome of sprinklered fires. In addition, there was reference to a new series of large-scale fire tests that the designer may consult.

The 2002 edition of NFPA 204 was converted from a guide to a standard, thus implementing mandatory requirements and updated language. The document was also updated to meet NFPA *Manual of Style* requirements. The only significant technical change is the treatment of venting for sprinklered buildings, presented in Chapter 11, "Venting in Sprinklered Buildings." This chapter is a single-paragraph statement: "Where provided, the design of venting for sprinklered buildings shall be based on a performance analysis acceptable to the authority having jurisdiction, demonstrating that the established objectives are met." An annex includes objectives that may be selected for the design, a review of research as in the preceding edition, subsequent research, and design considerations for venting of sprinklered buildings. Subsequent research (reviewed in this chapter under the heading "FPRF Program" in the Addendum) was deemed to be inconclusive as to benefits of automatic venting in sprinklered buildings. The design considerations are based on preventing automatic vents and draft curtains from interfering with sprinkler control of a fire, subject to the overall guide: "Draft curtains and open vents of venting systems should not adversely affect sprinklers that are capable of discharging water onto the fire, either in time of operation or in the water discharge pattern."

The technical questions that remain unresolved in application of venting to sprinklered buildings are related to the effects of (1) sprinkler discharge on venting effectiveness; (2) fresh air introduced into the building on the burning process and the water demand of the sprinkler system; and (3) curtain boards on the operation of sprinklers. Sprinkler discharge will cool the fire gases, perhaps to the extent that the vent discharge is reduced, hence reducing venting effectiveness. Additionally, the sprinkler sprays will entrain ambient smoke and air, transporting smoke to the floor level and possibly drawing gas from the vent exhaust wherever nozzles are located close to vents, further reducing venting effectiveness. Unless the building is very large, fresh air flowing into the building and replacing smoke escaping through the vents will increase the oxygen concentration in the fire space. The increased oxygen concentrations may cause a more vigorous fire than would otherwise exist, with the possible outcome of an increased number of operating sprinklers, in some cases overtaxing the water supply. Curtain boards may prevent or delay the operation of sprinklers capable of delivering water to the fire or interfere with the discharge of such sprinklers. Against these possible adverse effects must be balanced the likelihood that some improvement in visibility for fire fighting will result in many cases and the possibility that the number of operating sprinklers may sometimes be reduced because of the cooling effect of vent flows.

Many of the problems of combining sprinklers and vents may not appear if all the vents in the fire area are gang operated the moment a predetermined number of sprinklers have operated. Limited experiments on model scale[1] showed that opening all the vents in a test building at the moment of the *first* sprinkler operation could reduce the total number of sprinkler operations, compared to the corresponding unvented fire, and also prevent the total loss of visibility through the smoke which occurred in the corresponding unvented fire. Requiring more than one sprinkler to operate before the vents are opened, ideally all sprinklers that are capable of delivering water to the fire, would be a conservative approach for ensuring that sprinkler effectiveness is not compromised. Alternatively, prior to gang operation of the vents at the first sprinkler operation, any vent located within a small distance of the initial fire (to be determined) may be blocked from opening by signal from a fire proximity sensor. Experimental studies would be needed to confirm feasibility and establish design information.

Essential features specified in NFPA 204 include roof vents actuated by heat or smoke, curtain boards to confine heat and

prevent lateral fire spread, and openings for fresh air makeup at low levels (Figure 18.4.2). Two general classes of fires are considered: (1) limited growth fires, which are not expected to grow past a predictable maximum size, and (2) continuous growth fires, which can be expected to grow indefinitely until intervention by fire fighters. Guidance to vent design is based on engineering equations (hand calculations) or the use of the computer model LAVENT (or equivalent). Mechanical exhaust at ceiling apertures is treated as an option to natural ventilation at roof vents and is deemed a highly favorable option in sprinklered occupancies because of near immunity to adverse effects on venting efficiency of cooled fire gases and entrained fire gases by nearby sprinklers. The provisions of NFPA 204 may be applied to one-story buildings or to the top story of multiple-story buildings. With mechanical exhaust, lower stories of multiple-story buildings can also be vented.

INDUSTRIAL BUILDING VENTILATION

Although any opening in a roof will reduce some heat and smoke, building designers and fire protection engineers cannot rely on casual inclusion of skylights, windows, or monitors as adequate means of venting. Standards now exist (FM Approvals, Underwriters Laboratories Inc. [UL], etc.) that include design criteria and test procedures for unit vents and also call for simulated fire tests as well as engineering analysis.

Unit Vents

Unit vents are relatively small, usually 16 to 100 ft^2 (1.49 to 9.29 m^2) in area. Automatic unit vents are of two types, based on manner of operation—fusible link or drop-out plastic (Figure 18.4.3). The fusible link type consists of a metal housing with lids that depend on a temperature-rated fusible link to trip the lid mechanism, but alternative modes of operation are possible, for example, by heat or smoke detectors. The drop-out plastic type depends on a temperature-sensitive, transparent or translucent, thermoplastic dome that deforms from its setting and falls out of the roof. Vents designed for manual operation are constructed with metal lids to resist elevated fire temperatures and may be opened from the floor with wires and cables. These units can also be modified for automatic operation.

Vents may be a single unit, in which the entire unit opens fully with a single sensor, or multiple units in rows, clusters, groups, or other arrays that will satisfy the venting requirements for the specific hazard.

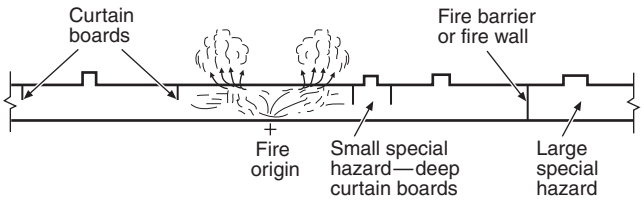

FIGURE 18.4.2 Behavior of Combustion Products Under Vented and Curtained Roof

FIGURE 18.4.3 Building with Roof Vents

Mechanical roof ventilators actuated by fire conditions are possible—and often preferable—alternatives to roof vents based on natural ventilation, especially in lower stories of multiple-story buildings. These ventilators must be capable of functioning under expected high-temperature fire conditions.

Curtain Boards

In large-area buildings, unless vented areas are subdivided by means of walls or partitions, curtain boards are important for prompt and positive actuation of vents because they bank up heat in the curtained area. They also limit the spread of heat and smoke beneath the ceiling during the design duration of the venting system. Curtain boards can be made from any substantial noncombustible material that will resist the passage of smoke.

The depth of curtain boards would normally be selected to correspond with the design depth of the smoke layer. However, the depth should not be less than 20 percent of the ceiling height, to prevent spillage of smoke under the curtain, where depth and ceiling height are referenced to the center of the lowest roof vent. It would rarely be desirable to have the curtain extend below 10 ft (3 m) from the floor. Around special hazards, the curtain should preferably extend down to this limit (Figure 18.4.4). Equipped

FIGURE 18.4.4 Deep Curtain Boards Around a Special Hazard (a Heat-Treating Department)

with proper venting, a noncombustible curtain board extending down from a ceiling around special hazards will prevent smoke and heat from mushrooming throughout the facility.

The distance between curtain boards should not exceed eight times the ceiling height, to ensure that vents remote from the fire will be effective within the curtained compartment. Smaller curtained areas may be desirable where occupancies are particularly vulnerable to damage. However, it is important that the distance between curtain boards not be less than two times the ceiling height, unless the curtain boards extend down to a depth of at least 40 percent of the ceiling height. The increased curtain depth is needed for these small curtain spacings to prevent significant spillage of fire gases underneath the curtain because of the close proximity of the fire.

Dimensioning and Spacing of Vents

When the area of an individual vent becomes sufficiently large, there is a possibility that a core of clear air from beneath the smoke layer will be included in the exhaust from the vent, which reduces the effectiveness of the vent. To prevent inclusion of clear air, called *plugholing,* the area of a unit vent or cluster of vents should not exceed $2d^2$, where d is the design depth of the smoke layer or curtain board. In the case of a row of unit vents or a monitor vent, the width of the row or monitor should not exceed d.

A large number of small vents on close spacing is preferable to a small number of large vents on wide spacing. This ensures early operation of the first vents in a fire, reducing the likelihood of initial smoke excursions beyond the curtained area above the fire. In no case should the vent spacing in a rectangular matrix exceed $4H$, where H is the ceiling height measured from the floor to ceiling for flat roofs, and from the floor to the center of the vent for sloped roofs. Alternatively, in a nonrectangular vent matrix in plan, the distance between any point on the floor and the nearest vent should not exceed $2.8H$ (the diagonal of a square whose side is $2H$). (The maximum vent spacings indicated in the 2002 edition of NFPA 204 are incorrect representations of the original formulation in NFPA 204M, 1982 edition.)

The total vent area for each curtained compartment under the ceiling depends on the severity of the expected fire and is discussed later in this chapter.

Fresh Air Makeup

Openings must be provided at or near floor level to allow the introduction of makeup air. This is critical in today's tightly constructed and insulated buildings. The total area of these openings must normally be at least as great as the largest installed vent area for a curtained compartment; otherwise, the inlets may effectively throttle the vent flow. The vent flow equation in NFPA 204 indicates the degree to which the vent flow rate is reduced by limiting the inlet opening area. If doors and windows below the designed smoke layer cannot meet the total required inlet area, special air inlet provisions are necessary.

It is essential that a dependable means be provided for admitting inlet air within approximately one minute after the first vent opens. If prompt air inlet is not provided, the entire building may quickly fill with smoke, which will clear slowly at lower levels (in the design clear layer) in response to the fully developed vent flow after the air inlets have been actuated.

Fire Characterization*

Each curtained compartment or the ceiling area of buildings requiring no curtain boards must be furnished with a total installed vent area (or exhaust capacity in case of mechanical ventilation) sufficient to vent fires of the expected severity. In addition to the expected fire severity, the installed vent area (or exhaust capacity) will depend on the depth of the curtain boards or design depth of the smoke layer. Furthermore, unless the occupancy or hazard is such that the expected fire will peak or level off at a predictable maximum size, the installed vent area (or exhaust capacity) will also depend on the minimum clear visibility design time as measured from the time the vents first operate. The fire severity is expressed differently according to the class of the fire, which for purposes of calculating vent areas is classified as either a limited-growth or a continuous-growth fire.

Limited-Growth Fires. These are fires that are not expected to grow past a predictable maximum size in terms of heat release rate, expressed in Btu per second or kW. Special-hazard fires can be assigned to this class, as can fires in occupancies with concentrations of combustibles separated by sufficiently wide aisles. The minimum aisle width to prevent lateral spread (by radiation), W_{min}, can be estimated from an equation[2] for radiant flux from a fire and a (conservatively low) value for the ignition flux of most materials (1.8 Btu/ft^2/sec or 20.4 kW/m^2):

$$W_{min}(\text{ft}) = 0.13\ [Q\ (\text{Btu/sec})]^{1/2} \qquad (1)$$

For example, if the predicted maximum fire size is 30,000 Btu/sec (31,600 kW), the aisle width should be at least 24 ft (7.3 m). Table 18.4.1 contains examples of heat release data, expressed as Btu per second per ft^2 of floor area. To obtain heat release in Btu per second, a number in the table is multiplied by the floor area underneath the combustible.

Continuous-Growth Fires. These are fires that can be expected to grow indefinitely until intervention by fire fighters (Figure 18.4.5). Starting after an incubation period, the heat release rate of these fires grows continuously, proportional to the square of time, sometimes referred to as "t-squared fire growth." The growth time of a given fire is defined as the interval of time between the effective ignition time and the time when the fire reaches an intermediate energy release rate of 1000 Btu/sec (1054 kW). Any reference heat release rate

*The theory and application of venting outlined in this chapter are presented in U.S. customary units. These units reflect the system used in the original research and are consistent with the background materials contained in NFPA 204. For those more familiar with SI units, quantities such as curtain board depth (in m) and heat release rate (in kW) should be converted to the appropriate conventional units (ft and Btu/sec, respectively), using the conversion factors given at the end of this footnote and at various points throughout the text. After conversion, design data should be inserted in unit-dependent formulas to calculate vent areas and mass flow rates. 1 ft = 0.305 m; 1 Btu/sec = 1.054 kW.

TABLE 18.4.1 Heat Release Rates of Some Limited-Growth Fires*

	Btu/sec/ft² of Floor Area
1. Wood pallets, stacked 1½ ft high (6–12% moisture)	120
2. Wood pallets, stacked 5 ft high (6–12% moisture)	340
3. Wood pallets, stacked 10 ft high (6–12% moisture)	600
4. Wood pallets, stacked 15 ft high (6–12% moisture)	900
5. Mailbags, filled, stored 5 ft high	35
6. Cartons, compartmented, stacked 15 ft high	200
7. PE letter trays, filled, stacked 5 ft high on cart	750

Note: PE = polyethylene; PS = polystyrene; PVC = polyvinyl chloride; PP = polypropylene; PU = polyurethane; FRP = fiberglass-reinforced polyester.
For SI units: 1 ft = 0.31 m; 1 ft² = 0.093 m²; 1 Btu/sec = 1.054 kW.
*Heat-release rate per unit floor area of fully involved combustibles, assuming 100 percent combustion efficiency.

could have been chosen with a corresponding change in the growth time. The rate 1000 Btu/sec (1054 kW) was chosen for convenience. Mathematically, *t*-squared fire growth can be expressed as

$$Q\ (\text{Btu/sec}) = 1000(t/t_g)^2 \qquad (2)$$

where t is the time in seconds from the effective ignition time and t_g is the growth time in seconds. Table 18.4.2 contains examples of growth times for continuous-growth fires.

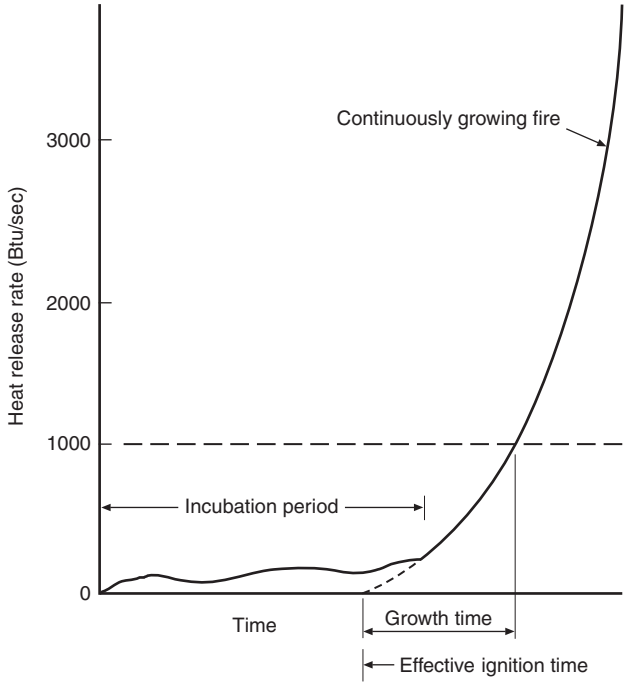

FIGURE 18.4.5 Conceptual Illustration of Continuous Fire Growth

INSTALLED VENT AREA

Limited-Growth Fires

Using the theory for air entrainment in fire plumes and gas flow through roof vents presented in NFPA 204, required vent areas can be calculated. Results for the minimum recommended curtain depth, 20 percent of the ceiling height, are presented in Figure 18.4.6 for vent area per curtained compartment (in ft²) versus expected maximum heat release rate (in Btu/sec) of the combustibles underneath the curtained compartment. These curves have been adopted from the 1991 edition of NFPA 204M, which employed the assumption that the base of the fire and the so-called "virtual origin" were both at the floor level. The simplified curves are useful for illustrating results of venting calculations and issues. Several ceiling heights in the range 15 ft to 60 ft (4.6 m to 18.3 m) are represented. An aerodynamic discharge coefficient of 0.6 has been assumed, which is normal for commercial unit vents. If the discharge coefficient is different from 0.6, the recommended vent areas need to be multiplied by the ratio of 0.6 to the actual discharge coefficient.

For each ceiling height in Figure 18.4.6, the respective curve begins at a heat release rate where vents operated by fusible links rated at 100°F (37.8°C) to 220°F (104°C) above ambient are first expected to operate promptly. Furthermore, for each ceiling height, the respective curve terminates near a heat-release rate, Q_{feasible}, beyond which the feasibility of roof venting, using the present approach, might be questioned. Q_{feasible} can be estimated from the equation

$$Q_{\text{feasible}}\ (\text{Btu/sec}) = 1130(H - d)^{5/2} \qquad (3)$$

TABLE 18.4.2 Growth Times of Some Continuous-Growth Fires*

		Growth Time (sec)
1.	Wood pallets, stacked 1½ ft high (6–12% moisture)	160–320
2.	Wood pallets, stacked 5 ft high (6–12% moisture)	95–190
3.	Wood pallets, stacked 10 ft high (6–12% moisture)	80–120
4.	Wood pallets, stacked 16 ft high (6–12% moisture)	75–120
5.	Mail bags, filled, stored 5 ft high	190
6.	Cartons, compartmented, stacked 15 ft high	60
7.	Paper, vertical rolls, stacked 20 ft high	17–27
8.	Cotton (also Pe, Pe/Cot Acrylic/Nylon/Pe), garments in 12-ft-high rack	22–43
9.	"Ordinary combustibles" rack storage, 15–30 ft high	40–270
10.	Paper products, densely packed in cartons, rack storage, 20 ft high	470
11.	PE letter trays, filled, stacked 5 ft high on cart	190
12.	PE trash barrels in cartons, stacked 15 ft high	55
13.	FRP shower stalls in cartons, stacked 15 ft high	85
14.	PE bottles packed in Item 6	85
15.	PE bottles in cartons, stacked 15 ft high	75
16.	PE pallets, stacked 3 ft high	150
17.	PE pallets, stacked 6–8 ft high	32–56
18.	PU mattress, single, horizontal	120
19.	PU insulation board, rigid foam, stacked 15 ft high	8
20.	PS jars packed in Item 6	55
21.	PS tubs nested in cartons, stacked 14 ft high	110
22.	PS toy parts in cartons, stacked 15 ft high	120
23.	PS insulation board, rigid foam, stacked 14 ft high	7
24.	PVC bottles packed in Item 6	9
25.	PP tubs packed in Item 6	10
26.	PP and PE film in rolls, stacked 14 ft high	40
27.	Distilled spirits in barrels, stacked 20 ft high	25–40

Note: Pe = polyester; Cot = cotton; PE = polyethylene; PS = polystyrene; PVC = polyvinyl chloride; PP = polypropylene; PU = polyurethane; FRP = fiberglass-reinforced polyester.
For SI units: 1 ft = 0.305 m.
*Growth times of developing fires in various combustibles, assuming 100 percent combustion efficiency.

where H is the ceiling height and d is the curtain depth ($0.2H$ in this case). At $Q_{feasible}$, the fire may become controlled by the ventilation rate allowed by the roof vents. Ventilation-controlled fires do not support a clear layer. Venting at heat release rates greater than $Q_{feasible}$ to maintain a clear layer would require larger vent areas than indicated in Figure 18.4.6.

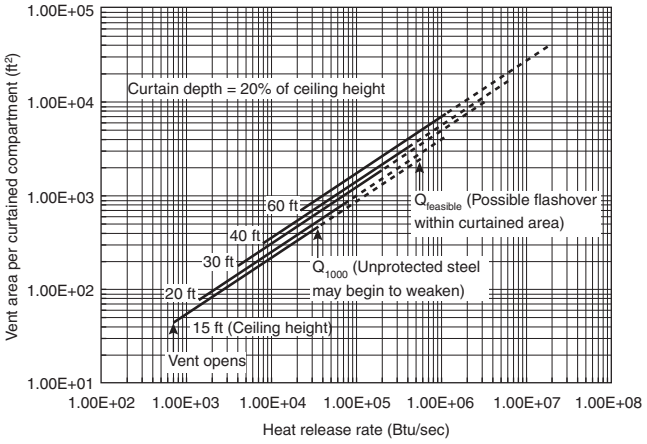

FIGURE 18.4.6 Limited Fire Growth: Recommended Vent Areas for Each Curtained Compartment for Various Maximum Heat Release Rates (Btu/sec)

Along the dashed segments of the curves in Figure 18.4.6, gas temperatures in excess of 1000°F (538°C) may be reached; unprotected structural steel may begin to lose strength and the possibility of flashover exists within the curtained area. The lowest rate of heat release at which this may occur, Q_{1000}, has been estimated from the equation

$$Q_{1000}\,(\text{Btu/sec}) = 69(H - d)^{5/2} \qquad (4)$$

where, in the case of Figure 18.4.6, $d = 0.2H$.

For curtain depths greater than 20 percent of the ceiling height, the vent areas read from Figure 18.4.6 may be multiplied by the factors indicated in Table 18.4.3. New values for $Q_{feasible}$ and Q_{1000} can be calculated using Equations 3 and 4, respectively, by inserting the appropriate values of H and d.

Continuous-Growth Fires

Required vent areas for each curtained compartment for fires in this class depend on ceiling height (H), growth time, spacing of

TABLE 18.4.3 Multiplication Factors for Vent Areas in Figure 18.4.6 for Curtain Depths Other Than 20 Percent of Ceiling Height

curtain boards (S_c) vent spacing, and means of vent actuation. They also depend on the desired minimum clear visibility time from the time the first vents operate. The minimum clear visibility design time will facilitate such activities as locating the fire, appraising the severity and extent of the fire, evacuating the building, and making an informed decision on deployment of personnel and equipment to be used for fire fighting.

Table 18.4.4 has been adapted from the 1991 edition of NFPA 204M (base of fire and virtual origin at floor level), and the values are limited to the minimum recommended curtain depth, 20 percent of the ceiling height. Table 18.4.4 lists vent areas per curtained compartment for vents spaced at no more than one-half the curtain board spacing. For other than square curtains, the spacing S_c is interpreted as the largest spacing defined by the curtained area. The tabulated areas are approximate, pertaining to vents that are operated by heat-responsive devices of an average response-time index (RTI) of 520 $(ft \cdot sec)^{1/2}$ [287 $(m \cdot sec)^{1/2}$] and rated between 100°F (37.8°C) and 220°F (104°C) above ambient temperature.[3,4] Each entry in the table gives the range of vent areas in 1000 ft^2 (92.9 m^2) associated with the selected range of temperature ratings. Boxed entries are not possible (since the vent areas exceed the largest possible curtained area of $S_c \times S_c$); however, these entries may be needed for curtain depths greater than 20 percent of ceiling height, as treated later in this chapter.

Notes:
1. Vents are assumed to be spaced at one-half of the curtain board spacing.
2. Curtain depth assumed at 20 percent of ceiling height.
3. Each entry is the vent-area range (in 1000 ft^2) associated with heat-responsive devices rated between 100 and 220°F (37.8 and 104°C) above ambient temperature.
4. No entries: Heat release rates greater than $Q_{feasible}$.
5. Entries boxed-in: Not possible, but needed for curtain depths greater than 20 percent.
6. Entries in parentheses: Correspond to levels of heat release greater than Q_{1000}.

For SI units: 1 ft = 0.305 m; 1 ft^2 = 0.093 m^2.

*Vent area (in 1000 ft^2) per curtained compartment for heat-responsive device-operated vents with various curtain board spacings (S_c) and minimum clear-visibility design times (5, 10, or 15 min).

Where values are not given, heat-release rates are greater than $Q_{feasible}$, as given in Equation 3; the vent area associated with $Q_{feasible}$ is $A_{feasible}$, which has been calculated from the following equation from the 1991 edition of NFPA 204M:

$$A_{feasible}\ (ft^2) = 8.5(H - d)^{5/2}/d^{1/2} \quad (5)$$

where, in the case of Table 18.4.4, $d = 0.2H$. Entries in parentheses in the table correspond to levels of heat release greater than Q_{1000}, as given in Equation 4. The vent area associated with Q_{1000} is A_{1000}, which has been calculated from the following equation from the 1991 edition of NFPA 204M:

$$A_{1000}\ (ft^2) = 1.6(H - d)^{5/2}/d^{1/2} \quad (6)$$

where, in the case of Table 18.4.4, $d = 0.2H$.

To illustrate the use of Table 18.4.4, consider an installation with heat-responsive devices rated approximately 100°F (37.8°C) above ambient, a ceiling height of 20 ft (6.1 m), a growth time of approximately 150 seconds, a (square) curtain spacing of 80 ft or 24.4 m ($S_c = 4 \times H$), a curtain depth of 4 ft or 1.2 m (4/20 = 20 percent of ceiling height), and a minimum clear visibility time of 10 minutes. In Table 18.4.4, the lower limit 100°F (37.8°C) of the appropriate entry indicates a vent area per curtained compartment of $0.64 \times 1000 = 640$ ft^2 (59.5 m^2) for this case.

The recommended vent area for each curtained compartment is reduced if larger curtain depths than minimum (20 percent of ceiling height) are installed. The reduced areas are calculated by multiplying the values listed in Table 18.4.4 by the appropriate multiplication factor listed in Table 18.4.3. To determine if Note 4 or 6 from Table 18.4.4 applies to the newly derived values for vent area, the value of $A_{feasible}$ associated with $Q_{feasible}$ is calculated from Equation 5, and the value of A_{1000} associated with Q_{1000} is calculated from Equation 6. Note 4 applies if a vent area is larger than $A_{feasible}$, and Note 6 applies if a vent area is larger than A_{1000}.

Vent areas for each curtained compartment should be distributed among individual vents within the constraints discussed in the subsection "Dimensioning and Spacing of Vents," earlier in this chapter. In some cases, the calculated number of vents may be so large that the vent spacing will be considerably smaller than the design spacing for vents assumed in Table 18.4.4 (½S_c) The closer vent spacing implies earlier operation of the first vents than is the case for the designs of Table 18.4.4. Earlier operation, such as that provided by an auxiliary fire detection system, would provide extra clear visibility times beyond the values of 5, 10, and 15 minutes selected in Table 18.4.4. The extra time available with vents spaced at less than ½S_c may be considered to represent a safety factor.

Selection of Design Basis

The vent area in a curtained compartment need not exceed the vent area recommended for the largest limited-growth fire predicted for combustibles beneath the curtained area. Using sufficiently small concentrations of combustibles and minimum aisle widths according to Equation 1, it may be possible to satisfy the venting needs using smaller vent areas than required by a continuous-growth fire vent design. For example, in the illustration discussed previously for the use of Table 18.4.4, the continuous-growth fire vent design for a growth time of 150 seconds led to a required vent area for each curtained compartment of 640 ft^2 (59.5 m^2). A limited-growth fire vent design for a 50 ft^2 (4.7 m^2) floor area concentration at 200 Btu/sec per ft^2 (2271 kW/m^2) (if that is the heat release rate per unit floor area of the combustible considered) involves a total heat release rate per fuel concentration of 10,000 Btu/sec (10,540 kW) and a minimum aisle width of 14 ft (4.3 m), according to Equation 1. For the relevant vent parameters of a ceiling height of 20 ft (6.1 m), curtain depth at 20 percent of ceiling height, and heat release rate of 10,000 Btu/sec (10,540 kW), Figure 18.4.6 indicates a vent area per curtained compartment of 250 ft^2 (23.2 m^2), which is considerably smaller than the 640 ft^2 (59.5 m^2) vent area according to the design for continuous-growth fire. Of course, the combustible and floor area concentrations must be carefully controlled when limited-growth fire vent designs are selected. Furthermore, designs incorporating heat release rates greater than Q_{1000} are risky, since the fire may flash over to all the combustibles under the curtained area. Such designs should be based on the potential heat release rate of all the combustibles under the curtained area and should not be attempted at all if the resulting heat release rate approaches $Q_{feasible}$. For continuous-growth fires, designs giving vent areas greater than A_{1000} cannot be recommended because of the flashover potential.

Mechanical Ventilators

For mechanical venting systems capable of functioning under the expected fire exposure, recommended exhaust capacities per curtained compartments are obtained by simple conversion from the recommended vent areas per curtained compartment. The conversion depends on the depth of the curtain board or the design depth of the smoke layer, according to Table 18.4.5. To avoid plugholing (i.e., inclusion of clear air from below the smoke layer in the vent flow), the exhaust flow (SCFM) for a vent should not exceed a maximum rate:

$$SCFM_{max} = 452 d^{5/2} \left[\frac{T_o}{T_s} \left(1 - \frac{T_o}{T_s} \right) \right]^{1/2} \quad (7)$$

TABLE 18.4.5 Conversion from Vent Area of Gravity Vents to Equivalent Mechanical Exhaust Capacity

Curtain Depth (ft)	*Mechanical Exhaust Capacity per Unit Area of Gravity Vent (SCFM*/ft^2)*
6	354
8	409
10	457
12	501
16	578
20	647
24	708

For SI units: 1 ft = 0.305 m; 1 ft^2 = 0.093 m^2.
*SCFM = Standard cubic ft per min (standard temperature and pressure).

where d is the depth of the smoke layer (ft), T_0 is the ambient temperature (°R), and T_s is the smoke layer temperature (°R).

ELEMENTS OF VENTING THEORY

To stop the descent of a smoke layer, the mass flow rate of hot gas out of the vents, $\dot{m}_v$, must match the mass injection rate of gas by the fire plume at the interface with the smoke layer, $\dot{m}_P$ (Figure 18.4.7). Therefore, expressions are needed for the vent flow and for the plume flow.

Vent Flow

The vent flow for sufficiently large area of inlet opening (see NFPA 204 for effect of restricted inlet area) can be calculated from the following equation:[5,6]

$$\dot{m}_v = (2\rho_o^2 g)^{1/2} \left[\frac{T_o(T_s - T_o)}{T_s^2} \right]^{1/2} A_v d^{1/2} \tag{8}$$

where $\dot{m}_v$ is the mass flow rate through the vent (lb/sec or kg/sec); ρ_o is the density of the ambient air (lb/ft^3 or kg/m^3); g is the acceleration of gravity (ft/sec^2 or m/sec^2); T_o is the ambient temperature (°R or K); T_s is the smoke layer temperature (°R or K); A_v is the aerodynamic vent area (ft^2 or m^2); and d is the depth of the smoke layer (ft or m), generally interpreted as the height of the center of the vent above the smoke interface.

The aerodynamic vent area, A_v, is always smaller than the geometric vent area. For simple apertures, A_v may be taken as 0.6 times the geometric through-flow area.

The temperature function $\left[\frac{T_o(T_s - T_o)}{T_s^2} \right]^{1/2}$ can be approximated at 0.50 for smoke layer temperatures in the range of 275 to 1400°F (135 to 760°C), which covers most vent applications. Then Equation 8 becomes simply

$$\dot{m}_v = (\rho_o^2 g)^{1/2} A_v d^{1/2} \tag{9}$$

To prevent air from the clear layer below from being entrained in the vent exhaust (plugholing), the area of the vent should not exceed $2d^2$.[7] If the vent is long and narrow, an analogous requirement would be that the width of the vent not exceed d.

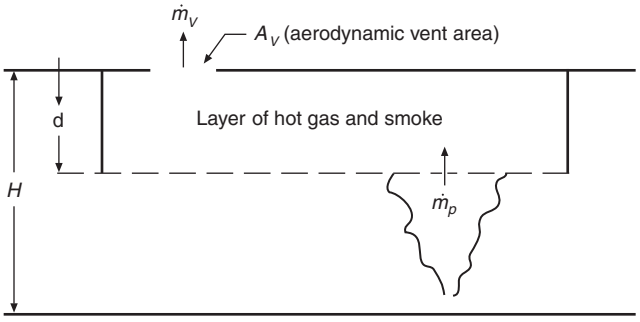

FIGURE 18.4.7 Schematic of a Venting System

Plume Flow

The mass flow rate injected into the smoke layer by the fire plume is practically equal to the air entrainment rate of the plume from the clear layer; the contribution of the fire source itself is small in comparison. The equations presented here are based on the updated engineering relations of NFPA 204, rather than the simplified equations of the 1991 edition of NFPA 204M.

The plume flow, $\dot{m}_p$, is calculated according to either of two equations, depending on whether the mean flame height is below the smoke layer (interpreted as below the curtain boards) or has entered the smoke layer (interpreted as at or above the bottom of the curtain boards). The mean flame height is calculated from

$$L = -1.02D + 0.79Q^{2/5} \tag{10}$$

where

L = Mean flame height above the base of the fire (ft)

D = Base diameter of fire (ft)

Q = Total heat release rate (Btu/sec)

When the mean flame height is below the smoke layer ($L < H - d$) the plume flow into the smoke layer is calculated from

$$\dot{m}_p = 0.022Q_c^{1/3}(H - d - z_0)^{5/3}[1 + 0.20Q_c^{2/3}(H - d - z_0)^{-5/3}] \tag{11}$$

where

$\dot{m}_p$ = Mass flow rate into the smoke layer (lb/sec)

Q_c = Convective heat release rate (approx. 0.7 Q) (Btu/sec)

z_0 = Height of virtual origin above base of fire (below the base if negative) (ft) calculated from

$$z_0 = 0.28Q^{2/5} - 1.02D \tag{12}$$

When the mean flame height reaches into the smoke layer ($L \geq H - d$),

$$\dot{m}_p = 0.0130Q_c(H - d)/L \tag{13}$$

Note that when the flames are just entering ($L = H - d$),

$$\dot{m}_p = 0.0130Q_c \tag{14}$$

For continuous-growth fires, the instantaneous fire diameter D in Equations 10 and 12 can be calculated from the instantaneous heat release rate, Q, and data on the heat release rate per unit floor area, Q'' (according to listings such as Table 18.4.2):

$$D = \left(\frac{4Q}{\pi Q''} \right)^{1/2} \tag{15}$$

Required Vent Area

For $L < H - d$, the expression for $\dot{m}_p$ in Equation 11 is set equal to the expression for $\dot{m}_v$ in Equation 9 and solved for A_v, the aerodynamic vent area. For $L \geq H - d$, the expression for $\dot{m}_p$ in Equation 13 is set equal to the expression for $\dot{m}_v$ in Equation 9 and solved for A_v. The aerodynamic vent area, A_v, is divided by the vent discharge coefficient, usually 0.6, to establish the geometric vent area.

For continuous-growth fires, the vent area is calculated for the fire conditions prevailing at the time $t = t_d + t_r$, where t_d is the detection time (often, but not necessarily, the actuation time of the first vent) and t_r may be selected to correspond to various critical events ("clear-visibility time" in context of Table 18.4.4):

1. Arrival of emergency response team
2. Arrival of fire fighters from the public fire department
3. Completion of evacuation
4. Other critical events

Detection times (t_d) for heat responsive devices (fusible links, heat detectors) can be calculated for *t*-squared fires, using a thermal response equation for heat responsive devices[3,4] together with generalized data on gas temperatures and velocities under flat ceilings.[8]

Limiting Heat Release Rates

Q_{1000} was defined in conjunction with Equation 4 as the heat release rate at which gas temperatures in excess of 1000°F (538°C) may be reached with possible weakening of structural steel and potentials for flashover within the curtained areas. The expression for Q_{1000} was derived first using Equation 13, with substitution for L from Equation 10 (suppressing $-1.02D$, which usually makes a relatively small contribution to the calculated value of L, and setting $Q_c = 0.7Q$), to obtain $\dot{m}_p$ expressed as

$$\dot{m}_p\,(\text{lb/sec}) = 0.0143(H - d)Q_c^{3/5} \tag{16}$$

where Q_c is in Btu/sec, and H and d are in ft.

The average temperature rise in the smoke layer, ΔT_s (°F), follows from

$$\dot{m}_p c_p \Delta T_s = \lambda Q_c \tag{17}$$

where c_p (Btu/lb/°F or kJ/kg/K) is the specific heat of air and λ is the surviving fraction of convective heat after heat loss to the ceiling and walls. With substitution of Equation 16 for $\dot{m}_p$, $c_p = 0.24$ Btu/lb/°F (1.00 kJ/kg/K) and $\Delta T = 1000$°F (538°C) in Equation 17, the resulting expression can be solved for Q_c. The result is Equation 4 if it is assumed $\lambda = 0.63$ which is a realistic convective fraction.[9]

Q_{feasible} was described in conjunction with Equation 3 as a heat release rate beyond which the feasibility of roof venting, using the present approach, might be questioned because of the onset of ventilation control of the burning process. Ventilation-controlled fires do not support a clear layer as, for example, in the case of the typical, flashed-over room fire. According to experiments on wood crib fires in enclosures, vented through doors or windows,[10] ventilation control appears to set in when the so-called ventilation parameter, $A_w\sqrt{h_w}$, in ratio to the mass burning rate, R, is less than 266 $\text{ft}^{5/2}$/lb/sec, where A_w is the window (or door) area, and h_w is the window (or door) height. Generalized to any combustible, the limiting ratio might be expressed as $A_w\sqrt{h_w}$ in ratio to the stoichiometric air requirement associated with the mass burning rate, Rr, where r is the stoichiometric mass ratio, air to combustible (assumed at 5.5 for wood). Now, the ventilation parameter, $A_w\sqrt{h_w}$, is proportioned to the mass flow rate of air through a window or door opening, $\dot{m}_v$:[11]

$$\dot{m}_v\,(\text{lb/sec}) = 0.064\,A_w\sqrt{h_w}. \tag{18}$$

where A_w is in ft^2, and h_w is in ft.

The limiting condition for ventilation control can, therefore, be expressed in terms of the mass venting rate of air in ratio to the stoichiometric air requirement, $\dot{m}_v Rr$, which turns out to be approximately 3. Using the fact that Rr can be written $Q/(\Delta H_c/r)$, where Q is the heat release rate and ΔH_c is the heat of combustion, the limiting mass rate ratio can be converted to a limiting heat release rate:

$$Q = \frac{1}{3}\,\dot{m}_v(\Delta H_c/r) \tag{19}$$

In application to roof vents, $\dot{m}_v$ can be expressed as in Equation 9. Furthermore, $\Delta H_c/r$ is quite constant among common combustibles. Substituting Equation 9 and taking $\Delta H_c/r =$ 1328 Btu per lb (3086 kJ/kg), Equation 19 becomes:

$$Q\,(\text{Btu/sec})\ 133A_v d^{1/2} \tag{20}$$

where A_v is in ft^2, and d is in ft.

In the simplified venting approach of the 1991 edition of NFPA 204M, an equation for A_v was presented (Equation 12 in that edition), applicable to heat release rates above a lower limit likely to be exceeded in all practical cases. When this equation is combined with Equation 20, the result is the expression for Q_{feasible} in Equation 3.

SUMMARY

Adequate venting in a building is necessary to prevent the buildup of heat and smoke during a fire, which can severely hamper fire-fighting efforts. Ventilation in industrial buildings is accomplished by the use of unit vents or mechanical ventilators and curtain boards. Unit vents are manufactured specifically to provide ventilation during a fire. Curtain boards contain smoke and heat, and the buildup of heat in the curtained area actuates the venting system. The required vent areas in a building are calculated on the basis of limited-growth fires, which involve maximum heat release rates, versus continuous growth fires, which involve growth times. Information is provided to calculate mechanical exhaust rates equivalent to required vent areas.

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on venting practices discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 204, *Standard for Smoke and Heat Venting*

ADDENDUM

AUTOMATIC HEAT AND SMOKE VENTING IN SPRINKLERED BUILDINGS

This addendum supplements the venting practices in this chapter as written by Dr. Heskestad. It presents in summary the various views on the controversial and unresolved subject of automatic venting in sprinklered buildings. The history of research testing on the subject is traced. Original contributors (sixteenth edition, 1986) include Ernest E. Miller, Thomas E. Waterman, and Edward J. Ward.* The author has expanded the section "New Sprinkler/Vent Research," which he wrote for the eighteenth edition of the *Fire Protection Handbook,* with material on additional research included in the nineteenth edition ("FPRF Program") and new material for this edition from the literature ("New Analysis of Past Studies").The updated section is headed "More Recent Sprinkler/Vent Research and Analysis".

*Ernest E. Miller was an executive engineer with Industrial Risk Insurance (IRI) at the time he contributed his views. Thomas E. Waterman was employed by the IIT Research Institute and conducted the IITRI test series of 1980–1981. Edward J. Ward was employed by Factory Mutual Research Corporation.

Differing Views

There has been controversy for more than four decades over automatic venting for sprinklered buildings.

Proponents of automatic venting in sprinklered buildings claim that venting will aid manual fire fighting by delaying loss of visibility, reduce the risk of structural failure by venting gases with dangerously high temperatures, vent the equivalent of an unsprinklered fire if the installed sprinklers are defeated by human failure or mechanical damage, and substitute for manual roof venting by fire service personnel.

Opponents believe that, in some cases, venting may be detrimental because it draws in fresh makeup air, keeping oxygen levels higher than they would be otherwise, causing more vigorous combustion with an increase in fuel consumption, and creating potential for loss of sprinkler control. They also believe sprinkler discharge will cool the fire gases, perhaps to the extent that the vent discharge is reduced, hence reducing venting effectiveness. Further, the sprinkler sprays will entrain ambient smoke and air, transporting smoke to the floor level and possibly drawing gas from the vent exhaust wherever sprinklers are located close to vents and further reducing venting effectiveness. Additionally, opponents see little, if any, evidence from research testing of the benefit to fire control obtained from the use of vents in a sprinklered building and believe that the high cost of installation does not justify their use.

Sprinkler/Vent Research

Research testing on the subject includes large-scale tests, FMRC model study, other FMRC large-scale testing, and IITRI full-scale venting research testing.

Large-Scale Tests. In 1956 Factory Mutual Research Corporation (FMRC), now FM Global, ran a series of large-scale tests from which it concluded that the effects of venting in sprinklered buildings are different from those in unsprinklered buildings. The research project[1] was conducted in a 120- by 60-ft (36.6- by 18.3-m) test building equipped with 5 ft (1.5 m) draft curtains and vent areas ranging up to 32 ft^2 (3 m^2) within a curtained area of 2280 ft^2 (212 m^2). This is a vent ratio of about 1:70—that is, 1 ft^2 (0.093 m^2) of vent area for every 70 ft^2 (6.5 m^2) of floor area. A 5-gal/min (18.9-L/min) gasoline spray fire was used as the exposure, and protection consisted of 160°F (71°C) automatic sprinklers installed on a 10 ft by 10 ft (3 m by 3 m) spacing.

The tests in the series were conducted using various combinations of vents, draft curtains, and sprinklers. Six of these were sprinklered tests (Table 18.4.6).

Comparison of average temperatures indicates that vents contributed significantly to temperature reductions in the unsprinklered tests in the series; however, they were of marginal value in the sprinklered tests. The greatest reduction in sprinkler operation was attributed to increased sprinkler discharge.

FMRC Model Study. In the early 1970s, an FMRC study was conducted.[2] The objective was to investigate experimentally the performance of automatic heat and smoke vents in sprinklered

TABLE 18.4.6 FMRC Test Results

fires in one-story buildings, principally in terms of sprinkler water demand, but also in terms of visibility conditions and fuel consumption. The study was performed at FMRC's Norwood, Massachusetts, laboratory and involved a 1:12.5 scale model of FMRC's fire test facility at West Gloucester, Rhode Island. Automatic, individually fused vents on 50 ft (15.2 m) spacing were employed, often in combination with a draft curtain encompassing a 10,000 ft^2 (929 m^2) curtained area.

Of primary interest were venting installations conforming to recommendations of standards-setting groups that were state of the art at the time. For a fire in cellulosic material that opened about fifty 212°F (100°C) sprinklers at a density of 0.27 gpm per ft^2 [11 (L/min)/m^2], distributed vents alone (without draft curtains) had no effect on the water demand but delayed loss of visibility from 13.1 to 15.7 minutes and increased fuel consumption by 31 percent. Vents and draft curtains caused a 35 percent increase in water demand relative to the unvented fire, delayed loss of visibility from 13.1 to 20.2 minutes, and increased fuel consumption by 66 percent.

Favorable effects of venting were observed for a series of large, heptane fires that opened an average of 112 sprinklers at 0.27 gpm per ft^2 [11 (L/min)/m^2]. Vents alone reduced the water demand by 8 percent and markedly improved visibility conditions; vents and draft curtains reduced the water demand by 18 percent but did not improve visibility conditions as much as without draft curtains.

The test results were based on ignition points that were equidistant from the four nearest vents in the vent matrix. Experiments with ignition directly under a vent indicated that some reduction in water demand could be expected for fires that opened fifty sprinklers or less. It was concluded, however, that for randomly started fires, less than about 13 percent of the fires would benefit, respective to water demand, from closeness to a nearby vent.

Critics counter that the 0.08-scale-model experiments, although carefully designed and executed, incorporated numerous uncertainties. Of particular concern was modeling of a full-scale fuel bed (rack storage configuration), by using ½-in. (12.7-mm) thick triwall cardboard. Some 10 years later, the modeling of room fire development has proceeded to an advanced state in all respects, except for the burning fuel; both analytical and experimental models address only the simplest of fuel configurations. Yet the model study assumed that both flame spread and burning rate of the fuel bed were modeled under conditions of depleted oxygen and impacting water droplets.

The FMRC model study was also criticized because of the configuration of the water discharge devices that were used. The study pioneered the use of nondescript miniature nozzles (representing sprinklers) arranged to be operated in small open-head deluge systems of groups of five to eleven nozzles controlled by individual sensors. Critics claim this arrangement magnified the known imprecision in measuring comparative sprinkler performance. It required multiplying the normal spread experienced in full-scale sprinkler operation by a variable factor of 5 to 11. Due to the small deluge systems, which operated as groups, sprinkler skipping occurred in units of five or more open nozzles, rather than the skipping of individual sprinklers as would be customary in full-scale fire research.

Lastly, the critics agreed that, although up to three times as much combustible material was consumed in the vented tests as compared to the unvented tests, the implication of detriment was improper. They claimed the explanation for the increased fuel consumption in the vented tests lies in the customary manner of conducting fire tests involving sprinklers. The test fires are allowed to continue far beyond sprinkler control to give the fires every opportunity to escape. During the additional minutes of these tests, the oxygen reduction in the unvented tests limited the fuel consumption, whereas oxygen remained abundant in the vented tests and resulted in greater fuel consumption. Since sprinkler-controlled fires continue to smolder and burn, it was felt that the reported increased fuel consumption was attributable to more complete burning of the rubble and did not represent increased fire damage. Had the fires spread to involve a significantly larger area, additional sprinklers would have operated.

Other FMRC Large-Scale Testing. More than 80 full-scale rack storage tests were conducted between 1968 and 1975. Only three tests employed perimeter ventilation (not to be confused with roof venting directly over a fire) and only one of these three (No. 72) was identical to two other tests (Nos. 65 and 66), except for the ventilation variable. Results of these tests are given in Table 18.4.7.

Comparing Test Nos. 65 and 66 to Test No. 72, researchers discovered that venting caused a dramatic detriment to the performance of the sprinklers. However, it is pointed out that Test No. 72 had a significantly different initial fire growth behavior compared to the other tests, which may have affected the outcome. FMRC's position on the effects of ventilation in these tests is that they are not conclusive.

TABLE 18.4.7 Rack Storage Tests

Test Number	*Ventilated*	*Number of Ceiling Sprinklers Operated*
65	No	45
66	No	48
72	Yes	92

Venting proponents argue that, although the influence of venting was inconclusive because the perimeter windows were too remote, the ventilated tests maintained visibility for 48:40 and 33:00 (minutes:seconds), as compared to 10:30 and 18:00 for the unventilated tests.

Venting opponents claim the effect of ventilation on fire control was best demonstrated during FMRC's large-scale fire testing of rubber tires in 1970. This test was made to evaluate sprinkler protection for automobile tires stored in portable steel racks. Storage was located in a single pile 35 ft by 50 ft by 18 ft (11 m by 15 m by 5.4 m) high. Protection consisted of 286°F (141°C), ½ in. (12.7 mm) sprinklers, spaced 50 ft^2 (4.6 m^2), each with a controlled discharge of 0.6 gal per minute per ft^2 [24.4 (L/min)/m^2]. There was no ventilation at the start of the test.

The fire was started at the base of a rack. The first sprinkler operated 2 minutes and 15 seconds after ignition. By 8 minutes and 20 seconds, 43 sprinklers had operated and controlled the fire. Only one additional sprinkler operated at 28 minutes. The fire remained under control until 60 minutes into the test, when all doors and windows were opened to ventilate the building and sprinklers were left on. The fire then began to spread and grow in intensity. At 117 minutes, when it was apparent that sprinklers were failing to control the fire, all doors and windows were closed. A total of 95 sprinklers operated, and water was discharged for over 5 hours. Only the ninety-fifth sprinkler operated after doors and windows were closed, and that was at 118 minutes, 1 minute after closure.

Critics reappraised the ventilated rubber tire fire test[3] and contended that the loss of initial sprinkler control was not due to remote window ventilation, as reported. Ceiling temperature gradients revealed that during the hour delay before hose extinguishment of the sprinkler-controlled fire was attempted, the fire had burrowed to the other end of the pile where sprinklers were not operating and had erupted with great intensity. The tightly stacked tires, stored on tread, formed horizontal tunnels that offered avenues of fire spread that were sheltered from sprinkler discharge.

IITRI Full-Scale Venting Research Testing. In 1977, the IITRI was commissioned by the intra-industry Fire Venting Research Committee to review past research and fire experience related to vent/sprinkler interactions in large-area single-story structures. Based on IITRI's review and other considerations, the committee ultimately funded some 45 large-scale segment experiments in 1980–1981.[4] The experiments were conducted in a 75 ft by 25 ft by 17 ft (23 m by 7.6 m by 5.2 m) high portion of IITRI's fire laboratory. Fires were placed in a corner to represent one-quarter of a larger fire in the center of a 150 ft by 50 ft (46 m by 15.2 m) room. To simulate the test area as part of an even larger area, two garage doors on the wall farthest from the fire were partially opened to represent a draft curtain. The area beyond the curtains was also enclosed by vertical air stacks to minimize extraneous wind effects.

To allow variations in vent area, two pairs of automatic roof vents were installed in the laboratory roof. A diagonal sprinkler pattern was chosen to eliminate aisles between sprinklers that were located between the test fires and the vents. Experiments were conducted using propane diffusion burners or stacked pallets as the fuel source. For each fuel source, fire size and sprinkler water supply pressure were varied until a condition of "marginal" sprinkler control was achieved. Then, vent areas were varied to assess effects of venting on sprinkler performance (number of operating sprinklers and temperature levels at various locations). The laboratory size and excessive recirculation of smoke due to the substitution of vertical stacks for added rooms precluded useful measures of smoke obscuration.

Propane-source fires produced results suggesting a slight reduction in water demand for vented fires when either 165 or 286°F (74 or 141°C) sprinklers were employed (vents were operated either with 165°F [74°C] links or by simulated smoke detector or waterflow switch actuation).

All pallet fire experiments employed 165°F (74°C) sprinklers and the same vent arrangement previously described. These experiments demonstrated that, under marginal sprinkler protection, the configuration of the test facility was extremely sensitive to variations in fire intensity from any cause. Once this possibility appeared, a final series of 10 "replicate" experiments was conducted, alternating between vented and unvented configurations. These experiments proved to produce widely varying results, apparently independent of the presence of automatic venting. The number of operating sprinklers varied from 7 to 22 per test, and the pattern of sprinkler operating times appeared unrelated to the time that vents opened. Other measured factors (temperature, O_2) varied in the same way. Although the number of operating sprinklers varied widely in these experiments with marginal sprinkler control, 84 sprinklers operated in the five unvented tests and 85 in the five vented tests. Earlier tests at higher water supply pressures produced good replication, independent of venting.

On the basis of the IITRI experiments, the test sponsors concluded that automatic roof venting did not detract from current state-of-the-art automatic sprinkler performance. Likewise, no particularly significant benefit to sprinkler performance was noted. Thus, it was suggested that automatic vents, if used in sprinklered properties, will perform the following functions:

1. Vent unsprinklered fires, if installed sprinklers are defeated by human failure or mechanical damage
2. Substitute for manual roof venting on arrival of fire service personnel

Primarily on the basis of the first listed application, the researchers recommended that, where they are used for sprinklered properties, the design and installation of automatic roof vents follow guidance provided by NFPA 204 for unsprinklered properties, until further research, testing, or experience suggests more beneficial alternative configurations.

Critics of the IITRI research effort do not agree that the experimental results support the main conclusion of the investigation, which is that automatic roof vents do not impair sprinkler control of fires capable of growth.[5] The critics also claim that the finding that automatic roof vents do not impair the ability of 165°F (74°C) sprinklers to control fires capable of growth contradicts the other studies described here, which have indicated that the increased availability of oxygen associated with open vents may lead to increased fire intensity (of

fires capable of growth), water demand, and consumption of combustibles.

The critics concluded that the reported results do not justify the overall conclusions and recommendations of the IITRI researchers. Their critique suggested the investigation suffered from a number of defects: (1) situations claimed to be unvented were not; (2) one of the most important principles of venting was violated (i.e., the provision of adequate openings for inlet air); and (3) inadequate control was exercised over the experimental conditions to the extent that major variations observed in fire behavior could not be attributed to the parameter under study.

Conclusions of the Research

The proponents of automatic venting in a sprinklered building cite the IITRI research work as substantiation of the merit of vents in sprinklered buildings. On the basis of those data, they believe that automatic roof venting can provide two major contributions to 165°F (74°C) sprinkler-protected (large one-story) properties:

1. Perform as vents in unsprinklered properties should installed sprinklers be defeated by human failure or mechanical damage.
2. Substitute for manual roof venting on arrival of the fire services.

The opponents of automatic venting in a sprinklered building believe that the high installation cost of vents is difficult to justify when one considers the limited benefits and possible detriment. They are not cost-effective because it is unlikely that a large loss will be averted solely due to the presence of vents when automatic sprinkler protection is inadequate or impaired.

Venting may or may not be detrimental, depending on many factors, such as the location of the fire origin in relation to the location of vents. More often than not, vents will increase the water demand.[2] Even when automatic vents result in some improvement, the improvement is not required for sprinklers to gain control. Vents can also create conditions that will inhibit or prevent sprinkler control.[5]

Installing automatic vents in unsprinklered buildings is acceptable. It would certainly be more beneficial to the building owner, however, to install sprinklers rather than vents to obtain active rather than passive fire control.

Installing manual vents in a sprinklered building is also acceptable, if desired by the building owner. These vents can be used during manual overhaul or at locations that would be expected to produce dense smoke. However, a similar effect can be achieved by venting through windows, by fire fighters cutting holes in the roof, or by ventilation equipment or smoke exhausters.

Through NFPA's consensus-making standards process, NFPA members agreed to the following statements for the 1985 edition of NFPA 204M:

> A series of tests was conducted to increase the understanding of the role of automatic roof vents simultaneously employed with automatic sprinklers [Section 6-5(c)]. The data submitted did not permit consensus to be developed as to whether sprinkler control was impaired or enhanced by the presence of automatic (roof) vents of typical spacing and area. (Section 6-3)
>
> While the use of automatic venting in sprinklered buildings is still under review, the designer is encouraged to use the available tools and data referenced in this document for solving problems peculiar to a particular type of hazard control. (Section 6-4)

Even though the issue has been argued for years, proponents maintain venting critics have been unable to cite a single fire in which automatic venting was blamed for loss of fire control by sprinklers. Thus, to proponents it is paradoxical that fire research, which is typically motivated only by adverse fire experience, should be the sole basis of suspecting venting to be a detriment. They urge that serious students of venting should obtain and carefully examine this research and compare it with related research, both direct and indirect.

More Recent Sprinkler/Vent Research and Analysis

Ghent Experiments. During the latter part of 1989, the Fire Research Station of the Building Research Establishment (U.K.) and Colt International (together with Verband der Sachversicherer eV and City of Ghent Fire Brigade) undertook a collaborative test program in a unique test building constructed in Ghent, Belgium, the Multifunctioneel Trainingcentrum.[6] The main objective was to validate a theoretical model for predicting the effect of venting on sprinkler operations, but the direct data are being generally used to assess the efficacy of venting in sprinklered buildings.

The test building in Ghent is designed for fire service training purposes and incorporates a hall of the dimensions 164 ft × 59 ft × 33 ft high (50 m × 18 m × 10 m). For the tests, a 10-ft (3.1-m) deep draft curtain was hung from the ceiling, creating a curtained, flat-ceiling area of 89 ft × 59 ft (27 m × 18 m) under which test fires were burned. A total of 20 roof vents, each with an area of 18 ft^2 (1.67 m^2), were installed in this area, centered on a grid measuring 15.9 ft × 14.8 ft (4.85 m × 4.5 m). Sprinklers on a spacing of 12 ft × 8 ft (3.7 m × 2.4 m) were also installed in this area (temperature rating of 155°F [68°C]). The ceiling area on the other side of the draft curtain was provided with 20 roof vents that were always open. A total of 16 inlet vents were installed at ground level in the sides of the building, each having an aerodynamic free area of 33.7 ft^2 (3.1 m^2). As fire sources were used, *n*-hexane floated on water near the floor level. One source had a steady output of 5100 Btu/s (5.4 MW). The other source provided an exponentially growing heat release rate (roughly equivalent to a continuous-growth fire of 50 seconds growth time) until the first sprinkler operated, at which time the heat releaser rate was leveled off (8700 to 12,300 Btu/sec [9.2 to 13.0 MW]).

Note that the vents were very closely spaced (although not all of the vents were used in all the tests) and, furthermore, that the building space on the side of the draft curtain away from the fire was amply ventilated, which may have been factors in the outcome. Other unusual features were that the vents were in effect short chimneys about 5 ft (1.5 m) high and, when venting was used, the vents were open from the start of the test.

The first test series involved the steady fire source. Combinations of 0, 1, and 5 operating sprinklers (at approximately 30 psi [2 bar]) with 0, 10, and 20 open vents were investigated.

With no sprinklers operating, the ceiling gas temperatures decreased significantly with the number of open vents, from 220°F (104°C) to 153°F (67°C) at a 20 ft (6 m) radius from the fire axis when conditions changed from no vents to 20 open vents. With 5 sprinklers operating, the drop in gas temperature at the same location was from 203°F (95°C) with no vents to 130°F (54°C) with 20 open vents. Extensive temperature, velocity, and CO_2 concentration data were recorded.

The second test series involved the growing-fire source and automatic operation of the sprinklers. The number of open vents in a test were mostly 0, 10, or 20, but a few tests were conducted using special patterns of 9 and 16 open vents. The water supply in the first tests was very weak. For the test providing data for this review, the water supply was boosted with a fire pump, yielding a pressure of about 88 psi (6 bar) for one open sprinkler, decaying to about 15 psi (1 bar) for 40 open sprinklers (roughly linear decay with number of open sprinklers). The time of the first sprinkler operation ranged from an average of 148 seconds for no open vents to an average of 160 seconds for 20 open vents. Subsequent sprinkler operations depended on the particular test scenarios, that is, the original, Scenario A, where the fire size was maintained constant to the end of the test at the value when the first sprinkler operated (leading to operations of all installed sprinklers with no open vents), or the revised, Scenario B, where the fire size was maintained constant for 30 seconds and then reduced by 20 percent. In Scenario B, an initial group of 6 sprinklers operated within an interval of 60 seconds for both 10 and 20 open vents, compared to an initial group of 9 sprinklers in the same interval with no vents. With 20 open vents, only one additional sprinkler operated (no additional operations for 10 open vents). With no vents, additional sprinkler operations began about 2 minutes after the first sprinkler operated, accumulating to a final total, nearly 6 minutes from ignition, of 37 sprinklers.

With respect to the issue of visibility through smoke, the report offers the following observation: "In the experiments with growing fires and the pumped supply, the water pressure was higher and the number of operating sprinklers greater than in the experiments with steady fires. There was then some tendency for the fire gases to be pulled down in both vented and unvented experiments." On other issues, the experiments provided no evidence that the flow through the vents was affected by the wind (wind speeds up to 26 ft/sec [7.8 m/sec]), and there were no observable effects of nearby sprinklers on the vent flow (nearest sprinkler about ¾ vent width from any part of the vent opening). The author often finds fair agreement between his theory and the experimental results but identifies areas needing further study, which are issues beyond the scope of this review.

On the effect of venting on sprinkler operations, the report concludes that (1) the prior opening of vents will have little effect on the operation of the first sprinkler with fast growing fires; (2) venting substantially reduced the total number of sprinkler operations; and (3) there was no indication that venting could increase the total number of sprinkler operations.

These conclusions of the report are deemed, by this reviewer, to be highly dependent on the special circumstances of the experiments, primarily (1) the use of a fire source that did not respond in heat output to the sprinkler spray per se, and (2) the fact that even unvented fires were supplied with unvitiated air, arriving from the adjacent, amply ventilated part of the building.

Further to the issue of responsiveness of the fire source to sprinkler spray, Gustafsson[7] observed from the sprinkler operation maps in the report that, in vented tests, sprinklers near the fire source often were delayed or did not operate altogether. Gustafsson makes the point very strongly: "It is clearly seen that the effect of ventilation on the operation of sprinklers was strong and detrimental in all cases. It must be appreciated that prevented or substantially delayed operation of any sprinkler close to, or directly above, the fire must be avoided."

Additional research and testing will be needed before definitively establishing the benefits and detriments of automatic venting in a sprinklered building.

FPRF Program. Large-scale tests to study the interaction of sprinklers, roof vents, and draft curtains were organized by the Fire Protection Research Foundation (FPRF), formerly known as the National Fire Protection Research Foundation (NFPRF), and reported in 1998 by McGrattan et al.[8] The tests were conducted in a building provided with a free-hung test ceiling underneath a fixed ceiling provided with exhaust to an abatement system, which made the tests difficult to interpret for field applications.

The 120 ft by 120 ft (36.6 m by 36.6 m) test building employed a 100 ft by 100 ft (30.5 m by 30.5 m) free-hung ceiling at a height of 27 ft (8.2 m) above the floor, underneath which the fires were burned. Smoke exhausted above the free-hung ceiling to a smoke abatement system, and makeup air entered through duct openings at four locations around the building perimeter, 10 ft (3.1 m) above the floor. Roof vents (4 ft by 8 ft [1.2 m by 1.2 m]), normally operated by fusible links, were installed on 50 ft by 50 ft (15.3 m by 15.3 m) spacing within a 70 ft by 75 ft (21.4 m by 22.9 m) draft-curtained area. Some tests were run without draft curtains.

A series of tests employed *heptane spray fires* with *t*-squared growth to a constant heat release rate of 10 MW in 75 seconds. Smoke exhaust and air supply for the test building were held constant at 24,000 scfm (13.6 kg/sec). Unless a fire was ignited directly under a roof vent, roof venting had no significant effect on sprinkler operations or near-ceiling gas temperatures. Ignitions directly under an automatic roof vent decreased the number of operated sprinklers compared to tests without vents. When 6-ft (1.8-m) deep draft curtains were installed (depth corresponding to 22 percent of the ceiling height), the number of sprinkler operations was considerably larger than without curtains.

Five tests were conducted with a 19-ft (5.8-m) high array of *cartoned plastic commodity.* In these tests, smoke exhaust and air supply for the test building were at a constant 60,000 scfm (34.1 kg/sec), requiring a velocity of make-up air at the building perimeter duct openings of 13 fps (4.0 m/sec). Three of the tests operated 20 to 23 sprinklers, with a potentially higher upper limit since sprinklers operated to the edge of the test ceiling. The remaining two tests operated 5 to 7 sprinklers. This large span was attributed[8] to variability in the initial fire growth and not to any variables under study. One of the tests with ignition near a draft curtain resulted in much larger fuel consumption than the other tests, attributed[8] to fire spread under the draft curtain. In a test in which four vents were opened manually at the same time as the first sprinkler operated, vent flow rate was one-third the

expected rate, attributed[8] to reduction in gas temperatures by the sprinklers.

In the test in which four vents were opened manually (series of five tests), the total vent flow rate is estimated from the report[8] to have been only one-quarter the flow rate of the smoke abatement system for these tests (60,000 scfm [34.1 kg/s]). Hence any observations on smoke behavior would be difficult to interpret for field applications. Furthermore, differences in oxygen vitiation and their effects on combustion, vented versus unvented cases, would be much smaller than in many field situations.

The FPRF tests can be summarized as follows:

1. In the heptane spray fires, venting had no significant effect on sprinkler operations unless a fire was ignited directly under a vent, in which case the number of sprinkler operations decreased.
2. When a draft curtain was installed in the heptane spray fires, the number of operating sprinklers increased.
3. In five tests with the cartoned plastic commodity, three tests operated 20 to 23 sprinklers and two tests operated 5 to 7 sprinklers, attributed to variability in the initial fire growth and not to any of the variables under study.
4. One of the tests with ignition near a draft curtain consumed much more fuel than the other tests did, attributed to fire spread under the draft curtain.
5. Effects of venting through roof vents on smoke obscuration could not be determined because of the dominant effect of the building smoke abatement system.

New Analysis of Past Studies

In January 2001 Beyler and Cooper presented a review of past studies deemed to have some relevance to assessing combined use of sprinklers and smoke/heat vents.[9] The authors conclude that (1) venting clearly does not have a negative effect on sprinkler performance, (2) venting limits spread of combustion products, and (3) venting remains a valuable aid to manual control of the fire in the event the sprinklers do not operate. In a letter to the editor following the publication of this paper, Heskestad[10] argues the view that the first two of the authors' conclusions are performance measures that are not met, or not well met, by current technology, based on the studies cited by the authors. With respect to the third conclusion, Heskestad refers to the FM Global position that venting, installed as a backup to an automatic sprinkler system that is inadequate or impaired, is not cost effective because it is unlikely a large loss will be averted solely due to the presence of vents.

Beyler and Cooper[9] recommend that design practice move to methods that ensure early operation of vents, that vent operation be ganged, and that draft curtains be placed over aisles rather than over storage. It is agreed that this recommendation may lead to much improved technology (as reflected in the next-to-last paragraph of the section headed "Historical Background"), but it will require a significant research effort.

ADDENDUM SUMMARY

Automatic venting in sprinklered buildings is a controversial and unresolved subject. Proponents contend that venting will delay loss of visibility, reduce the risk of structural failure by venting gases with dangerously high temperatures, offset problems caused by failure of the sprinkler system, and substitute for manual roof venting by fire fighters. Opponents claim that venting may be detrimental by drawing in fresh makeup air, thus raising oxygen levels and causing more vigorous combustion. Opponents also believe that sprinkler operation would reduce the effectiveness of automatic vents to the point where installation costs would not justify their use.

Research on this dispute has included a large-scale test run by FMRC in 1956, the FMRC model study conducted in the 1970s, more than 80 full-scale rack storage tests carried out by FMRC between 1968 and 1975, and IITRI full-scale testing in 1977. The results of that research failed to resolve the issue, and consensus is yet to be reached. More recent research involves a collaborative test program in Ghent, Belgium, and large-scale tests organized by the FPRF to study the interaction of sprinklers, roof vents, and draft curtains. Again, the results of the research were not conclusive as to the definitive benefits and detriments of automatic venting in sprinklered buildings. A fresh review of past research has suggested benefits, but its conclusions have been challenged.

Chapter 5

Penetration Sealing

John E. Kampmeyer

Chapter Contents

Historical Background
Through-Penetration Firestop Systems
Perimeter Fire Containment Systems
Joint Systems

Key Terms

Browns Ferry nuclear power plant fire, fire barrier, fire containment, fire resistance, firestop, health care facility, penetration sealing

As construction for new buildings or renovations to existing buildings are planned, it is important to include fire containment penetration sealing systems, which include through-penetration firestop systems, perimeter fire containment systems, and joint systems. These systems must be properly installed to contain fires and smoke and prevent their spread.

A series of tests has been developed for testing materials in combination with various fire barrier constructions, so that today, the Underwriters Laboratories (UL) Fire Resistance Directory devotes 2975 pages in two volumes to sealing of penetrations. These are divided into the following three categories:

1. *Through-penetration firestop systems.* Used to seal openings where mechanical or electrical systems pass through rated walls or floors
2. *Perimeter fire containment systems.* Used to seal openings between floors and curtain walls
3. *Joint systems.* Used to seal openings where two elements of construction come together such as joints where two walls meet or where two different floor systems meet

For related topics, see Section 12, Chapter 8, "Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety"; Section 18, Chapter 1, "Confinement of Fire in Buildings"; and Section 18, Chapter 3, "Smoke Movement in Buildings."

HISTORICAL BACKGROUND

Prior to 1975, sealing of penetrations through fire-resistant assemblies was relatively simple. Once an opening was made through a fire barrier and a pipe, conduit, or other similar penetrating service was installed, the annular space was filled with a noncombustible material such as mineral wool, fiberglass, or asbestos (before asbestos was known to be a carcinogen).

On March 22, 1975, workers at the Browns Ferry nuclear power plant in northern Alabama were using a candle to check for air leaks at openings in a wall where trays of electrical cables pass from one room to another. As a worker held a candle near one of the openings, the flow of air through it drew the flame toward polyurethane foam that had recently been installed to seal the openings. The foam ignited and fire spread along the cables, shorting out backup safety systems as the cable insulation burned off.[1]

This fire demonstrated that it was not only important to properly seal penetrations to limit the spread of fire, but also to limit the spread of smoke. Previously used materials were found to be inadequate for this purpose. One of the first materials used to provide safer sealing of penetrations was silicone room temperature vulcanizing (RTV) foam, which can withstand high temperatures and confine hazards such as smoke, fire, and gases.

John E. Kampmeyer, P.E., FSNPE, FASHRAE, has practiced both mechanical and fire protection engineering since 1961. He is a senior project engineer at Triad Fire Protection Engineering Corp. in Springfield, Pennsylvania. Mr. Kampmeyer is chairman of NFPA's AEBO Section, a member of the *NFPA 5000*® Technical Committee, and a member of the Smoke Management Committee. He also teaches short courses in fire protection systems, smoke control, mechanical codes, and energy codes.

THROUGH-PENETRATION FIRESTOP SYSTEMS

Through-penetration firestop systems represent the majority of the systems contained in the Underwriters Laboratories Directories. Each system deals with a specific firestop material, penetrating element, and construction system. In order to apply the systems, there are a number of steps that must be developed.

Determining the Fire Barrier Location and Rating

The first step in determining the proper firestop method to be used is to identify the location of the fire barriers and their hourly rating. In new construction projects, these are generally shown on the architectural drawings or, in the case where a fire protection engineer is part of the design team, a separate set of fire barrier drawings may be provided which show their locations and hourly ratings.

In existing construction, there may be little or no guidance from drawings. It will be necessary to study the building and the local building code to determine the locations of fire barriers. In multistory buildings, each floor is generally separated by 1 or 2 hour rated construction, although it could be greater in some cases. Shafts and stairs are generally separated by 1 or 2 hour rated construction depending on the height of the building. Boiler rooms, incinerator rooms, storage rooms over 100 ft^2 (9.3 m^2), paint shops, and maintenance shops will often be separated by 2 hour rated construction. Enclosed corridors used for access to exits, separations between tenants, and separations between dwelling units generally carry a 1 hour rating, although in some cases these may be nonrated partitions in buildings that are provided with automatic sprinklers. Storage rooms under 100 ft^2 (9.3 m^2), trash chute access rooms, linen chute access rooms, and laboratories are examples of rooms which may be separated by 1 hour rated construction.

Health Care Occupancies

Health care occupancies such as hospitals and nursing homes have an additional requirement for smoke barriers to separate floors, so that patients can be moved to an area protected from smoke in the event of fire. Unlike other occupancies, these smoke barriers must also carry a 1 hour fire resistance rating, and penetrations through them must be protected with through-penetration firestop systems. One method which may be used, although not always accurate (since rated assemblies may have been used because they were available but not required), is to look for labels on doors and door frames which contain hourly ratings. Generally, the ratings of fire doors are as listed in Table 18.5.1.

TABLE 18.5.1 Fire Door Ratings

Door Rating	*Wall Rating*
20 min	½–1 hr
¾ hr	1 hr
1 hr	1 hr
1½ hr	1½–2 hr
3 hr	3–4 hr

F, T, and L Ratings

Firestop systems are tested in accordance with either ASTM E814, *Standard Test Method for Fire Tests of Through-Penetration Fire Stops*[2] or UL 1479, *Fire Tests of Through-Penetration Firestops*.[3] These tests yield three ratings which are used in the published listings for the systems:

- *F rating.* Evaluates the time that the system will withstand the passage of flame expressed in hours
- *T rating.* Evaluates the time that the system will limit the temperature on the unexposed side to not more than 325°F (163°C) expressed in hours
- *L rating.* Evaluates the air leakage through the system at ambient and/or 400°F (204°C) at an air pressure differential of 0.30 in. of water (74.6 Pa) expressed in cubic feet per minute per square foot of opening (cfm/ft^2); the test for L ratings is not a requirement of ASTM E814 and is optional in UL 1479.

Both the 2006 edition of *NFPA 5000®, Building Construction and Safety Code®,* and the 2006 edition of the ICC *International Building Code* (IBC)[4] require that penetrations through all fire barriers be protected with a through-penetration firestop system having an F rating equal to the hourly rating of the assembly. NFPA places the additional requirement that the F rating cannot be less than 1 hour. There is an exception in both codes: where the penetrating items are 6 in. diameter (152 mm) maximum steel, copper, or cast iron pipes, the annular spaces can be filled with grout to the full depth of the assembly. The T rating is not required for these assemblies, because they are generally located above any combustible materials which could come in contact with the penetrating item.

For horizontal fire barriers (floors and floor/ceiling assemblies), both building codes require additionally that the T rating of the through-penetration firestop system be equal to the hourly rating of the assembly, except where the penetration is contained within a fire-rated wall or partition assembly. The additional T rating requirement is in recognition of the fact that many vertical pipes may come in contact with combustible materials that are on the floor of the areas where the penetration firestop system is located. If it can be assured that there will be no combustibles near the piping, NFPA allows that the T rating requirement may be dropped.

Neither of the building codes call for an L rating on smoke barriers at the present time. The only reference to a pressure differential is in the IBC, which requires the firestop system to be tested under a differential pressure of 0.01 in. of water (2.484 Pa). The ASTM E814 and UL 1479 standards require a 0.01 in. of water (2.484 Pa) positive pressure as a minimum for all through-penetration firestop system tests. This is done to assure that the system will withstand a fire pressure attempting to push the heat through it. It is typically more of an issue with nonmetallic penetrating items, where the fire could push through burned-off sections, penetrating piping or conduits.

Firestop System Selection

Once the required hourly ratings for the through-penetration firestop system have been determined, the search for a specific system begins. Note that the term "system" and not "product" has been used. In order to determine the proper application of any product, it is necessary to know more about the construction of the fire barrier as well as the penetrating item. These three elements, fire barrier, penetrating item, and firestop product go together to form a system that makes up the through-penetration firestop. The testing laboratories list thousands of systems, each of which is specific to a type of construction, hourly rating, and manufactured product(s). On the surface, this appears to be a formidable task. In order to solve these difficulties, it is necessary to consider the elements of the construction described in the sections that follow.

Type of Fire Barrier Designation. The first consideration is the configuration of the fire barrier being penetrated. Is the barrier a floor (or horizontal barrier) requiring protection from vertical fire spread or is it a wall (or vertical barrier requiring protection from horizontal fire spread)?

Fire Barrier Construction Type. The second consideration is the type of construction used to create the fire barrier. Some examples follow, each having different firestop systems associated with it:

- Concrete floors of varying thicknesses
- Framed floors
- Steel
- Floor/ceiling assemblies consisting of layers of construction materials with horizontal spaces for ductwork, piping, and wiring
- Concrete or masonry walls of varying thickness
- Framed walls
- Bulkheads in marine vessels
- Composite walls

A through-penetration firestop system tested for a concrete block wall may not be applicable to a wall constructed of metal studs and drywall.

Penetrating Item Designation. The last consideration is the general type of penetrating item through the rated assembly, examples of which are the following:

- No penetrating item where a void in construction is to be sealed
- Metallic pipe, conduit, or tubing
- Nonmetallic pipe, conduit, or tubing
- Electric cables
- Cable trays with electric cables
- Insulated pipes
- Miscellaneous electrical items such as bus ducts
- Miscellaneous mechanical penetrating items, including air ducts
- Combinations of penetrating items including any combination of items listed above

Each of the systems will be listed for a particular size of penetrating item and the specific material of the penetrating item. For example, a system may be listed for steel pipes up to 24 in. (0.61 m) and copper pipes up to 6 in. (152.4 mm) with 2 in. (50.8 mm) or less insulation in diameter, whereas another system is listed for steel or copper pipes up to 4 in. (101.6 mm) with 1 in. (25.4 mm) or less insulation.

These systems illustrate a major problem facing designers in finding systems for floor penetrations using metallic pipes. It is difficult to get T ratings that will equal the F rating. This is because the metal transmits heat through the fire barrier at a greater rate than either the fire barrier construction or the firestop sealant, resulting in less time to reach the 325ºF (163º C) maximum temperature. Generally, it will be necessary to use insulation on the piping and the result will probably be an F rating greater than needed for the particular fire barrier. This is generally not as great a problem when using nonmetallic piping because of the lower heat transmission rate.

Thus, the search can be narrowed down to 1000 to 2000 possible choices. Each of these choices is very specific as to the size and type of penetrating items, as well as the details of the construction of the floor or wall being penetrated. It is necessary to study these details to be certain that the construction details in the listing meet the details of the fire barrier being penetrated before choosing a system to be used.

In summary, to select the appropriate firestop sealant for a particular project you need to determine the following:

- Fire resistance rating of the construction being penetrated
- Type of pipe, conduit, or other item being using to penetrate the fire barrier
- Type of penetrated construction—floor, wall, or both
- F, T, and L ratings required or desired
- Construction details and materials of the rated construction

PERIMETER FIRE CONTAINMENT SYSTEMS

Building Construction and Fire Resistant Materials

Perimeter fire containment systems were developed as the result of the increased use of exterior curtain wall construction in buildings, particularly high-rise buildings. In typical building construction used prior to the turn of the twentieth century, the exterior walls were either load bearing or were supported on the floor slabs and extended between the floors (See Figure 18.5.1). In the late nineteenth century and early twentieth century, lightweight panelized systems were developed that could cover the exterior of the building more economically but covered the edge of the floor slab only, leading to the term "curtain wall" construction.[5] In this construction, the floor slab does not extend to the exterior wall but is separated by a nonrated vertical construction, which extends unbroken past the edge of the slab, creating a void through which fire can pass from floor to floor (Figure 18.5.2).

Early methods employed to firestop these voids involved the use of fibrous fire retardant materials such as mineral wool. These materials provided an effective method of restricting

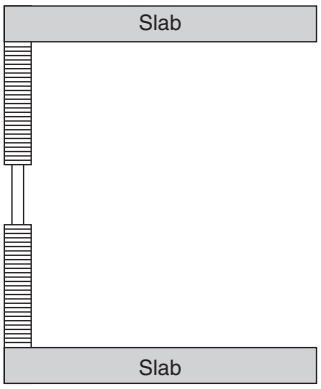

FIGURE 18.5.1 Floor Slabs in Typical Building Construction Before 1900

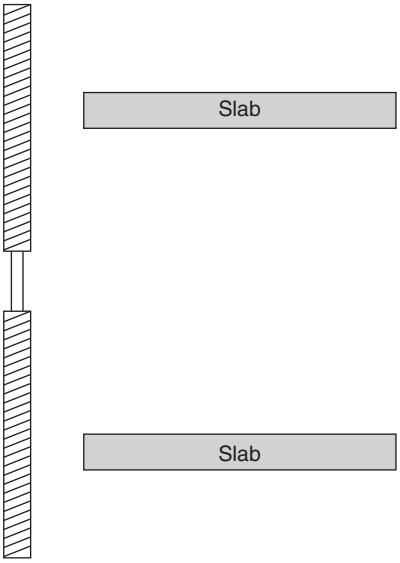

FIGURE 18.5.2 Floor Slab for Curtain Wall Construction

flame passage between floors, but were not effective in controlling the movement of smoke. Therefore, elastomeric sealants were developed that, in conjunction with fire-resistant materials, could effectively limit the spread of both flame and smoke between floors.

Testing and Ratings

Systems designed to protect curtain wall construction are tested in accordance with ANSI/UL 2079, *Tests for Fire Resistance of Building Joint Systems,*[6] using test methods and conditions given in NFPA 285, *Standard Fire Test Method for Evaluation of Fire Propagation Characteristics of Exterior Non-Load-Bearing Wall Assemblies Containing Combustible Components.*

Integrity Rating and Insulation Rating. Just as fire resistance ratings are given for through-penetration firestop systems, two fire resistance ratings are given in hours for perimeter fire containment systems: integrity rating and insulation rating. The integrity rating is analogous to the F rating on firestop systems and is a measure of the system's ability to limit the spreads of flame through the construction. The insulation rating is analogous to the T rating on firestop systems and is a measure of the system's ability to limit the temperature 1 in. (2.54 cm) above the fill material to 325°F (163°C). Where space between the slab and the curtain wall exceeds 6 in. (15.24 cm), there is an additional restriction on the insulation rating that the temperature will not rise more than 250°F (121.1°C) above the starting temperature.

Maximum Linear Opening Width Rating. A third listing for perimeter fire containment systems is the maximum linear opening width. This places a limitation on the width of the protected space between the slab and the curtain wall. Where the system is subject to movement, the components of the system are cycled prior to the fire test for 500 or 100 complete movement cycles at a minimum rate of 1, 10, or 30 cycles per minute. This results in the system being given a Class I, II, and/or III designation as shown in Table 18.5.2.

Using these tests, the joints are assigned a nominal joint width and a percentage factor for either compression or extension. From these, the minimum and maximum allowable joint widths are calculated using the formulae:

$$W_{min} = W_{nom} [1 - (\% \text{ Exp}/100)] \quad (1)$$

where

W_{min} = Minimum joint width (in.)
W_{nom} = Nominal joint width (in.)
% Exp = Percent movement capability in the compression direction

and

$$W_{max} = W_{nom} [1 - (\% \text{ Comp}/100)] \quad (2)$$

where

W_{max} = Maximum joint width (in.)
W_{nom} = Nominal joint width (in.)
% Comp = Percent movement capability in the extension direction

Movement Capabilities Rating. When a system has capabilities of resisting shear movement, the system is given a movement capabilities rating expressed in percent vertical shear. From this

TABLE 18.5.2 System Movement Capabilities

Movement Class	*Mininum Number of Cycles*	*Minimum Cycling Rate (cycles per minute)*
Class I	500	1
Class II	500	10
Class III	100	30

data, the maximum vertical shear the system can withstand can be calculated from the formula:

$$\text{Shear} = W_{nom} (\% \text{ Shear}/100) \quad (3)$$

where

Shear = Vertical shear movement
W_{nom} = Nominal joint width (in.)
% Shear = Percent in shear movement

Leakage Rating. There is a fifth rating, leakage rating, which is optional and not part of every listing. This rating determines the amount of air leakage in cfm per lineal foot through the joint at ambient temperatures and/or 400ºF (204ºC). The test is conducted at a differential pressure of 0.20 in. of water (49.8 Pa) and provides an indication of the amount of smoke which could be transmitted through the joint.

Curtain Wall Penetration Protection

When evaluating curtain wall penetration protection, there are two considerations which must be investigated: movement capabilities and maximum clearance.

Movement Capabilities. It must be determined whether the through-penetration fire stop system is static (i.e., the system does not have movement capabilities) or dynamic (i.e., the system has movement capabilities).

Maximum Clearance. This system will be listed for varying maximum clearance distances between the curtain wall and perimeter of the floor. The following are the usual ranges of clearances:

Less than or equal to 2 in. (50.8 mm)
Greater than 2 in. (50.8 mm) and less than or equal to 6 in. (152.4 mm)
Greater than 6 in. (152.4 mm) and less than or equal to 12 in. (304.8 mm)

JOINT SYSTEMS

Testing and Ratings

Fire resistance rated construction is tested and rated to provide a barrier which can resist the passage of fire and smoke for the period given in the hourly rating of the construction. However, the mating of two construction elements creates a space through which fire, heat, and/or smoke can pass, thereby reducing the effectiveness of the fire-resistant barrier. Joint systems protect these gaps. These systems are tested per ANSI/UL 2079, *Tests for Fire Resistance of Building Joint Systems.*

Similar to perimeter fire containment systems, systems with movement capabilities are tested by cycling the components of the system prior to the fire test under one of three conditions. The movement class, minimum number of cycles, and minimum cycling rate per minute are the same as those shown in Table 18.5.2.

Using these tests, the joints are assigned a nominal joint width and a percentage factor for either compression or extension. From these, the minimum and maximum allowable joint widths are calculated using the formulae:

$$W_{min} = W_{nom} [1 - (\% \text{ Exp}/100)] \quad (4)$$

where

W_{min} = Minimum joint width (in.)
W_{nom} = Nominal joint width (in.)
% Exp = Percent movement capability in the compression direction

and

$$W_{max} = W_{nom} [1 - (\% \text{ Comp}/100)] \quad (5)$$

where

W_{max} = Maximum joint width (in.)
W_{nom} = Nominal joint width (in.)
% Comp = Percent movement capability in the extension direction

As was the case with perimeter fire containment systems, there is an optional L (leakage) rating, which determines the amount of air leakage in cfm per lineal foot through the joint at ambient temperatures and/or 400ºF (204ºC). The test is conducted at a differential pressure of 0.3 in of water (74.6 Pa), and provides an indication of the amount of smoke which could be transmitted through the joint.

There is an L rating which is the same as for through-penetration firestop systems. This evaluates the air leakage through the system at ambient and/or 400ºF (204ºC) at an air pressure differential of 0.3 of water (74.6 Pa). and is expressed in cubic feet per minute per square foot of opening (cfm/ft^2). The test for L ratings is optional in ASI/UL 2079.

Factors to Consider Before Beginning Construction

When evaluating joint systems, there are three factors to consider: arrangement of construction elements, movement capabilities designation, and maximum clearance.

Arrangement of Construction Elements. Several types of joint systems can be used depending on the particular construction arrangement as follows:

- Floor-to-floor (typically at expansion joints in floors)
- Wall-to-wall (typically at expansion joints or corner joints in walls)
- Head of wall
- Bottom of wall

Movement Capabilities Designation. A decision must be made on whether the through-penetration fire stop system is static (i.e., the system does not have movement capabilities) or dynamic (i.e., the system has movement capabilities).

Maximum Clearance. This system will be listed for varying maximum clearance distance between the curtain wall and perimeter of the floor. The following are the usual ranges of clearances:

Less than or equal to 2 in. (50.8 mm)
Greater than 2 in. (50.8 mm) and less than or equal to 6 in. (152.4 mm)
Greater than 6 in. (152.4 mm) and less than or equal to 12 in. (304.8 mm)
Greater than 12 in. (304.8 mm) and less than or equal to 24 in. (61 m)
Greater than 24 in. (0.61 m)

A further complication is introduced when a floor-to-floor joint system is considered. This is the situation which is often represented by expansion joints in concrete floors. Not only will the joint require consideration of its movement, it is often necessary to consider the probability of smoke movement through the joint. Therefore, these systems also carry L ratings.

SUMMARY

The Browns Ferry nuclear power plant fire of 1975 demonstrated that building construction must be properly sealed to limit the spread of both fire and smoke. Because materials used before 1975 to seal penetrations were found to be inadequate, new sealing materials were developed along with a series of tests for rating the use of these materials in combination with various fire barrier constructions. The initial concentration was on sealing of pipes and conduits penetrating fire barriers. However, the sealing of joints around pipes and conduits and in joints between elements of fire resistance rated construction has come a long way from the simple selection of a "fire caulk" and then using it to plug up the opening. The sealing of joints requires consideration of a number of factors including the following:

- Desired fire resistance rating
- Maximum allowable opening width
- Nature of the item penetrating to fire resistance rated construction where applicable
- Allowable temperature rise where applicable
- Need for the system to resist movement
- Need for the system to resist the passage of smoke as well as fire

This chapter outlines three categories of sealing penetration systems: through-penetration firestop, perimeter fire containment, and joint. The chapter describes steps for determining which firestop method should be used, the unique sealing requirements of different types of facilities, rating systems, and building codes, standards and regulations for the application of penetration sealing.

Deflagration (Explosion) Venting

Richard F. Schwab

Chapter Contents

Fundamentals of Deflagrations
Fundamentals of Deflagration Venting and Enclosure Design Considerations

Key Terms

combustible dust, deflagration, detonation, enclosure, explosion venting, fireball, flammable gas, pressure effect

The first document by NFPA concerning explosion (deflagration) venting was NFPA 68-T, *Standard on Explosion Venting,* tentatively adopted by NFPA in 1945. The *Guide for Explosion Venting,* tentatively adopted by NFPA in 1954, brought together the best available, albeit sparse, information on the design and utilization of vents to limit pressures developed by "explosions." The 2007 edition of NFPA 68 is titled *Standard on Explosion Protection by Deflagration Venting.*

NFPA 68 clearly differentiates the terms *deflagration, detonation,* and *explosion.* A *deflagration* is defined as the propagation of combustion zone from the ignition point at less than the speed of sound in the unreacted medium. A *detonation* results when the combustion zone proceeds at greater than the speed of sound. An *explosion* is the bursting of an enclosure or container due to the development of internal pressure. The standard refers to cases in which vents are designed to relieve pressures developed by the combustion process proceeding at less than the speed of sound as explosion (deflagration) venting. Detonations cannot be vented.

Unfortunately, the data available in 1954 was primitive and without theoretical basis. It was customary at the time to express vent area in terms of vent ratios (square feet/cubic feet of enclosure volume). Very little regard was given to the strength of the enclosure and its effect on vent sizing, although it was recognized that a strong enclosure or a heavy building did not need as much vent area as a weak enclosure or building. It was qualitatively recognized that the rate of pressure rise had an effect on the size of vent required for a given enclosure; that is, a combustible or flammable gas showing test data with high rates of pressure rise required a larger vent ratio than those with lower rates of pressure rise. Also, increasing the mass of the vent closure was undesirable because it slowed down the opening of the closure, resulting in the buildup of destructive pressures within the enclosure.

This unfortunate state of affairs prevailed into the late 1960s and early 1970s, when work done at the U.S. Bureau of Mines and more extensive work done in Great Britain, Germany, and Switzerland increased the pool of knowledge to the extent that the 1974 edition of NFPA 68, *Guide for Venting of Deflagration,* was issued. Bartknecht provides additional historical information on the development of deflagration venting.[1]

For related topics, see Section 2, Chapter 8, "Explosions"; Section 6, Chapter 15, "Explosives and Blasting Agents"; Section 17, Chapter 8, "Explosion Prevention and Protection"; and Section 18, Chapter 4, "Venting Practices."

FUNDAMENTALS OF DEFLAGRATIONS

The following conditions are necessary to initiate a deflagration:

- A fuel concentration between upper and lower combustible limits
- Sufficient oxidant (usually air) to support combustion
- An ignition source of sufficient energy to ignite the combustible mixture

Richard F. Schwab, P.E., is a fellow of the American Institute of Chemical Engineers and of the Society of Fire Protection Engineers. He is retired manager of process safety and loss prevention at Honeywell International (formerly Allied-Signal, Inc.) in Morristown, New Jersey.

Once a deflagration has been initiated, the associated pressure needs to be characterized. The deflagration pressure in the enclosure generally follows the gas law equation, which can be expressed as follows:

$$P = \frac{n \times R \times T}{V} \quad (1)$$

where

R = Universal gas constant

P = Pressure

T = Absolute temperature

V = Volume

n = Number of moles of gases generated by the deflagration

The maximum deflagration pressure P_{max} and the maximum rate of pressure rise $(dP/dt)_{max}$ are determined by test. For most fuel, the maximum deflagration pressure is 6 to 10 times the absolute pressure at the time of the ignition.

The fundamental basis for deflagration venting theory is the so-called cubic law that can be stated as follows:

$$K = \left(\frac{dP}{dt}\right) \times V^{1/3} \quad (2)$$

The deflagration index K is computed from the maximum rate of pressure rise in a closed vessel multiplied by the cube root of the enclosure volume. It should be noted that the deflagration index is not a constant, although it has been referred to as such in some of the older literature. The deflagration index for gases is K_G; for dusts it is K_{St}. The maximum rate of pressure rise occurs at an optimum concentration. If the optimum concentration is either not reached or exceeded, the rates of pressure rise are less than the optimum. Further, the energy of the ignition source affects the rate of pressure rise. If the energy is less than standard test method requirements, then the rate of pressure rise will be lower.

Test methods are usually used by laboratories to measure these factors; the determination of optimum concentration requires a series of tests over a range of concentrations. The ignition energy used is high to ensure that the rate of pressure rise is at its maximum.

Table 18.6.1 provides values for the key factors, P_{max} and K_G, for some common flammable materials.

Three hazard classes have been defined for dusts based on the magnitude of the dust deflagration index, K_{St}. Table 18.6.2 displays three hazard classes for dust deflagrations

TABLE 18.6.1 Typical Flammability Parameters of Gases Measured in a 5 L Sphere (0.005 ft^3) with an Ignition Energy of 10 J

Flammable Material	P_{max} *(bar)*	K_G *(bar-m/sec)*
Acetophenone[a]	7.6	109

TABLE 18.6.2 Hazard Classes of Dust Deflagrations

Hazard Class	K_{St} *(bar-m/sec)**	P_{max} *(bar)**
St-1	≤200	10
St-2	201–300	10
St-3	>300	12

*K_{St} and P_{max} are determined in approximately spherical calibrated test vessels of at least 20 L capacity per ASTM E1226, *Standard Test Method for Pressure and Rate of Pressure Rise for Combustible Dusts.*

Source: NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* 2007 ed., Table B.1.

Fuel

Any mixture that is capable of reacting with an oxidizing medium (which in most cases is air) can be classified as a fuel. The fuel can exist in the gaseous, liquid, or solid state. Liquid fuels are dispersed in air as fine mists, solid fuels are dispersed in air as dusts, and hybrid mixtures can be mixtures of dusts and flammable or combustible gases (or mists) very similar to gaseous fuels.

The concentration of a gaseous fuel is usually expressed in volume percent (vol%) or mole percent (mol%) and concentrations of combustible dusts and mists are expressed as mass per unit volume, such as grams per cubic meter (g/m^3) or ounces per cubic foot (oz/ft^3).

Flammable Gas

The flammable gas must be present in air (the oxidizing media) between the lower and upper flammable limits (LFL and UFL).

LFL is the lowest concentration of material that will propagate a flame from an ignition source through a mixture of flammable gas or combustible dust dispersion with a gaseous oxidizer; LFL is also known as the minimum explosible concentration. UFL, on the other hand, is the highest concentration of material that will propagate a flame from an ignition source through a mixture of flammable gas or combustible dust dispersion with a gaseous oxidizer. Ignition can occur between the lower and upper flammable limits. The maximum deflagration pressure of a flammable gas in a particular oxidizing medium is determined by test and is generally on the fuel rich side of the stoichiometric mixture. The concentration at which the maximum rate of pressure rise $(dP/dt)_{max}$ and the maximum pressure P_{max} occur can differ slightly. These experimental values are used to calculate K_G values according to Equation 2.

Combustible Dust

Solid particulates smaller than 0.017 in. (420 μm) capable of passing through a U.S. No. 40 standard sieve are classified as dusts. The fineness of the dust is characterized by the particle size distribution. Generally speaking, the maximum rate of pressure rise increases with a decrease in dust particle size, along with the maximum pressure. The experimental K_{St} of a combustible dust sample is determined by the optimum rate of pressure rise at the optimum concentration multiplied by the cube root of the test enclosure volume as shown in Equation 2.

The minimum ignition energy of the dust cloud decreases as the particle size decreases. Experimental data shows this trend, though it is generally not extensively reported. Particle shape also has an effect on the combustion characteristics of dusts. Dust particles with an irregular shape, such as those that would be obtained from polymer dust generated in a hammer mill, have different combustion characteristics from a dust with a spherical shape, such as those that would be obtained from a similar polymer generated by a suspension polymerization process, even though the general particle size distribution of the two may be similar. The irregularly shaped dust particles of the hammer mill product show a higher rate of pressure rise. This is one of the reasons for testing sample dusts coming from a particular process and not trying to extrapolate dust test data from a completely unrelated process even though particle size distribution may appear to be similar.

The lower combustible limit of a dust-air mixture, also called the minimum explosible concentration (MEC), exists along with the upper limit, although upper combustible limit numbers are of no practical value for designing a viable explosion protection system. The upper combustible limit is usually not reported.

Burning Velocity and Flame Speed

The burning velocity is the rate of flame propagation relative to the unburned gas that is ahead of it. The fundamental burning velocity, S_u, is the burning velocity of a laminar flame under stated conditions of composition, temperature, and pressure of the unburned gas. Table 18.6.3 lists typical fundamental burning velocities of flammable gases in air.

Flame speed is the speed of a flame front relative to a fixed reference point. Its minimum value is equal to the fundamental burning velocity times the expansion factor equal to the ratio of the density of the unburned gas to the density of the burned gas. Flame speed is influenced by the degree of turbulence in the gas-air mixture, which can be induced by obstructions in the flame path, volume of the enclosure, ignition energy, temperature of the mixture, and so on, and cannot be determined by the properties of the flammable gas mixture alone.

Hybrid Mixtures

The addition of a flammable gas to a dust-air mixture is called a hybrid mixture. The presence of a flammable gas in a dust-air mixture reduces the LFL and the ignition energy required to initiate the deflagration. This effect can occur even though flammable gas is below its LFL (when considered alone as a flammable gas-air mixture) and the dust is below its LFL (MEC). The addition of the flammable gas to a combustible dust cloud will increase the effective K_{St} value, which means that the required vent area will have to be increased (Figure 18.6.1).

Introduction of an inert gas into the fuel-air mixture will reduce the rate of pressure rise and the maximum pressure attained. If it is desired to take these effects into account when designing the deflagration vents, the effects on the rate of

pressure rise and the maximum pressure must be determined experimentally.

Introduction of an inert gas into a combustible dust-air cloud affects the rate of pressure rise (which will decrease) and the maximum pressure attained (which will decrease) after ignition of the cloud. When considering this technique for reducing the hazard of combustible dust, additional problems concerning the possibility of segregation of inert material from the combustible material must be considered. See Bartknecht,[1] Eckhoff,[2] and NFPA 68.

FUNDAMENTALS OF DEFLAGRATION VENTING AND ENCLOSURE DESIGN CONSIDERATIONS

Deflagration venting is intended to limit the amount of damage to a protected enclosure. It is not a preventative measure. It presupposes that a combustible mixture will occur in the enclosure and that it will ignite. Properly designed venting will limit the damage to a predetermined acceptable level. Some users will ac-

cept a permanently deformed enclosure, while others will only accept elastic deformation. Accepting permanent deformation means that while the enclosure will not rupture during the event, a rectangular box might well become somewhat spherical and unserviceable. The user must weigh the probability of the event against the potential for lost productivity.

A deflagration vent is an opening in an enclosure through which material expands and flows, thus relieving pressure. If no venting is provided, the maximum pressures developed during the deflagration are typically 6 to 10 times the initial absolute pressure. In most cases it may be impractical to construct an enclosure that can withstand or contain such pressures. The reduced pressure P_{red} is the maximum pressure developed in a vented enclosure during a vented deflagration.

The rate of pressure rise is the most important parameter that is used in the design of deflagration venting. A rapid rate of pressure rise means that only a short time is available for successful venting, whereas a slower rate of pressure rise allows the venting to proceed more slowly while remaining effective. It also follows that, all other factors being equal, the more rapid rate of pressure rise requires the greater area for effective venting.

The vents provided are intended to limit the buildup of pressure within the enclosure so that damage to the enclosure does not occur or is limited to acceptable levels. As the vent area increases, the reduced pressure for a given static activation pressure of the vent closure decreases. Open vents are more effective than covered vents. Lightweight closures are more responsive than heavy closures. Damage can result if a deflagration occurs in an enclosure that is too weak to withstand the pressure of a deflagration. An ordinary masonry wall of 8 in. (20 cm) brick or concrete block cannot withstand a pressure difference greater than 0.5 psi (0.035 bar).

Since the pressure development during deflagration is rapid, it could be experienced as a dynamic load by the enclosure (building) rather than a static load. Therefore, a suitable design safety factor is applied to P_{red} in the absence of detailed structural response analysis.

Common design standards allow P_{red} to be selected for up to two-thirds of the enclosure strength (see Taminini and Valiulis[3] and NFPA 68). NFPA 68 should be consulted for specific guidance for enclosure design pressure requirements when permanent deformation can or cannot be accepted.

Flames and pressure waves that emerge from an enclosure during the venting process must be taken into account to ensure that they do not ignite nearby combustible material or injure personnel who may be exposed to their effects.

Enclosure Length to Diameter

In NFPA 68, the combustion process in an enclosure involves the ignition of a combustible with an oxidant where the length/diameter (L/D) ratio is 2 or less. If the L/D ratio is greater than 2, modifications in the calculation, leading to an increase in the necessary vent area, must be taken into account for the venting design. The P_{red} developed within an enclosure decreases as the available vent area for the enclosure increases. If the enclosure is small and relatively symmetrical, then one large vent can be effective; however, for large enclosures, it is recommended that the vents be distributed over the surface area of the enclosure to the greatest extent possible.

The L/D of an elongated enclosure is determined based on the general shape of the enclosure, the location of the vent, the shape of any hopper extensions, and the furthest distance from the vent at which the deflagration could be initiated. The calculation involves the worst case flame path length to the farthest side of the vent and an effective diameter of the enclosure. The position of the vent along the enclosure can change the effective L/D. In this way a single vent located midway along the central axis of an elongated vessel would result in a smaller L/D than the same vent located at one end of the vessel. In no case can the effective L/D of an enclosure be less than 1, meaning that as the vents get closer together along the central axis, at some point the controlling flame path length would become, for instance, the diameter of the cylindrical enclosure. Detailed explanation of this approach can be found in NFPA 68.

Effect of Vent Duct Length

When a vent duct is added to the vent closure to direct the vented combustion gases to a safe outside area, this introduces a resistance to the relief of the vented gases from the enclosure and must therefore be taken into account. This basically means that the size of the vent area must be increased to accommodate this restriction. Different equations are used to determine the vent duct effect for gases as compared to dusts. In general, the solution for required vent area with a vent duct is trial and error and the calculations limit the length of the vent duct. This solution is iterative (trial and error). The following equations are to be used for this iterative calculation:

$$A_{vf} = A_{v4} \times (1 + 1.18 \times E_1^{0.8} \times E_2^{0.4}) \times \sqrt{\frac{K}{K_0}} \qquad (3)$$

where

A_{v4} = Vent area after adjustment for turbulence (m^2)

A_{vf} = Vent area required when duct is attached to the vent opening (m^2)

K_0 = 1.5, the resistance coefficient value assumed for the test configurations that generated the data used to validate the basic dust venting equations

$$E_1 = \frac{A_{vf} \times L_{\text{duct}}}{V} \qquad (4)$$

where

L_{duct} = Vent duct overall length (m)

$$E_2 = \frac{10^4 \times A_{vf}}{(1 + 1.54 \times P_{\text{stat}}^{4/3}) \times K_{St} \times V^{3/4}} \qquad (5)$$

where

P_{stat} = Nominal static opening pressure of the vent cover (bar)

V = Enclosure volume (m^3)

$$K \equiv \frac{\Delta P}{{}^1/_2 \times \rho \times U^2} = K_{\text{inlet}} + \frac{f_D \times L}{D_h} + K_{\text{elbows}} + K_{\text{outlet}} + \ldots \qquad (6)$$

where

K = Overall resistance coefficient of the vent duct application

K_{inlet}, K_{elbows}, K_{outlet} = Resistance coefficients for fittings

U = Fluid velocity (m/sec)

D_h = Vent duct hydraulic diameter (m)

f_D = D'Arcy friction factor for fully turbulent flow (see NFPA 68 Annex)

ρ = Fluid density × $1/G_c$

Note: In this chapter pressure is expressed as bar gauge (bar g) unless it is otherwise noted as bar absolute (bar a). It is recommended that NFPA 68 (2007) be consulted for details describing this calculation.

Enclosure Strength

The vent designed for an enclosure according to NFPA 68, whether for a high strength enclosure or a low strength enclosure, is intended to allow the deflagration pressure P_{red}, to attain two-thirds the strength of the enclosure without rupturing the enclosure. In all cases

$$P_{red} \le \frac{P_{es}}{\text{DLF}} \tag{7}$$

where

P_{red} = Maximum pressure developed during venting (bar [psi])

P_{es} = Enclosure strength evaluated bases on static pressure calculations for either deformation or burst (bar [psi])

DLF = X_m/X_s

X_m = Maximum dynamic deflection

X_s = Static deflection or, in other words, the displacement produced in the system when the peak load is applied statically

In the absence of detailed structural response analysis, a conservative value of DLF = 1.5 is used and design is based on the weakest structural element of the enclosure.

Two alternative conditions apply to the concept of enclosure strength, presuming that the enclosure is a ductile design, that is, designed to be somewhat elastic or deform without rupture under pressure:

- Permanent deformation, but not rupture, of the enclosure can be accepted.
- Permanent deformation of the enclosure cannot be accepted.

When the enclosure is a pressure vessel designed according to ASME or similar code, the allowable P_{red} is greater than the maximum allowable working pressure (MAWP) for the vessel. The ASME code specifically allows the NFPA 68 method for determining the allowable reduced pressure P_{red} during a deflagration.

If permanent deformation, but not rupture, of the enclosure can be accepted,

$$P_{red} \le \left(\frac{2}{3}\right) \times F_u \times P_{\text{MAWP}} \tag{8}$$

If permanent deformation of the enclosure cannot be accepted,

$$P_{red} \le \left(\frac{2}{3}\right) \times F_y \times P_{\text{MAWP}} \tag{9}$$

where

P_{red} = Maximum pressure developed in a vented enclosure (bar [psi])

F_u = Ratio of the ultimate stress of the enclosure to the allowable stress of the enclosure per ASME *Boiler and Pressure Vessel Code*[4]

P_{MAWP} = Enclosure design pressure [bar (psi)] according to ASME *Boiler and Pressure Vessel Code*

F_y = Ratio of the yield stress of the enclosure to the allowable stress of the materials of construction of the enclosure per ASME *Boiler and Pressure Vessel Code*

Note: The ASME *Boiler and Pressure Vessel Code* contains data on the ultimate and yield stresses for various materials of construction plus the allowable stress. The ratios can be calculated from this information. It is anticipated that ambient conditions will apply when applying Equations 8 and 9.

Venting of Gas or Mist Deflagrations in Low Strength Enclosures

A low strength enclosure is capable of withstanding a P_{red} of not more than 1.5 psi (0.1 bar g).[5,6]

$$A_v = \frac{C \times A_S}{P_{red}^{1/2}} \tag{10}$$

where

A_v = Vent area (m^2 or ft^2)

C = Venting parameter, in units consistent with P_{red}

A_S = Internal surface area of the enclosure (m^2 or ft^2)

P_{red} = Maximum pressure developed in a vented enclosure during a deflagration (bar [psi])

The venting parameter shall be defined by the following equations for fundamental burning velocity (less than 60 cm/sec):

For C ($bar^{1/2}$):

$$C = 1.57 \times 10^{-5} \times (S_u)^2 + 1.57 \times 10^{-4}(S_u) + 0.0109 \tag{11}$$

where S_u is fundamental burning velocity (less than 60 cm/sec).

For C ($psi^{1/2}$):

$$C = 6.1 \times 10^{-5} \times (S_u)^2 + 6.1 \times 10^{-4}(S_u) + 0.0416 \tag{12}$$

Figure 18.6.2 shows the venting parameter as a function of fundamental burning velocity.

In contrast to the earlier editions of NFPA 68, the available data on fundamental burning velocity can now be used to determine venting parameters for more individual fuels. This introduces the need to understand the potential range of fuels that could be present in the enclosure. The designer should consider the material with the highest fundamental burning velocity when designing the vent.

Venting Gas Deflagrations in High Strength Enclosures

The recommended equation for venting enclosures with an L/D of 2 or less is

$$A_v = \{[(0.127) \times \log_{10}(K_G) - (0.0567)] \times P_{red}^{-0.582}\} \times V^{2/3} + [(0.175) \times P_{red}^{-0.572}(P_{stat} - 0.1)] \times V^{2/3} \quad (13)$$

where

$K_G \leq 550$ bar-m/sec

$P_{red} = 2$ bar and at least 0.5 bar $> P_{stat}$

$P_{stat} \leq 0.5$ bar

$V \leq 1000$ m^3

For L/D values from 2 to 5 and for P_{red} no higher than 2 bar, the vent area A_V calculated from Equation 13 should be increased as follows:

$$\Delta A = \frac{A_v \times K_G \left(\frac{L}{D} - 2\right)^2}{750} \quad (14)$$

where D is the hydraulic diameter. For noncircular cross sections it is determined by $4(A/p)$, where A is the cross sectional area normal to the longitudinal axis of the space and p is the perimeter of the cross section.

In the case where the vent mass is greater than that calculated in Equation 15

$$M_T = \left(6.67 P_{red}^{0.2} \times n^{0.3} \times \frac{V}{K_G^{0.5}}\right)^{1.67} \quad (15)$$

where

n = Number of panels

M_T = Threshold mass (kg/m^2)

P_{red} = Vented pressure (bar)

K_G = Gas deflagration index (bar-m/sec)

$V > 1$ m^3

If the vent mass is within the above constraints and greater than M_T calculated, then Equation 16 is used to determine the incremental vent area to maintain the desired P_{red}.

$$\Delta A_i = A_v \times (0.0075) \times M^{0.6} \times \frac{K_G^{0.5}}{n^{0.3}} \times V \times P_{red}^{0.2} \quad (16)$$

where

M = Mass of vent panel (kg/m^2) ≤ 40 kg/m^2

A_v = Vent area calculated by Equation 12

$V > 1$ m^3

If K_G is less than 75 bar-m/sec, use $K_G = 75$ in the equation.

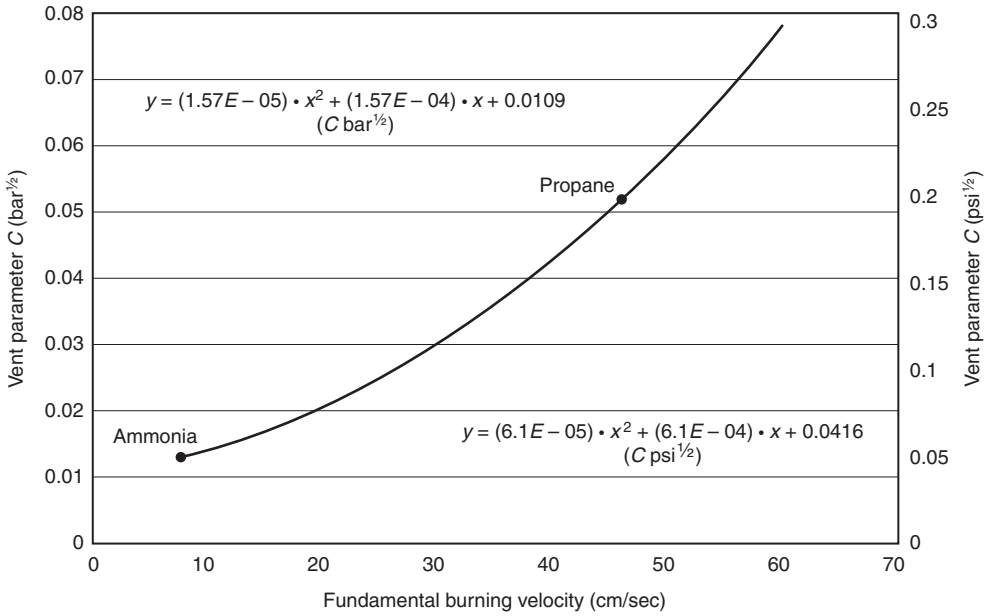

FIGURE 18.6.2 Venting Parameter as a Function of Fundamental Burning Velocity (Source: NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* 2007 ed., Figure 7.2.2.2)

When dealing with enclosures that require ducts to carry the forces of the deflagration and the fireball to a safe location, several problems introduced by using ducts have to be considered. For example, the introduction of ducts results in an increase of pressure inside the enclosure being vented. Consequently, the forces of reaction on the enclosure being vented (dust collector, silo, etc.) must be taken into account, along with considering where the fireball that will be emitted from the ductwork will be vented.

In a situation in which a vent duct is installed after the vent closure to direct the discharge of the gases to an outside safe location, a pressure drop occurs that must be taken into account. The way to do this is to increase the area of the vent. The ductwork leading to the discharge point must be as short and straight as possible. This is the intent of NFPA 68.

NFPA 68 also intends to keep the mass of the vent closure as low as possible. Where vent panels with insulation are needed to prevent heat loss, this need requires a higher vent mass and can affect the achieved P_{red}. It is the intention of NFPA 68 to encourage keeping the relieving panels as light as possible and keeping the relieving ductwork as short and direct to a safe location as possible.

Venting of Deflagrations of Dusts and Hybrid Mixtures

Equation 17 is intended to apply to the design of vents for dust deflagration and hybrid mixtures for high-strength—greater than 1.5 psi (0.1 bar)—enclosures. The recommended design equations for the dust deflagration and the hybrid mixture deflagration for high-strength enclosures are given next. The *L/D* ratio of the design equation is limited to 2 or less. With the initial pressure before the ignition being 1 bar (absolute ±0.2 bar)

$$A_{vo} = 1 \times 10^{-4} \times (1 + 1.54 \times P_{stat}^{4/3}) \times K_{St} \times V^{3/4} \left(\frac{P_{max}}{P_{red}} - 1 \right)^{0.5} \quad (17)$$

where

A_{vo} = Vent area calculated from Equation 17 (m^2)

P_{stat} = Nominal static burst pressure of the vent (bar)

K_{St} = Deflagration index (bar-m/sec)

V = Enclosure volume (m^3)

P_{red} = Reduced pressure after vent operation (bar)

P_{max} = Maximum deflagration pressure (bar)

The following limitations must also apply to Equation 17:

- 5 bar ≤ P_{max} ≤ 12 bar
- 10 bar-m/sec ≤ K_{St} ≤ 800 bar-m/sec
- 0.1 m^3 ≤ V ≤ 10,000 m^3
- P_{stat} ≤ 0.75 bar

In cases where *L/D* is greater than 2 but less than or equal to 6, the calculated A_{v1} is determined by Equation 18:

$$A_{v1} = A_{vo} \left[1 + 0.6 \times \left(\frac{L}{D} - 2 \right)^{0.75} \times \exp(-0.95 \times P_{red}^2) \right] \quad (18)$$

For the case where we have a top-fed bin, hopper, and silo the *L/D* can be increased to 8.

Effects of Initially Elevated Pressure

In the case where we have a combustible dust cloud in an enclosure that is pressurized at greater than 0.2 bar, deflagration vents can only be used when the following conditions are met:

- Vent duct length *L/D* is to be ≤ 1
- $M \le M_T$ (threshold mass, kg/m^2) and $M < 40$ kg/m^2
- V_{axial} and $v_{tan} < 20$ m/sec
- No allowance for partial volume
- 0.2 bar < $P_{initial}$ < 4.0 bar
- Use Equation 19 to calculate the needed vent area

$$A_{vep} = \frac{A_{v1}}{A_{vo}} \cdot 10^{-4} \cdot \left[1 + 1.54 \cdot \left(\frac{P_{stat} - P_{initial}}{1 + P_{effective}} \right)^{4/3} \right] \cdot K_{St} \cdot V^{3/4} \cdot \sqrt{\frac{1}{\pi_{effective}} - 1}^{0.5} \quad (19)$$

where

A_{vep} = Vent area (m^2)

P_{stat} = Static burst pressure of the vent (bar)

$P_{initial}$ = Enclosure pressure at the moment of ignition (bar)

$P_{effective}$ = ⅓$P_{initial}$ (bar)

K_{St} = Deflagration index (determined at atmospheric pressure) (bar-m/sec)

V = Enclosure volume (m^3)

$\pi_{effective}$ = $(P_{red} - P_{effective}) / (P^E_{max} - P_{effective})$

P_{red} = Reduced pressure (bar)

P^E_{max} = Maximum pressure of the unvented deflagration at initially elevated pressure (bar) [$(P_{max} + 1)$ $(P_{initial} + 1)/(1$ bar-abs $- 1)$]

P_{max} = Maximum pressure of the unvented deflagration initially at atmospheric pressure (bar)

Discharge of Fireballs from Explosion Vents

When flammable gas, combustible dust, or a hybrid mixture is ignited in a vented enclosure, consideration must be given to the discharge of the resultant fireball and its effects. See NFPA 68 for similar treatment of fireball effects for gases. In the case of dust deflagration or hybrid mixture, the distance which this expected fireball will travel is estimated from the following equation:

$$D = K \left(\frac{V}{n} \right)^{1/3} \quad (20)$$

where

D = Axial distance (front) from the vent (ft or m)

K = Flame length factor ($K = 10$ for metal dusts; $K = 8$ for chemical and agricultural dusts)

V = Volume of vented enclosure (m^3 or ft^3)

n = Number of evenly distributed vents

The axial distance calculated by Equation 20 shall be limited to 200 ft (60 m).

In the case of a vented gas or vapor deflagration the equation is

$$D = 3.1\left(\frac{V}{n}\right)^{0.402} \quad (21)$$

where

D = Axial distance (front centerline) from vent (m)

V = Volume of the vented enclosure (m^3)

n = Number of evenly distributed vents

The hazard zone measured radially (to the sides, measured from the centerline of the vent) shall be calculated as one-half D.

In the case where it is necessary to vent an enclosure containing a combustible dust or a hybrid mixture internally into a building through a flame-arresting and particulate retention device, the resulting pressure increase in an unvented building is estimated to be

$$\Delta P = 1.47 \times P_o \times \left(\frac{V_1}{V_o}\right) \quad (22)$$

where

V_o = Free volume of the building

V_1 = Volume of the protected equipment

P_o = Ambient pressure (14.7 psia or 1.013 bar absolute)

ΔP = Pressure rise in the building (in same units as P_o)

External Pressure Effects

When a deflagration is vented from an enclosure, pressure effects are created in the atmosphere external to the enclosure. These effects are due to the vented products and in the case of a dust explosion are the further effects of the combustion of the unburned dusts and the gases external to the enclosure. NFPA 68 allows the designer to calculate the maximum external pressure that will be seen when an explosion vent opens, where those pressure effects will be seen as a function of the distance from the vent opening, and the distance that the fireball travels from that vent opening.

NFPA 68 allows a designer to calculate the maximum external pressure effects as follows:

$$P_{\max,a} = 0.2 \times P_{red} \times A_v^{0.1} \times V^{0.18} \quad (23)$$

where

$P_{\max,a}$ = External pressure

A_v = Vent area (m^2)

V = Volume of the vented enclosure (m^3)

Once this is known, the designer can estimate the pressure at any point from the vent knowing the distance that the fireball will travel from the vent. The pressure at any point from the vent can be estimated from the following equation:

$$P_{\max,r} = P_{\max,a} \times \left(\frac{0.20D}{r}\right) \quad (24)$$

where

D = Axial distance traveled by the fire ball from the vent (m) (Equation 20)

$P_{\max,r}$ = Maximum external pressure

r = Distance from vent ≥ 0.2D (m)

SUMMARY

Explosion venting is a damage limiting protection technique. It is intended to protect an enclosure against damaging pressures generated by a deflagration within the enclosure by safely venting these pressures to a safe location. The chapter discusses the design techniques used to accomplish this objective.

Deflagration is the propagation of combustion zone from the ignition point at less than the speed of sound in the unreacted medium. Three conditions are necessary to initiate a deflagration: a fuel concentration between the upper and lower combustible limits, sufficient oxidant (usually air) to support combustion, and an ignition source of sufficient energy to ignite the combustible mixture (e.g. flammable gases, combustible dusts, or hybrid mixtures). An explosion (deflagration) vent is an opening in an enclosure through which material expands and flows, thus relieving pressure.

SECTION 19

Structural Fire Protection

Milosh T. Puchovsky

19.1 Types of Building Construction
19.2 Structural Integrity During Fire
19.3 Structural Fire Safety in One- and Two-Family Dwellings
19.4 Analyzing Structural Fire Damage
19.5 Approaches to Calculating Structural Fire Resistance

Fire can present a significant challenge to the structural integrity of buildings. Section 19 of the *Fire Protection Handbook*® provides information on protecting structural elements from fire. A new chapter in the section describes techniques for calculating structural fire resistance.

Chapter 1, "Types of Building Construction," identifies the basic types of building construction in terms of their anticipated performance during a fire. It also addresses fire protection of building elements; the value of exterior walls, interior walls, and partitions; floor framing systems; trusses; floor/ceiling assemblies; and roof framing and coverings.

The first part of Chapter 2, "Structural Integrity During Fire," describes common fire resistance test procedures. The chapter also introduces methods of calculating fire endurance (resistance) ratings, the behavior of building materials at elevated temperatures, and design approaches for structural integrity in a fire.

Chapter 3, "Structural Fire Safety in One- and Two-Family Dwellings," addresses the structural elements of one- and two-family dwellings and manufactured homes as they affect fire safety.

Chapter 4, "Analyzing Structural Fire Damage," reviews building types and structural systems before providing guidance on evaluating fire-damaged structures and specific materials. The chapter also considers fire during construction.

The section concludes with a new chapter: Chapter 5, "Approaches to Calculating Structural Fire Resistance." The chapter provides an overview of structural fire resistance calculation techniques and includes information on alternative approaches to fire resistance and selecting a design fire for structural analysis.

Milosh T. Puchovsky, P.E., is NFPA's assistant vice-president for codes and standards administration and is secretary to the NFPA Standards Council.

Key Terms

building construction (types of), combustible construction, construction (Type I), construction (Type II), construction (Type III), construction (Type IV), construction (Type V), fire-resistive construction, floor framing system, heavy timber construction, noncombustible construction, ordinary construction, roof, structural element, truss, wood frame construction

A well-established means of codifying the performance of a building's structural elements during a fire is to classify them by types of construction, based on the materials used for the structural elements and the degree of fire resistance afforded by each element.

In early codes, only two classifications of construction were identified: fireproof and nonfireproof. The term *fireproof* was replaced by the term *fire resistive,* because it was recognized that no material or building is totally fireproof and that the building contents can produce a significant fire without involving the structure. It is possible, however, to design buildings that will resist a fire without suffering serious structural damage. Appropriate fire-resistive design, balanced against anticipated fire severity, is the objective of structural fire protection requirements in modern codes.

Several distinct types of construction that use combustible framing were originally classified based on the materials—masonry or wood—used in the exterior wall construction and the type and size of the framing members (i.e., heavy timber versus conventional framing). As fire resistance ratings for construction assemblies were recognized in building codes, subclassifications of building types were added for both noncombustible and combustible types of construction, based on the degree of fire resistance provided.

Code regulations governing the size, area, and height of buildings and their allowable uses are usually predicated on the relative fire load and other factors represented by the occupancy and the construction materials used in the building.

This chapter identifies the basic types of building construction in terms of their anticipated performance during a fire. These construction types are recognized in NFPA 220, *Standard on Types of Building Construction,* and in the model building codes. It also recognizes the current classification system of building construction equated with the traditional descriptive terms used to identify building types (e.g., *fire resistive, noncombustible, ordinary, frame,* etc.) that no longer are prime references to construction types. It also addresses fire protection of building elements; the value of exterior walls, interior walls, and partitions; floor framing systems; trusses; floor/ceiling assemblies; and roof framing and coverings.

For related topics, see the following: Section 1, Chapter 2, "Fundamentals of Structurally Safe Building Design"; Section 12, Chapter 1, "Planning for Public Fire-Rescue Protection"; Section 18, Chapter 1, "Confinement of Fire in Buildings"; Section 19, Chapter 2, "Structural Integrity During Fire"; and Section 19, Chapter 4, "Analyzing Structural Fire Damage."

CONSTRUCTION CLASSIFICATIONS

U.S. Classifications

The construction types currently identified by NFPA and the International Code Council (ICC) fall into ten subtypes in the NFPA system and nine subtypes in the ICC system. Subtypes are derived from

Peter J. Gore Willse, P.E., is the director of research at Global Asset Protection Services, Avon, Connecticut. He chairs the Technical Committee on Structures, Construction, and Materials and is a member of the Technical Committee on Building Construction.

five fundamental construction types, in almost every case: (1) fire resistive, (2) noncombustible, (3) ordinary (exterior protected), (4) heavy timber, and (5) wood frame. The previously published Standard Building Code (SBC) used six construction types. These descriptive names, while still referenced, no longer define the construction types as precisely as needed. The names are helpful, however, in tracing the development of building types.

ICC was formed by Building Officials and Code Administrators (BOCA), International Congress of Building Officials (ICBO), and Southern Building Code Congress International (SBCCI). The 2000 ICC International Building Code (IBC) was meant to succeed the building codes of these organizations. However, earlier editions of their building codes are still being adopted in some places—for example, California. Drawing on its experience with addressing structural fire protection, NFPA has also developed a building code as documented in NFPA 220 and NFPA *101®*, *Life Safety Code®*.

Classification Notation

To achieve better uniformity of building construction classifications, the Model Codes Standardization Council (MCSC) established a committee in 1972 to study the classifications and fire resistance requirements for the types of construction used in the model building codes and to develop recommendations for the model building code organizations.

As a result of the MCSC comparative study, its successor, the Board for the Coordination of the Model Codes (BCMC) proposed that the basic types of construction now recognized in the codes be continued but that they be reordered to some degree and be divided into two groups: (1) noncombustible and (2) combustible. It was also proposed that the identifying names for types of construction, such as *fireproof, ordinary, heavy timber,* and so on, be dropped because current design methods and architecture no longer follow the concepts in use when the named building types were established. The classifications proposed are shown in Table 19.1.1. These are the classifications recognized in NFPA 220 and *NFPA 5000®*, *Building Construction and Safety Code®*.

The MCSC also concluded that to rationally compare the various types of construction, a notational system was needed to identify the fire resistance required for three basic elements of the building. These elements are: (1) the exterior wall, (2) the primary structural frame, and (3) the floor construction. A three-digit notation was developed, as follows:

1. *First digit*. Hourly fire resistance requirement for exterior-bearing wall fronting on a street or lot line
2. *Second digit*. Hourly fire resistance requirement for structural frame or columns and girders supporting loads from more than one floor
3. *Third digit*. Hourly fire resistance requirement for floor construction

A comparison of types of construction, based on the MCSC notational system, as found in five building codes, is shown in Table 19.1.2.

For heavy timber construction, the notation *H* and not a digit was used for the structural frame and floor construction designations. Heavy timber construction is unique because it is identified by detailed requirements relating mainly to the size of structural members and their connections. Properties such as combustibility or fire resistance are not specifically included in the requirements for heavy timber construction, except that exterior walls are required to be of noncombustible construction.

Thus, for example, a "332" building would have 3 hour fire-resistant exterior bearing walls, a 3 hour fire-resistant structural frame, and 2 hour fire-resistant floor construction, and would correspond to the *NFPA 5000* Type I (332) building, the BOCA National Building Code Type 1B building, the ICBO Uniform Building Code Type I FR (fire resistive) building, the SBCCI Standard Building Code Type II building, and the ICC International Building Code Type 1A.

A standard nomenclature was also developed for identifying and defining the structural elements in buildings as they relate to fire resistance. For example, it was found in reviewing various codes and fire protection standards that floor construction was referred to by such terms as "floors," "floor assemblies," "floor and ceiling assemblies," and "floor deck construction." If codes agree, for example, that "floor construction" includes the floor deck and all structural elements directly supporting the loads from the floor, as recommended by MCSC, then some misinterpretation of a code's intent would be avoided.

International Perspective

With regard to building construction in Australia, Belgium, Canada, Denmark, Finland, France, Germany, Great Britain, Italy, Japan, Netherlands, New Zealand, Norway, Russia, Sweden, Switzerland, and the United States, time temperature curves used to conduct fire resistance tests for building materials are virtually identical for the first 2 hours. After that period of time, most countries use a slightly similar curve, except for Japan, which uses a less severe exposure after 2 hours. Some countries limit heat transmission as a requirement for fire doors. In most cases this is not a requirement in the United States, and when it is a requirement, it is for only the first 30 minutes of the test. Two other building construction-related differences are that fire departments tend to be more aggressive in the United States than they are in most European countries and that there are many more unsprinklered properties outside the United States than there are within the United States.

Construction type classification in building codes is more of a convenience than a necessity. The National Building Code of Canada (NBCC) does not classify buildings in the traditional manner as do United States codes but rather specifies fire-resistive requirements for the structural components of a building, depending on its occupancy and its story height and floor area. In this code, two basic types of construction (i.e., combustible and noncombustible) are recognized. These are further subdivided by the characteristics of the materials used in construction under fire conditions.

CLASSIFICATION OF BUILDING CONSTRUCTION TYPES

Following the completion of the MCSC recommendations in 1974, a number of changes were adopted to the requirements for types of construction to agree with the MCSC classifications. However, it was recognized that some conflicts still remained among building codes. In 1975, the BCMC established a committee to develop more detailed recommendations for types of construction.

In 1980 the committee's recommended definitions of types of construction and fire resistance requirements were finalized. The requirements are based on five basic types of construction. Two are identified as noncombustible construction (Types I and II) and three as combustible construction types (Types III, IV, and V). Table 19.1.3 gives the fire resistance requirements for the structural frame, interior bearing walls, floor construction, and roof construction of the five basic types of construction. The table lists the building components that are essential to the stability of the building as a whole and comprise the "structural frame." The members of floor or roof panels that have no connection to the columns are considered part of the floor or roof construction and are not classified as a part of the structural frame.

Some of the terminology used to describe and classify building construction types is presented as follows:

- *Fire resistance rating.* The time, in minutes or hours, that materials or assemblies have withstood a fire exposure as determined by tests, or methods based on tests, as prescribed by the applicable building code. Applicable test methods include NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials,* ASTM E119, *Standard Test Methods for Fire Tests of Building Construction and Materials,* or UL 263, *Standard for Fire Tests of Building Construction and Materials.* Where other methods such as calculation procedures are used to determine fire resistance, the calculations are to be based on the fire exposure and acceptance criteria specified in standardized test procedures such as NFPA 251. Standardized calculation methods include ASCE/SFPE 29, *Standard Calculation Methods for Structural Fire Protection,* and ACI 216.1/TMS 0216.2, *Standard Method for Determining Fire Resistance of Concrete and Masonry Assemblies.* The referenced test methods and associated calculation methodologies are useful in comparing the fire resistance of building materials but are not necessarily indicative of how the building materials might perform in an actual building fire. See Section 19, Chapter 2, "Structural Integrity During Fire," for more information on how the fire performance of building materials is determined.
- *Noncombustible material.* A material that, in the form in which it is used and under the conditions anticipated, will not ignite, burn, support combustion, or release flammable vapors when subjected to fire or heat. Materials that are reported as passing ASTM E136, *Standard Test Method for Behavior of Materials in a Vertical Tube Furnace at 750 Degrees C,* shall be considered noncombustible materials.
- *Limited-combustible material.* Refers to a building construction material not complying with the definition of noncombustible material that, in the form in which it is used, has a potential heat value not exceeding 3500 Btu/lb (8141 kJ/kg) where tested in accordance with NFPA 259, *Standard Test Method for Potential Heat of Building Materials,* and includes either of the following: (1) materials having a structural base of noncombustible materials, with a surfacing not exceeding a thickness of 1/8 in. (3.2 mm) that has a flame spread index not greater than 50; and (2) materials, in the form and thickness used, having neither a flame spread index greater than 25 nor evidence of continued progressive combustion, and of such composition that surfaces that would be exposed by cutting through the material on any plane would have neither a flame spread index greater than 25 nor evidence of continued progressive combustion, when tested in accordance with NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials.* Materials subject to increases in combustibility or to a flame-spread index beyond the limits herein established through the effects of age, moisture, or other atmospheric conditions are considered combustible.
- *Combustible material.* A material that, in the form in which it is used and under the condition anticipated, will ignite and burn. It is further described as a material that does not meet the definition of noncombustible material or limited-combustible material.

Type I Construction

Type I construction (formerly referred to as fire resistive) is construction in which the structural members are noncombustible

TABLE 19.1.3 Fire Resistance Ratings for Type I Through Type V Construction (hr)

and have a fire resistance as specified in Table 19.1.3. This classification is divided into two subtypes, Type I (442) and Type I (332). Reductions in the hourly rating might be permitted by the applicable building code. The basic difference between the subtypes is in the level of fire resistance specified for the structural frame. The fire resistance requirements for Type I (442 and 332) construction were selected because they provide reasonable fire safety for the structure for occupancies with moderate- and low-combustible contents. In occupancies with higher fire loads and hazardous uses, fire resistance may be supplemented by additional protection, usually including an automatic fire-extinguishing system. Even in occupancies with moderate fire loads, such as in mercantile and in some factory industrial and storage uses, supplementary fire safety precautions are usually required. These include restrictions on the building size or requirements for automatic fire-extinguishing equipment.

In Type I construction, only noncombustible or limited-combustible materials are permitted for the structural elements of the building. This regulation is well accepted and appears in practically every modern building code. Obviously, if combustible structural materials were allowed in noncombustible building types, the whole concept of their allowable use (height and area) would become meaningless. However, for practical reasons, the use of some combustible materials in Type I and Type II buildings are permitted for other than structural components. Roof coverings, some types of insulating materials, and limited amounts of interior finish and flooring do not add significantly to the fire hazard or fire load if these materials are properly regulated and qualified by fire tests.

Some codes have attempted to regulate combustible materials by using two or three alternatives that allow for the acceptance of materials having relatively low fuel content and surface burning characteristics. The purpose of this definition was to recognize certain materials or nonhomogenous assemblies containing limited amounts of combustible materials, such as gypsum wallboard which, although covered with paper, is used as a fire-resistive material. These alternate definitions include limits on surface flame spread rating (per NFPA 255) and on the heat content (per NFPA 259)—the latter being 3500 Btu per lb (8050

J/kg) for limited-combustible material, somewhat less than half that of untreated wood.

Rather than complicate the definition for the accommodation of certain materials, a more fundamental approach is to define limited uses and combustibility characteristics of materials that may be acceptable in buildings of Type I construction. This approach was followed in the NBCC and by the BCMC committee in its recommendations for the allowable kinds and extent of use of combustible material in the construction of Type I and II buildings.

Type II Construction

Type II construction (formerly referred to as noncombustible construction) is a construction type in which the structural elements are entirely of noncombustible or limited-combustible materials. Type II construction can be further classified as protected—Type II (222) or Type I (111)—in which the structural members have some degree of fire resistance, either 2 hour or 1 hour, or unprotected—Type II (000)—in which the structural members have no fire resistance rating. An example of protected construction is structural steel with spray-on fire proofing applied. Applicable building codes typically include additional provisions for exterior structural bearing walls of Type II construction.

The fire resistance required in Type II (222 or 111) construction will afford adequate fire safety for residential, educational, institutional, business, and assembly occupancies, without supplementary restrictions. Height limits, however, are commonly prescribed for this type of construction. When used for other occupancies involving a greater fire loading, additional fire safety precautions are usually required, such as more stringent area limitations and automatic fire-extinguishing equipment. In occupancies with a low fire load attributed to contents, the absence of fuel in noncombustible construction not only helps prevent the spread of fire but also reduces potential risk of a fire starting within the structure itself.

The limitation on combustible material is valuable because it acts to prevent fire from spreading through concealed spaces or involving the structure itself. Because of this attribute, a fire in a building of Type I and Type II construction can be controlled more readily (Figure 19.1.1). Requirements for exterior walls of Type II construction are specified by the applicable building code or standard that is used by the authority having jurisdiction (AHJ).

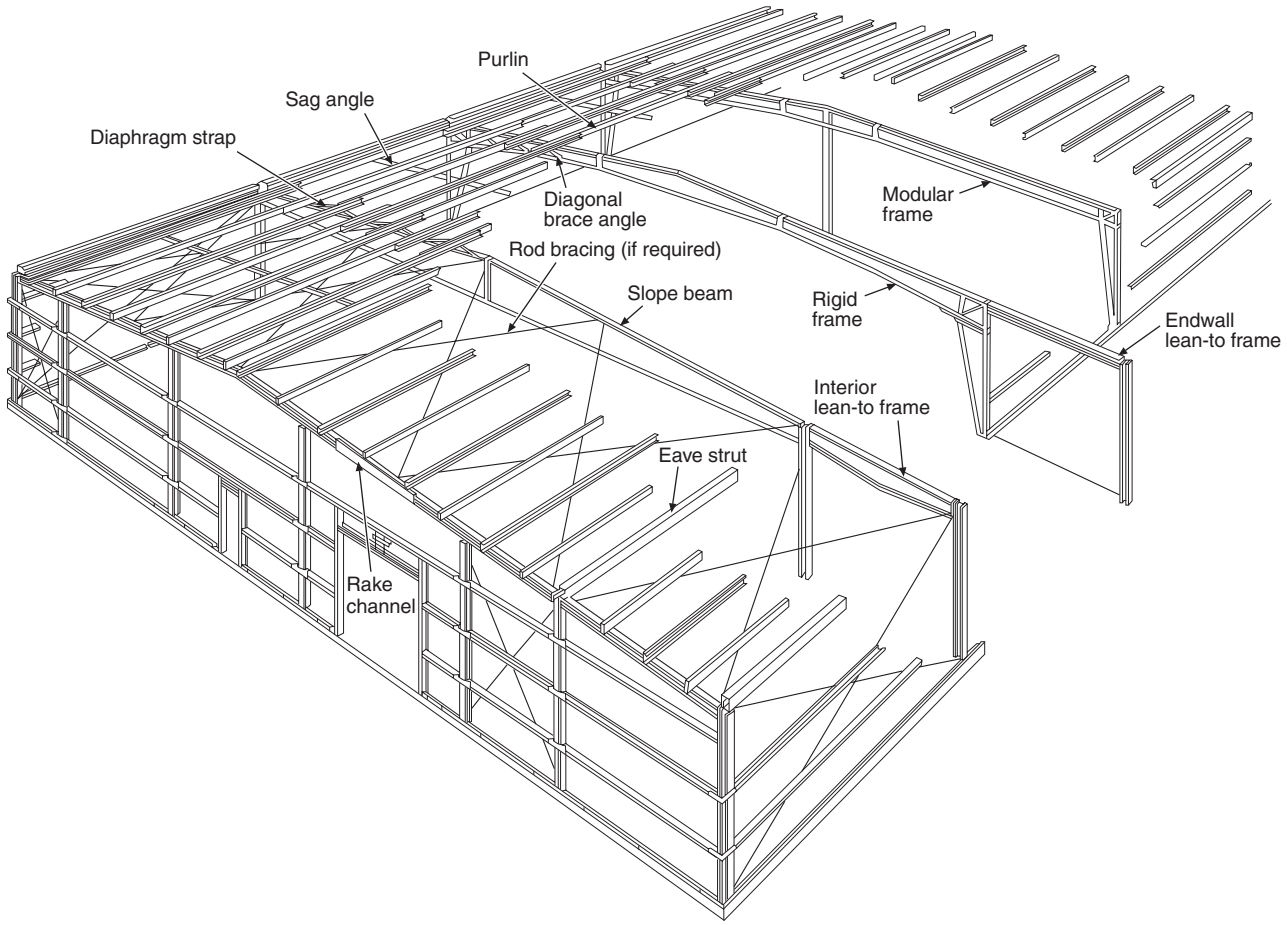

FIGURE 19.1.1 Framing System Representative of Type II (Noncombustible, Unprotected) Construction, Showing Preengineered Pitched Roof and Lean-To Framing with Structural Elements of Unprotected Steel

Type III Construction

Type III construction (formerly referred to as exterior protected or ordinary construction) is a construction type in which all or part of the interior structural elements may be of noncombustible, limited-combustible, or approved combustible materials as permitted by the applicable building code. The exterior walls are required to be of noncombustible or limited-noncombustible materials possessing a fire resistance rating in accordance with the applicable building code. Type III construction is further divided into protected and unprotected subtypes. Protected construction, Type III (211), has a 1 hour fire resistance for the floors and structural elements. Type III (200) construction has no fire resistance for the floors or structural elements. Whether or not fire resistance is provided, it is essential that all concealed spaces be properly fire blocked in buildings of combustible construction. This must be done with care in all furred spaces, partitions, ceiling spaces, and attics. Codes are very specific as to the materials used for fire blocking and the locations where it is required. To be effective, fire blocking must completely close off and subdivide the combustible construction into limited areas, thereby restricting the spread of fire and hot gases and allowing additional time for detection and evacuation of the building or area involved.

The 1 hour fire resistance provided in Type III (211) construction offers a measure of safety for fire fighting and evacuation before the construction itself becomes involved. However, combustible parts of any fire-rated assembly are likely to be burning actively before the end of the rated time period. For this reason, that portion of the fire load represented by combustible structural elements must be considered as part of the total potential fire load, whether or not the construction is protected.

Type IV Construction

Type IV construction (formerly referred to as heavy timber) is a construction type in which structural members—that is, columns, beams, arches, floors, and roofs—are basically of unprotected wood (solid or laminated) with large cross-sectional areas, with minor exceptions. No concealed spaces are permitted in the floors and roofs or other structural members. NFPA 220 and most model building codes are specific in the minimum dimensions permitted for the various wood structural members and minimum fire-resistive ratings required for interior columns, arches, beams, girders, and trusses of materials other than wood that may be permitted as acceptable alternatives to wood members (Table 19.1.4).

Walls, both interior and exterior, including structural members framed into them, can be of noncombustible or limited-combustible materials acceptable to the code being applied. Brick and stone were the traditional materials used in early heavy timber, or "mill," construction.

During a fire, heavy timber construction resists failure longer than a conventional wood frame structure because the structural members are larger, have a smaller surface to mass ratio, and take longer to burn. As the wood member burns, a layer of char develops, which acts like insulation and slows down the rate of burning. The large wood members, therefore, can continue to carry their structural loads due to the mass of unburned wood.

TABLE 19.1.4 Recommended Nominal Dimensional Requirements for BCMC Type IV (2HH) Construction

	Supporting Floors	*Supporting Roofs*
Columns	8 in. × 8 in.	6 in. × 8 in.
Beams and girders	6 in. × 10 in.	4 in. × 6 in.
Arches	8 in. × 8 in.	6 in. × 8 in., 6 in. × 6 in., 4 in. × 6 in.
Trusses	8 in. × 8 in.	4 in. × 6 in.
Floors	3 in. T & G or 4 in. on edge w/1-in. flooring	
Roofs		2 in. T & G or 3 in. on edge or 1⅛ in. plywood

Note: T & G = tongue and groove.
For SI units: 1 in. = 25.4 mm.

Heavy timber construction is more properly considered a building system, not just a construction type using large-size framing members. It was developed during the mid-1800s by insurance interests for the purpose of reducing fire losses in the many textile factories, paper mills, and storage buildings in the New England states. Through the intelligent use of combustible materials of sufficient mass, the absence of concealed spaces, and by paying attention to details to avoid sharp corners and ignitable projections, the chance of rapid spread of fire is lessened and the probability of serious structural damage is reduced. Examples of heavy timber construction are shown in Figures 19.1.2 and 19.1.3.

Type V Construction

Type V construction (formerly referred to as wood frame) is a type of construction in which the structural members are entirely of wood or any other material permitted by the code being applied (Figure 19.1.4). Depending on the exterior horizontal separation to adjacent buildings, the exterior walls may or may not be required to be fire resistive.

Type V construction is probably more vulnerable to fire, both internally and externally, than any other building type. Accordingly, it is essential that greater attention be given to the details of construction of this basically light wood-frame building. Fire blocking in exterior and interior walls at ceiling and floor levels, in furred spaces, and other concealed spaces can retard the spread of fire and hot gases in these vulnerable areas. Type V construction is subdivided into two subtypes: Type V (111) construction, which has 1 hour fire resistance throughout, including the exterior walls; and Type V (000) construction, which has no fire protection or fire resistance requirements, except for the exterior walls when horizontal separation is less than 10 ft (3 m).

FIGURE 19.1.2 Elements of a Building of Type IV (Heavy Timber) Construction. Note the large size of the columns and beams and the absence of concealed spaces. The exterior nonbearing wall at far left is of lightweight corrugated steel.

FIGURE 19.1.3 A Variation of Type IV (Heavy Timber) Construction with Haunched Arches of Laminated Wood (Glue-Laminated Construction) and Beams Anchored to Arches by Steel Hangers

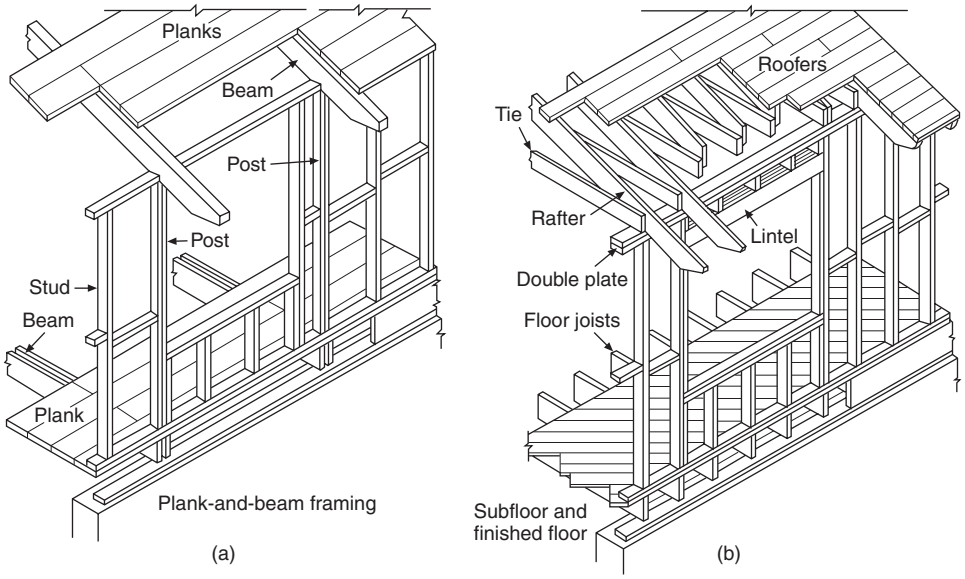

FIGURE 19.1.4 Two Variations on Basic Type V (Wood Frame) Construction: (a) Plank-and-Beam Framing in Which a Few Large Members Replace Many Small Members Used in Typical Wood Framing, (b) Conventional Wood Framing (Western or Platform Construction). Fire blocking is essential in concealed spaces.

Mixed Types of Construction

Where two or more types of construction are used in the same building, it is generally recognized that the requirements for occupancy or height and area would apply for the least fire-resistive type of construction. However, in cases where each building type is separated by adequate fire walls or area separation walls (see NFPA 221, *Standard for High Challenge Fire Walls, Fire Walls, and Fire Barrier Walls*) having appropriate fire resistance, each portion may be considered as a separate building.

Another general limitation included in some codes prohibits construction types of lesser fire resistance to support construction types having higher required fire resistance. In the event of a fire, the risks of a major structural collapse are generally too great to permit this type of design. This limitation does not necessarily apply where construction supports nonbearing separating partitions that provide protection for exit corridors or tenant spaces.

FIRE PROTECTION OF BUILDING ELEMENTS

Fire protection of structural elements is provided for two reasons: (1) to minimize the likelihood that the structural member will contribute to the fuel load, and (2) to ensure that the structural elements will maintain their integrity when exposed to fire. Loss of integrity of the building structure (total or partial collapse) will render fire-fighting measures less effective. Protection of other building elements, such as non-load-bearing interior walls, is also desired under certain conditions to mitigate the spread of fire within or into the building. See Section 19, Chapter 2, "Structural Integrity During Fire," for further discussion.

There are two groups of building elements: (1) load-bearing and (2) non-load-bearing. Load-bearing elements are those that support significant loads other than their own weight. Non-load-bearing elements support only limited loads in addition to their own weight. Removal of non-load-bearing elements would have no effect on the structural behavior of the building as a whole. Table 19.1.5 lists the structural elements that are common to most buildings, separated into these two general categories.

Building codes provide requirements for both structural loads and superimposed live loads. Structural failures are generally the result of application of unanticipated loadings. In a fire situation, "loads" are induced by heat which may cause thermal stresses. These stresses may be increased if the members are in any way restrained against expansion. Also, heat from fire may cause a loss of strength and increase in deflection, if not actual consumption of the member. Although restraint in some designs may offset any loss in strength, there is the increased likelihood of collapse in the event of a protracted fire. Properly designed and constructed assemblies having a fire resistance adequate for the exposure will retain adequate strength during fire exposure and continue to resist collapse.

Columns serve to carry building loads to the foundation where the loads are distributed to the supporting ground or rock. The material of the column is established by the type of construction—steel or reinforced concrete if noncombustible, or wood, including heavy timber designs, if combustible. In a fire, interior columns are the most severely exposed of any structural members, as they may be enveloped in fire on all sides.

TABLE 19.1.5 Structural Elements of a Building

Load-Bearing Elements	*Non-Load-Bearing Elements*
Compressively stressed columns	Curtain or panel walls
Walls, exterior or interior	Partitions
Flexurally stressed beams, girders, trusses, floors, roofs	Ceilings

WALLS

Building walls may serve one or more functions and they may be either bearing or nonbearing and exterior or interior. The following brief definitions describe the general functions that walls may serve:

Bearing wall: A wall that supports significant vertical loads in addition to its own weight

Cavity wall: A wall of two parallel wythes (vertical wall of bricks or concrete blocks) with an air space between them. The wythes are connected by metal ties.

Curtain wall: An exterior wall supported by the structural frame of the building. Also called a panel wall.

Exterior wall: A wall that forms a boundary to a building and is usually exposed to the weather

Faced wall: A wall composed of two different masonry materials: (1) the facing wythe and (2) the backup wythe, which are bonded together to act as a single unit

Fire partition or *fire barrier wall:* An interior wall that serves to restrict the spread of fire, but does not qualify as a fire wall

Fire wall: A wall of sufficient fire resistance, durability, and stability to withstand the effects of an uncontrolled fire exposure, which may result in collapse of the structural framework on either side. Openings in the wall, if allowed, must be protected.

Hollow wall: A wall of two parallel wythes, with an air space between them, but without ties to hold the wythes together

Nonbearing wall: A wall that supports only limited loads in addition to its own weight

Parapet wall: A portion of an exterior, fire, or party wall that penetrates through and extends above the roof line

Partition: An interior wall, not more than one story in height, that separates two areas in the same building but is not intended to serve as a fire barrier

Party wall: A wall that lies on a common lot line for two buildings and is common to both buildings. These walls may be constructed with a wide range of materials or assemblies.

Sandwich wall: A nonbearing wall whose outer faces enclose an insulating core material

Shaft wall: An interior wall that separates a vertical opening for a stairway, elevator, duct space, and so on, and connects two or more floors

EXTERIOR WALLS

The primary function of all exterior walls is to protect the inside of the building from the elements, such as heat and cold, water, wind, and windblown dust and dirt. In addition, some exterior walls may support floor and roof framing systems and may include portions that support girders or beams.

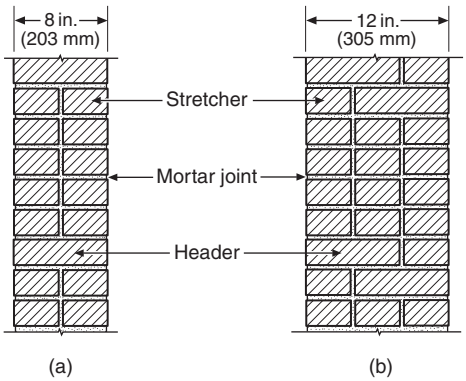

FIGURE 19.1.5 Typical Types of Wall and Partition Assemblies: (a) 8 in. (203 mm) Brick Bearing Wall, (b) 12 in. (305 mm) Brick Bearing Wall

The fire resistance required for exterior walls is determined not only by the type of construction but also by the distance the wall is set back from a lot line or an exposing structure. The greater that distance, the less severe the exposure and, hence, the less fire resistance that would be needed. NFPA 80A, *Recommended Practice for Protection of Buildings from Exterior Fire Exposures,* may be used to determine acceptable combinations of separation distance and exterior wall fire resistance or active protection.

Load-Bearing Exterior Walls

Load-bearing exterior walls are generally constructed of either masonry units (such as stone, brick, concrete block, or a combination of these materials) or concrete. Brick veneer is sometimes used as a facing in wood or metal-stud wall construction. In this case, the studs support the applied loads, while the veneer provides an attractive, useful exterior surface. Veneers are also used as the exterior face of cavity walls. Figures 19.1.5, 19.1.6, 19.1.7, 19.1.8, and 19.1.9 illustrate some common forms of exterior wall construction.

Exterior walls of reinforced concrete are poured-in-place, precast, or tilt-up type. Masonry veneers are sometimes used as the exposed surface of reinforced concrete walls. The brick veneer is tied to the concrete by metal ties fastened to the concrete and set into the mortar bed joints of the masonry. If the walls are load-bearing, the reinforced concrete is designed to support all of the applied loads.

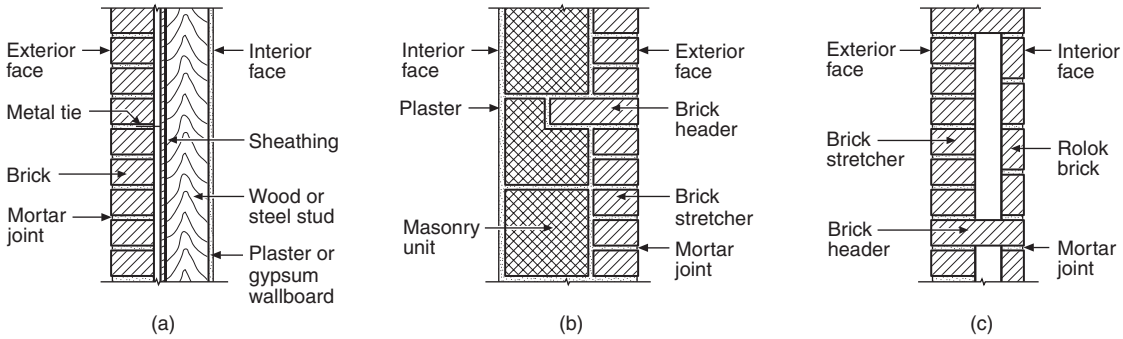

FIGURE 19.1.6 Typical Types of Wall Assemblies: (a) Exterior Brick Veneer on Wood-Frame Wall, (b) 12 in. (305 mm) Exterior Faced or Veneered Wall, (c) 8 in. (203 mm) Exterior Hollow Rolok Bak® Brick Wall

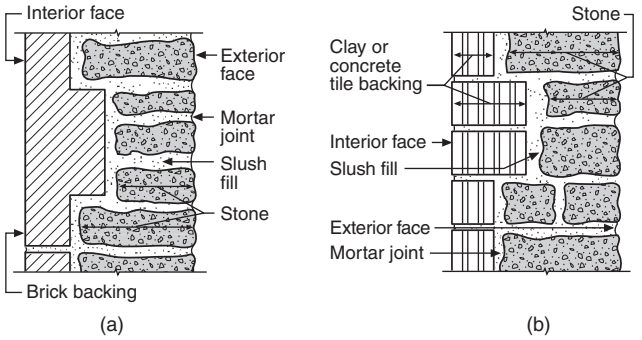

FIGURE 19.1.8 Stone-Faced Wall Assemblies: (a) with Brick Backing, (b) with Tile

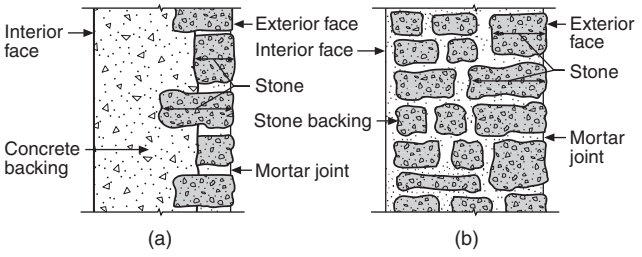

FIGURE 19.1.9 (a) Wall of Concrete Backing and Stone Face, (b) Solid Stone Wall

Exterior masonry walls may be non-load-bearing, that is, essentially supporting only their own weight. The floor and roof framing is supported by columns that transfer the loads to the foundation. Usually each story of the exterior wall is supported on spandrel beams, which frame into the columns. Some of the structural difficulties experienced with masonry walls in fires are illustrated in Figure 19.1.10.

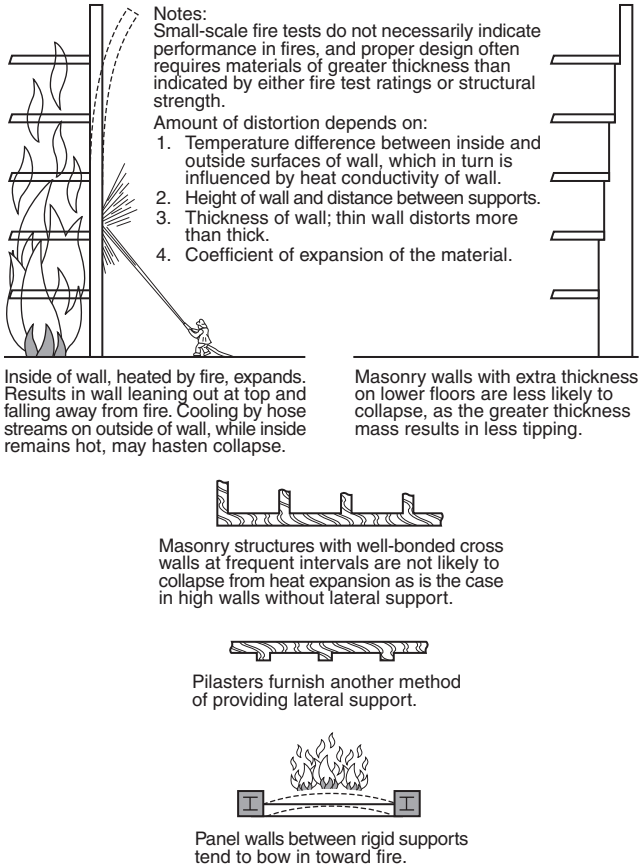

FIGURE 19.1.10 Heat Expansion Effects on Ordinary Masonry Walls

Openings in Exterior Walls

Openings such as doors and windows in masonry walls must have supports to carry the weight of the wall structure above the openings. These supports, called lintels, can be constructed of several materials, including steel shapes, precast concrete beams, and stone or brick arches. Figures 19.1.11 and 19.1.12 illustrate several types of lintels. Steel lintels used in fire-resistive walls should have a fire-protective covering, such as concrete, or a spray-applied cementitious or mineral coating to prevent failure of the lintel and wall section above the opening. Openings may need to be limited in size and number when the exterior wall is close to the lot line. Openings that are protected do not have fire resistance as such but can impede the spread of fire. See the section entitled "Protection of Openings" in Section 18, Chapter 1, "Confinement of Fire in Buildings."

Openings for which protection (windows, doors) does not have the insulating value as that of the fire barrier wall or fire wall may hamper egress, cause personal injury in a fire, or allow autoignition of combustibles located near the unexposed face of

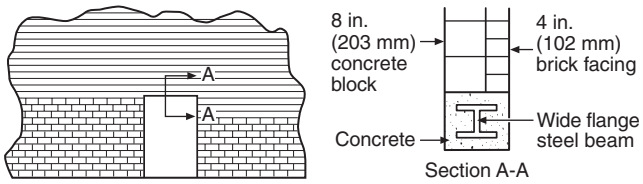

FIGURE 19.1.11 Lintels in Brick-Faced, Concrete Block Wall

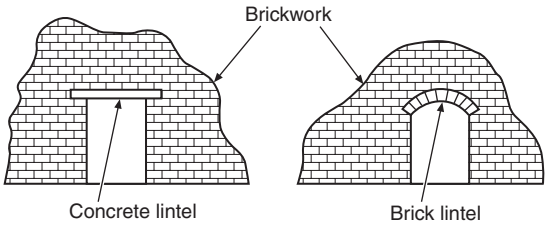

FIGURE 19.1.12 Use of Concrete and Brick Lintels in Masonry Walls

the opening. Maintaining a minimum separation distance (perpendicular to the face of the opening) equal to the maximum dimension of the opening will help prevent this.

Curtain Walls

Most multistory buildings consist of a protected steel or reinforced-concrete frame (columns, girders, and beams). The building envelope may be enclosed with nonbearing walls supported at each level. These walls are often identified as either curtain or panel walls. Many materials and types of construction are used for curtain walls. Aluminum and stainless steel curtain walls are, by far, the most common, but copper and copper alloys, carbon steel, galvanized metals, porcelain enamel finish, concrete, glass, and plastics are also used. Large window areas are common in this type of wall. Figure 19.1.13 shows an example of contemporary curtain wall construction.

A complete curtain wall assembly may consist of a panel with finished outside and inside surfaces, insulation, and means of attachment to the building frame. However, this type is not used as frequently as is a metal or glass skin assembly reinforced by conventional construction. Curtain walls are required to have fire resistance ratings up to 2 hours, depending on the separation distance between the wall and a lot line or exposing structure. Secure fastening of curtain walls is important for many reasons, including stability during fire exposure. Curtain walls are generally bolted to clips attached to the columns, spandrel, or floor slab. There is usually a space between the outer end of the floor slab and the inside face of the curtain wall. Unless adequately fire blocked, this space may act as a route for vertical fire spread for the entire height of a building.

Parapet Walls

A parapet wall is an extension of the wall construction above the roof line. The parapet on a fire wall helps to prevent a fire from spreading across the roof over the fire wall and can aid manual fire fighting. Where walls extend only a few inches above the roof, ignition of an adjoining roof is more likely to occur, depending on wind direction and velocity and the type of the roof covering. NFPA 220, *NFPA 5000,* GAP Guideline GAP 2.2.1, and FM Global Data Sheet 1-22,[1] for example, specify a parapet height of 30 in. (762 mm). Many building codes permit lesser heights, and in large sections of the country, 18 in. (457 mm) parapets are considered standard. The higher the parapet, the greater the degree of safety, but considerations of expense and appearance often dictate overall compromises.

Fire may also extend around the ends of fire walls where the exterior walls of the building on both sides of the fire wall are combustible. There are two methods of minimizing this danger: (1) extend the fire wall several feet out beyond the wall of the building or (2) provide blank fire-resistive exterior wall construction at each end of the wall (Figure 19.1.14 and Table

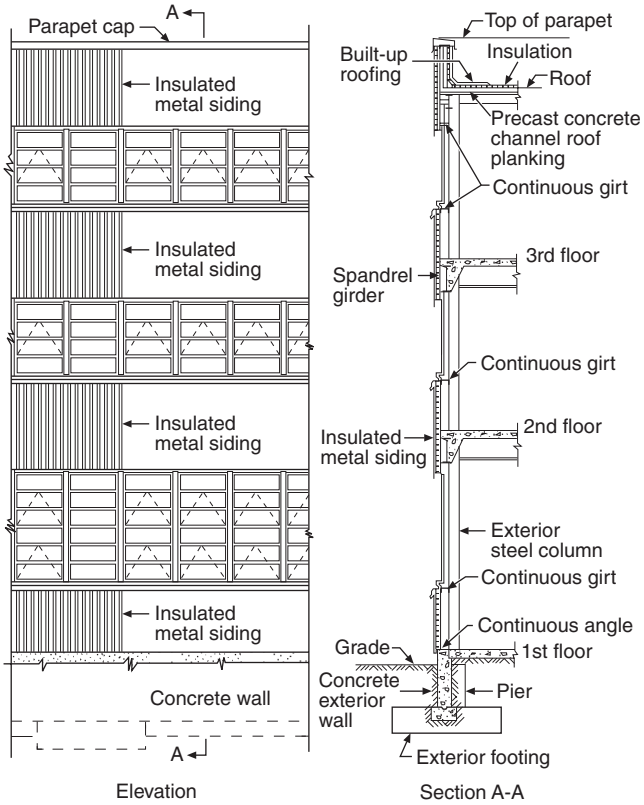

FIGURE 19.1.13 Elevation of Typical Bay of Steel Frame Curtain Wall Construction

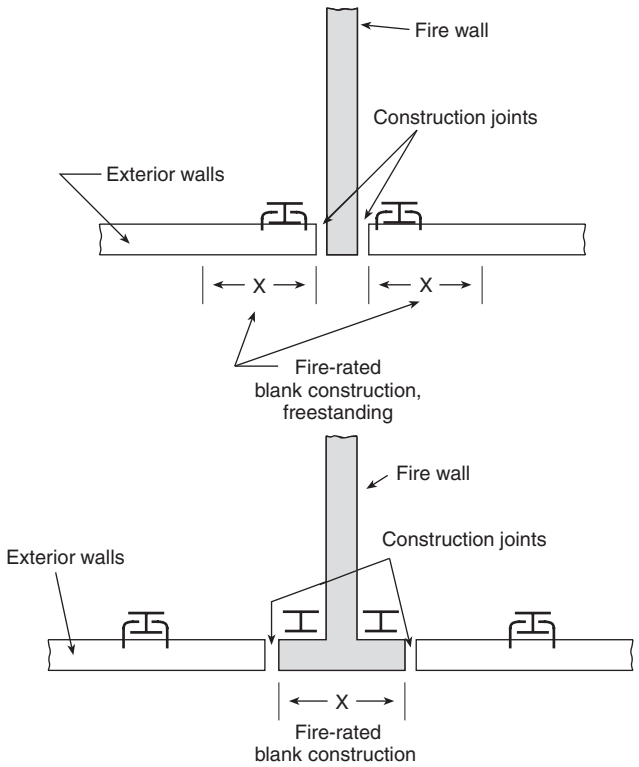

FIGURE 19.1.14 End Wall Exposure Protection: (a) End Walls Tied to Structural Framing, (b) End Walls Not Tied to Structural Framing (see Table 19.1.6)

19.1.6). The fire resistance rating of the end walls should be from the outside and should be a minimum of 1 hour but not more than 2 hours less than that of the fire wall. Where combustible roofs or cornices project beyond the walls of the building, fire walls should be extended to form a break in such combustible construction, as shown in Figure 19.1.15. Otherwise effective fire walls have failed because wood platforms or projecting canopies along the sides of buildings have spread fire from one fire area to another.

INTERIOR WALLS AND PARTITIONS

Interior walls and partitions used for building corridors or rooms may be either bearing or nonbearing. Bearing partitions are common in the older, wall-bearing construction systems and are also employed with industrialized building systems, particularly those of precast concrete. Newer construction tends to use nonbearing partitions.

The need for open space flexibility in modern construction has led to floor and interior partition design that allows nonbearing partitions to be installed at any location. These moveable partitions are often made of steel studs and gypsum board, and they may be installed, then dismantled and reinstalled at another location when occupancy needs change. Normally, moveable partitions extend only from the floor to the underside of the ceiling.

Interior partitions, particularly non-load-bearing partitions, can be installed with a number of other different materials. Wood stud and gypsum board or plaster is another very common type of partition. Partitions constructed of masonry units, such as concrete block, structural clay tile, terra cotta, and gypsum block are or have been commonly used in a wide variety of buildings and are more permanent. Figure 19.1.16 shows typical partition constructions.

Properly designed interior partitions can act as barriers to the spread of fire. To protect certain areas more completely than would be possible with ordinary partitions, wall assemblies possessing a fire resistance rating such as fire walls or fire barrier

TABLE 19.1.6 Length of End Wall Protection

71 (21.6) and over	14 (4.3)

*Protection should consist of blank, fire-rated construction.

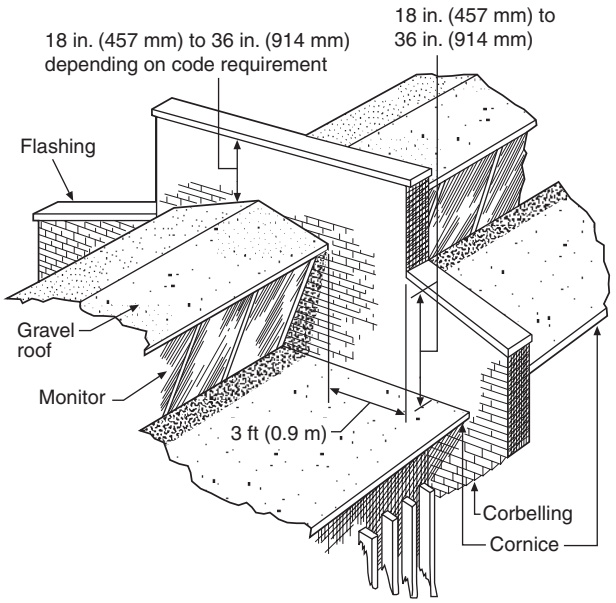

FIGURE 19.1.15 Fire Wall Installation on Building with Combustible Roof and Monitor

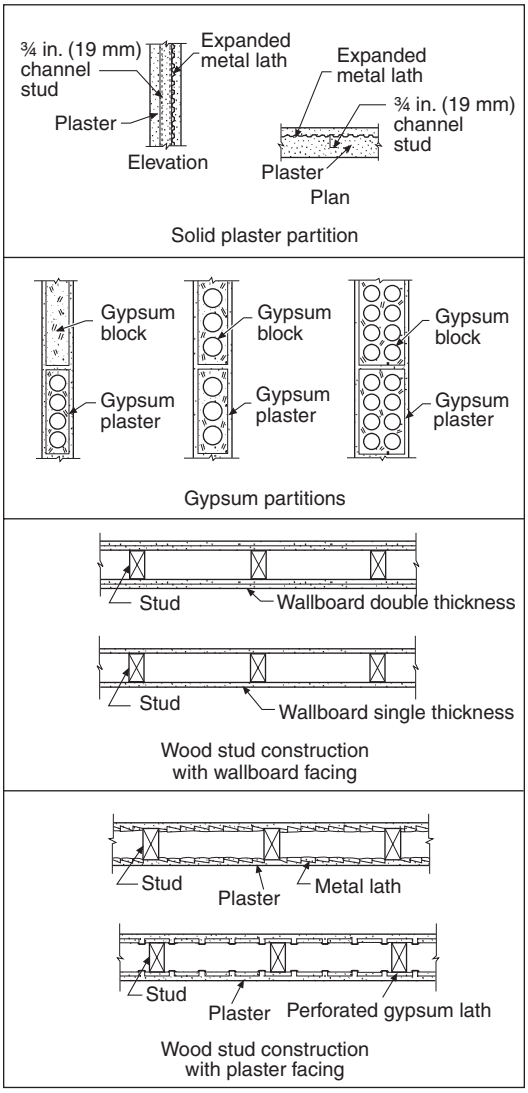

FIGURE 19.1.16 Typical Interior Wall and Partition Constructions

walls are constructed. Fire partitions may also be referred to as fire barrier walls; however, they are often incorrectly called fire walls.

Fire Walls and High Challenge Fire Walls

Fire walls and high challenge fire walls are interior walls providing a fire separation between areas of the same building. These walls are fire resistive, of noncombustible construction, often self-supporting, and cannot be readily modified to meet changing building needs. They are designed to maintain structural integrity, even in cases of complete collapse of the structure on either side of the fire wall. They are constructed of reinforced concrete, concrete block, prestressed concrete, and sometimes brick. Concrete or masonry walls generally require some type of steel reinforcement to withstand heat expansion effects. Adequate cover thickness of concrete must be provided over steel reinforcement. This is particularly important in the case of prestressed concrete walls. When designing prestressed concrete walls, refer to *Design for Fire Resistance of Precast Prestressed Concrete.*[2] Also, they may be buttressed by pilasters if of considerable height or length. In fire-resistive buildings, structure-supported fire division walls may be used, provided the structure has equal or greater fire resistance than that of the wall. Requirements for fire walls can be found in NFPA 221 and *NFPA 5000.*

Fire Barrier Walls

Usually, a fire barrier wall (or fire partition) subdivides a floor or an area and is erected to extend from the floor to the underside of the floor or roof above. Fire partitions may be constructed of noncombustible, limited-combustible, or protected combustible materials, and should be attached to and supported by structural members having fire resistance at least equal to that of the partition. A fire barrier wall normally possesses somewhat less fire resistance than a fire wall and does not extend from the basement through the roof, as does a fire wall. The fire resistance ratings for such partitions range from a half hour to as much as 4 hours. Requirements for fire barrier walls are less involved than those for fire walls and are also contained in NFPA 221 and *NFPA 5000.*

FLOOR FRAMING SYSTEMS

Floor framing systems typically include not only the flooring assembly but also its supporting beams, girders, or trusses. Beams and girders are nearly always an integral part of the floor system, whereas trusses may serve other purposes (and, hence, are discussed separately). The range of different types of floor framing systems that include beams and girders and the variety of components that may be included in a given assembly is best portrayed through drawings. Figures 19.1.17 through 19.1.27 are typical of many designs that are currently used.

Types of Floor Systems

Steel and Reinforced-Concrete Floor Assemblies. Figures 19.1.17 and 19.1.18 are generalized framing plans for steel and reinforced-concrete floor assemblies. The steel beams shown in Figure 19.1.17 support the floor assembly and are, in turn, supported by girders. Interior girders support beams on both sides. Girders are often concealed within partitions where their depth is not apparent, and they can directly support the weight of partitions in the space above. The girders frame into steel columns. Figure 19.1.18 illustrates a slab beam girder column system cast

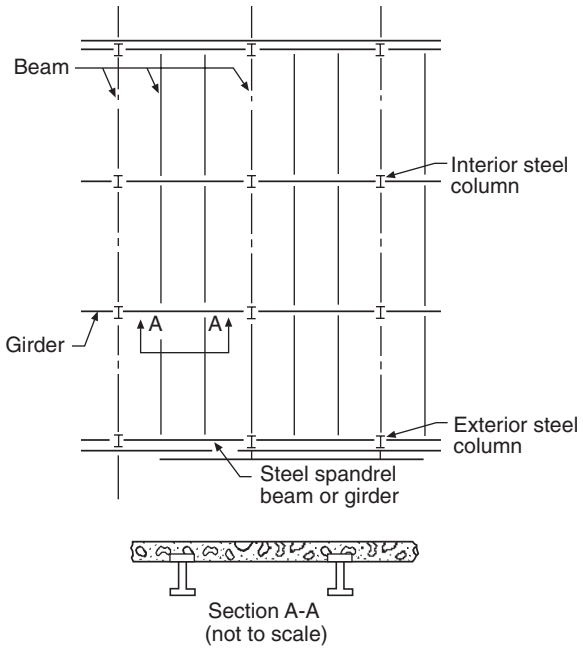

FIGURE 19.1.17 Portion of Floor Plan of Steel Frame Structure

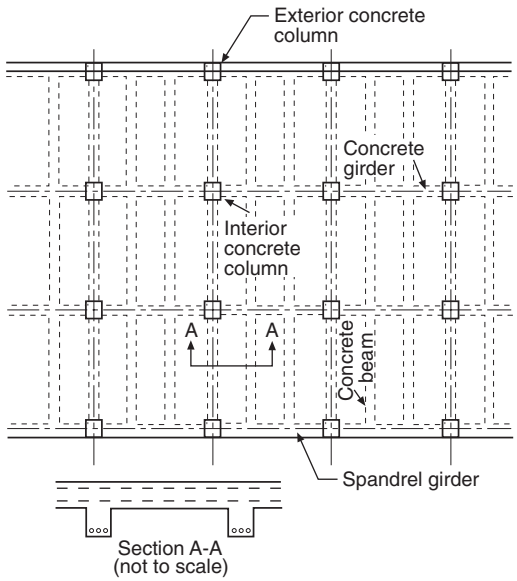

FIGURE 19.1.18 Portion of Floor Plan of Reinforced Concrete Beam and Girder Construction

monolithically (no joints) of reinforced concrete. The functions of the various components are the same as those described for the steel frame.

The floor slab supported by the steel beams shown in Figure 19.1.17 need not be of reinforced concrete. Alternative types of deck are the composite decks shown in Figures 19.1.19 and 19.1.20. This type of floor system offers many construction advantages. The metal deck acts as a form for the concrete and remains in place after curing. In addition, the cellular panels can be used for building service raceways where desired. The cellular panels can carry all three basic building services—power, telephone, and data transmission lines. A feature of this floor system is that the steel deck also acts as the tensile reinforcement of the concrete floor slab. A spray-applied fire-resistive coating on the steel deck underside may be required in some cases.

Another floor deck modification is to replace the reinforced-concrete floor slab with a precast concrete system. Figure 19.1.21 illustrates three common precast concrete floor slabs. The precast concrete planks generally have voids through their length that reduce the weight of the planks and act as building service raceways. The planks may be supported by either steel beams or reinforced concrete beams.

Open-web joists, which are lightweight prefabricated trusses, may replace steel beams as the intermediate flexural framing and are a very common type of construction both for floors and roofs. The spacing of floor joists is approximately 2 ft (0.61 m), and generally about 6 ft (1.8 m) for roof joists. Figure 19.1.22 illustrates this type of construction.

Because the spacing of the joists is so close, the floor slab can be thinner and still support the same load. Corrugated steel forms with 2½ in. (64 mm) of concrete as a wearing surface is a

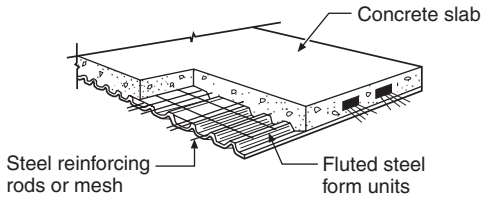

FIGURE 19.1.19 Concrete Floor Construction Showing Composite Floor Assembly

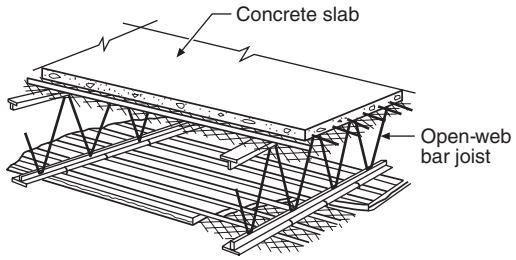

FIGURE 19.1.22 Concrete Floor Construction Showing Open-Web Steel Joist

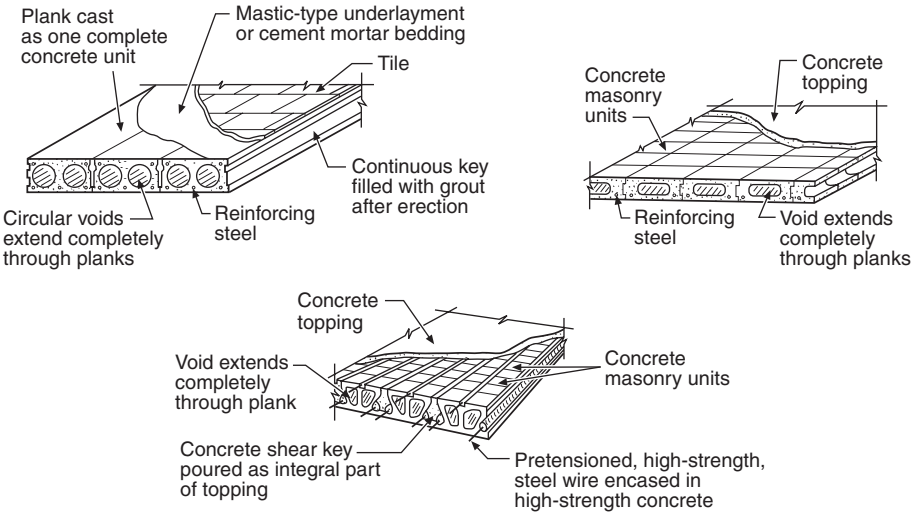

FIGURE 19.1.21 Three Precast Concrete Floor Slabs

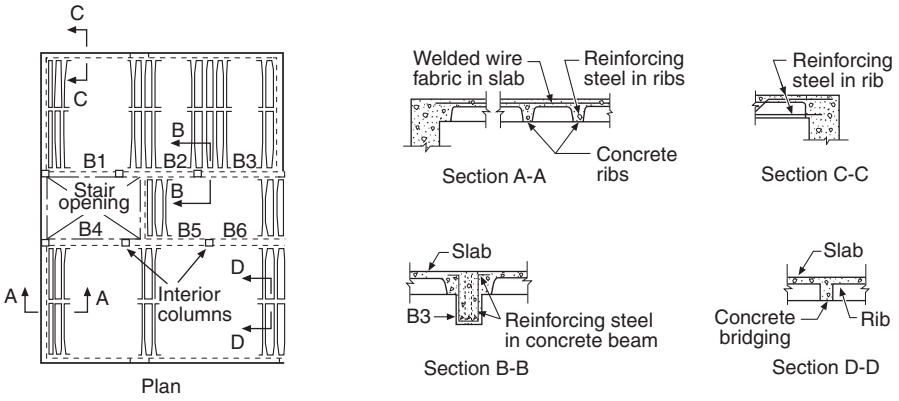

FIGURE 19.1.23 Partial Plan of a Concrete Joist Floor with Four Sectional Views

typical design. The corrugated deck acts as a form for the concrete and contributes to the support of live loads. Lightweight concrete is often used in place of normal-weight concrete to reduce the dead load.

Similarly, the reinforced concrete beams shown in Figure 19.1.18 may be spaced more closely together, permitting both a thinner floor slab and smaller beams. This type of construction is generally called a ribbed reinforced-concrete system or a concrete joist system. The ribbed system can be either cast in place or precast. Figure 19.1.23 illustrates the concrete joist floor, while Figure 19.1.24 illustrates two of the more common forms of ribbed precast systems. In each illustration, the ribs are the intermediate flexural framing.

The two-way flat slab is an increasingly popular floor system. Two-way reinforced-concrete slabs, used since the turn of the century, include reinforcement placed in two directions. The slab performs the functions of deck, intermediate flexural framing, and primary flexural framing. The underside of the slab may be either flat or ribbed in two directions. Figures 19.1.25 and 19.1.26 illustrate two different forms of this type of construction.

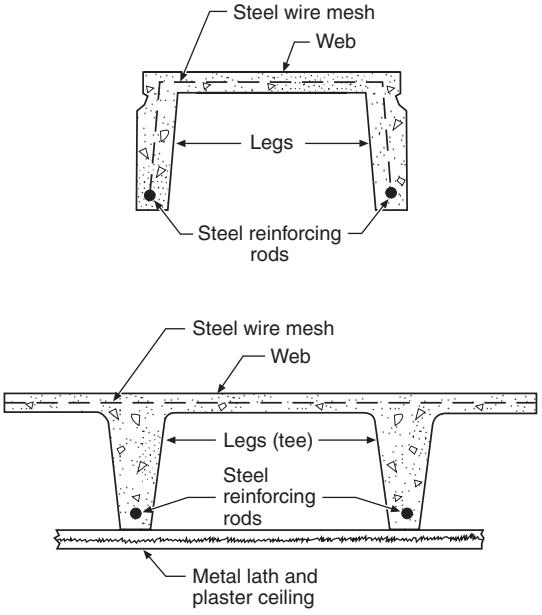

FIGURE 19.1.24 Sections Through Channel and Double-Tee Concrete Slabs. The slab at bottom shows a metal lath and plaster ceiling attached directly to the ribs of the slab. These slabs may be used as part of floor or roof framing systems.

Wood Floor Systems. Wood floor systems can be designed to perform the same functions as the basic model in Figure 19.1.17. If the reinforced-concrete deck were replaced with heavy wood planking 2 in. (51 mm) or more in thickness, and

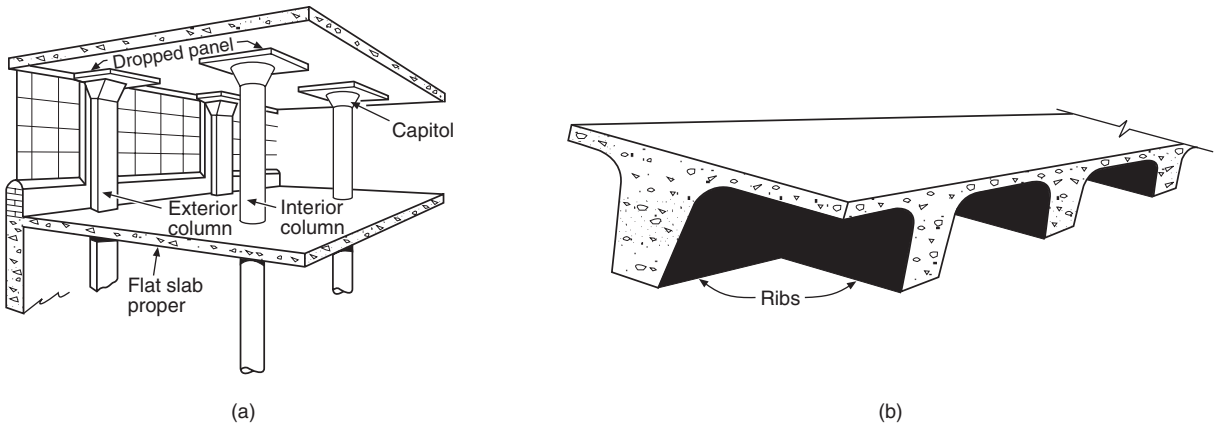

FIGURE 19.1.25 Two Types of Two-Way Flat Slabs: (a) Flat Underside, (b) Two-Way Ribbed Underside

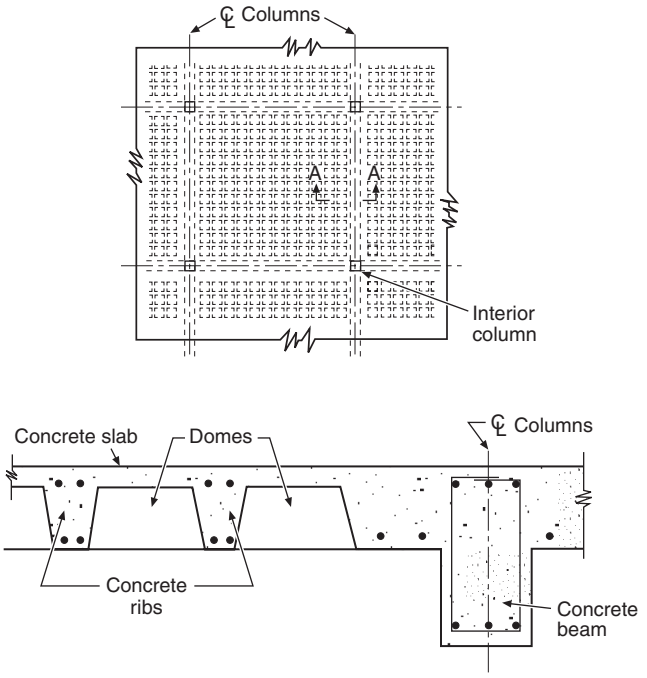

FIGURE 19.1.26 Partial Typical Interior Two-Way Ribbed Floor Slab with Section View A-A

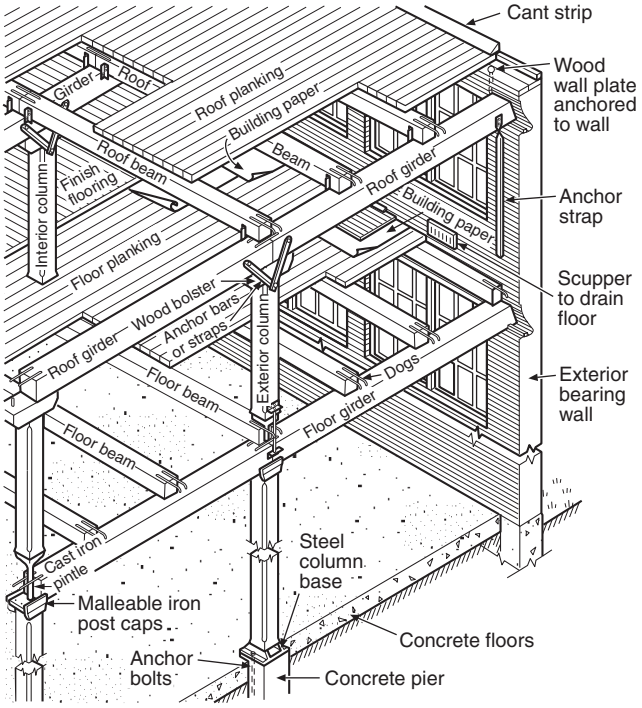

FIGURE 19.1.27 Components of a Heavy Timber Building Showing Floor Framing and Identifying Components of a Type Known as Semimill

the steel beams, girders, and columns with large wood members with a minimum dimension of 6 in. (152 mm), the basic form would be that of mill construction. This construction, shown in Figure 19.1.27, was quite common for industrial buildings and warehouses during the nineteenth century. The general design is still used in locations where wood has aesthetic appeal.

Lightweight, wood-frame construction is usually used in buildings of limited size. Floor joists in such construction are normally spaced 16 in. (406 mm) on center, and the vertical supports are often 2 in. by 4 in. (51 mm by 102 mm) or 2 in. by 6 in. (51 mm by 152 mm) wall-bearing studs, again spaced 16 in. (406 mm) on center. The stud walls may extend only from floor to floor in platform framing (Figure 19.1.28), or they may be extended continuously for two or three floors, a type of framing identified as balloon construction (Figure 19.1.29).

Wood-frame construction has little fire resistance because flames and hot gases can penetrate into the spaces between the joists or the studs. Fire blocking must be installed at critical locations throughout the building to prevent the rapid vertical and horizontal spread of fire. Fire blocks are normally made of wood blocks or noncombustible material. Figures 19.1.29 and 19.1.30 illustrate critical locations for fire blocking in balloon frame and in platform frame construction; Figure 19.1.31 shows the fire blocking for these constructions in greater detail.

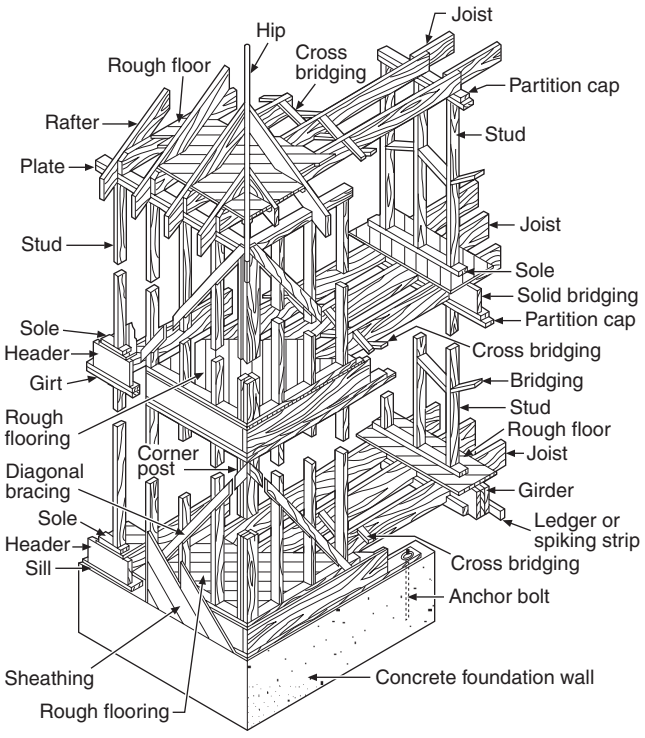

FIGURE 19.1.28 Wood-Frame Platform Construction Common to Dwellings with Structural Members Identified

Watertightness and Drainage of Floors

In addition to the effectiveness of floor framing systems as barriers to fire spread, there is another consideration involving floors in multistory buildings that can have a bearing on their performance in fires. This consideration is the degree of wa-

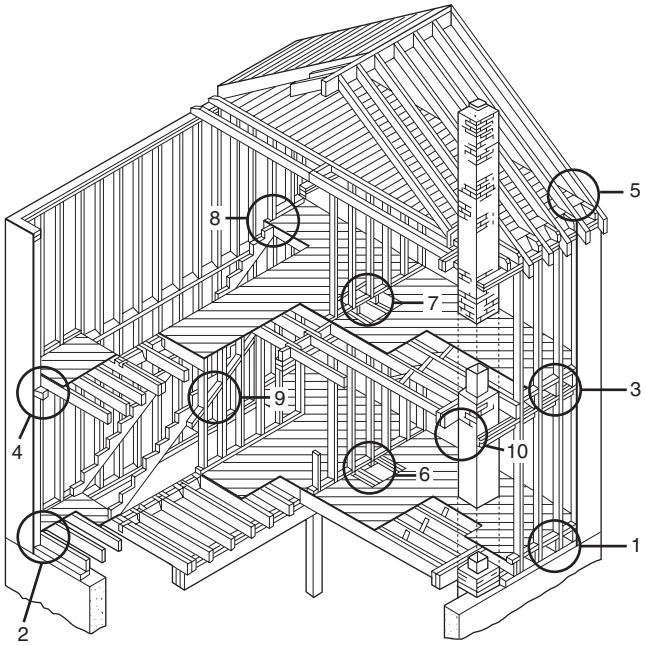

FIGURE 19.1.29 Wood Balloon Frame Construction Showing Points to Be Fire Blocked. Expanded views of points are shown in Figure 19.1.31.

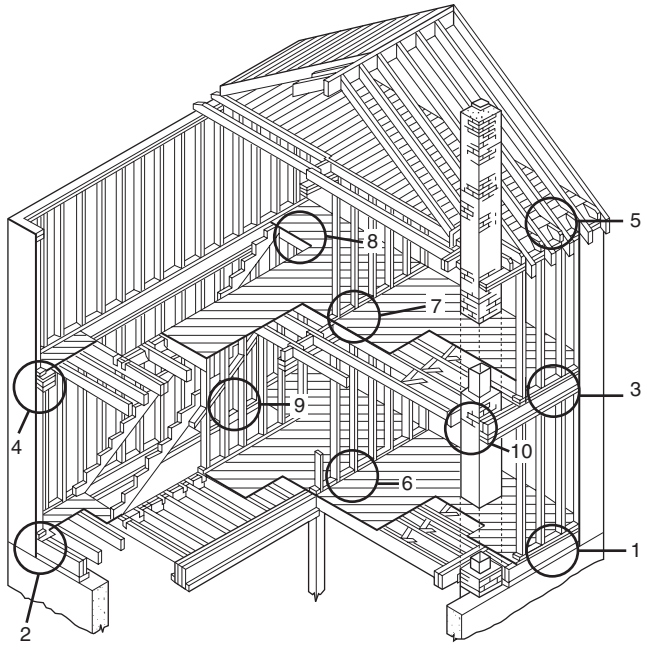

FIGURE 19.1.30 Wood Platform Frame Construction Showing Points to Be Fire Blocked. Expanded views of points are shown in Figure 19.1.31.

tertightness of construction and drainage arrangements for the floors. Massive quantities of water are sometimes needed on fires in unsprinklered buildings of combustible construction or buildings of noncombustible construction with significant occupancy fuel loads. Without good drainage and/or waterproofing arrangements, water could pose the threat of increased water damage on floors below.

TABLE 19.1.7 Sizes for Scuppers and Drains

Floor Areas	*Number of 4 in. (102 mm) Scuppers or Drains*
500 ft^2 (46 m^2) or less	2
750 ft^2 (70 m^2)	3
1000 ft^2 (93 m^2)	3

Note:
Additional scuppers for areas over 1000 ft^2 (93 m^2):
For Extra-Hazard Occupancies, Group 1 or 2 (quantity and combustibility of contents is very high), or floors of questionable watertightness, or contents especially subject to water damage—one scupper for each additional 500 ft^2 (46 m^2).
For Ordinary-Hazard Group 2 Occupancies (quantity and combustibility of contents is moderate) with watertight floors—one scupper for each additional 1000 ft^2 (93 m^2) or fraction thereof.
For Ordinary-Hazard Occupancies Group 1, or Light-Hazard Occupancies (quantity and combustibility of contents is low) with strictly watertight floors—one scupper for each additional 2000 ft^2 (186 m^2) or fraction thereof.

Where acceptable, one inexpensive method of drainage is to provide scuppers in the exterior walls. Floor drains connected to ample size headers or a combination of scuppers and floor drains may be used. The number of scuppers or drains is dependent upon the hazard and the amount of water likely to be used. For average conditions, the recommendations in Table 19.1.7[3] are considered good practice.

Waterproofing techniques, such as waterproof membranes, hot mastics, asphalt emulsions, cementitious surfacings, and so on, are available that can be applied to the floors depending on the basic type of floor construction in question. The intent of these applications is to provide a watertight barrier on the floor itself, which extends up 4 to 6 in. (100 to 150 mm) at walls and columns. Water impounded by these protective measures must be carried off before its weight becomes a loading threat to the building.

TRUSSES

Where large areas must be column free or where special occupancy requirements may warrant, trusses may be used for purposes other than roof support. Three such applications are identified as (1) transfer trusses, (2) staggered trusses, and (3) interstitial trusses.

Transfer Trusses

Load transfer trusses create a clear space on a lower floor by directly supporting the loads from columns above the truss or, at times, from tension members below. This design allows large, column-free areas for auditoriums, ballrooms, and so on, at any level in a multistory building. Since transfer trusses carry loads from more than two floors, building codes generally require that the fire protection be provided by individual protection for each of the truss elements, or by complete enclosure of the truss (for its entire height and length) with envelope protection.

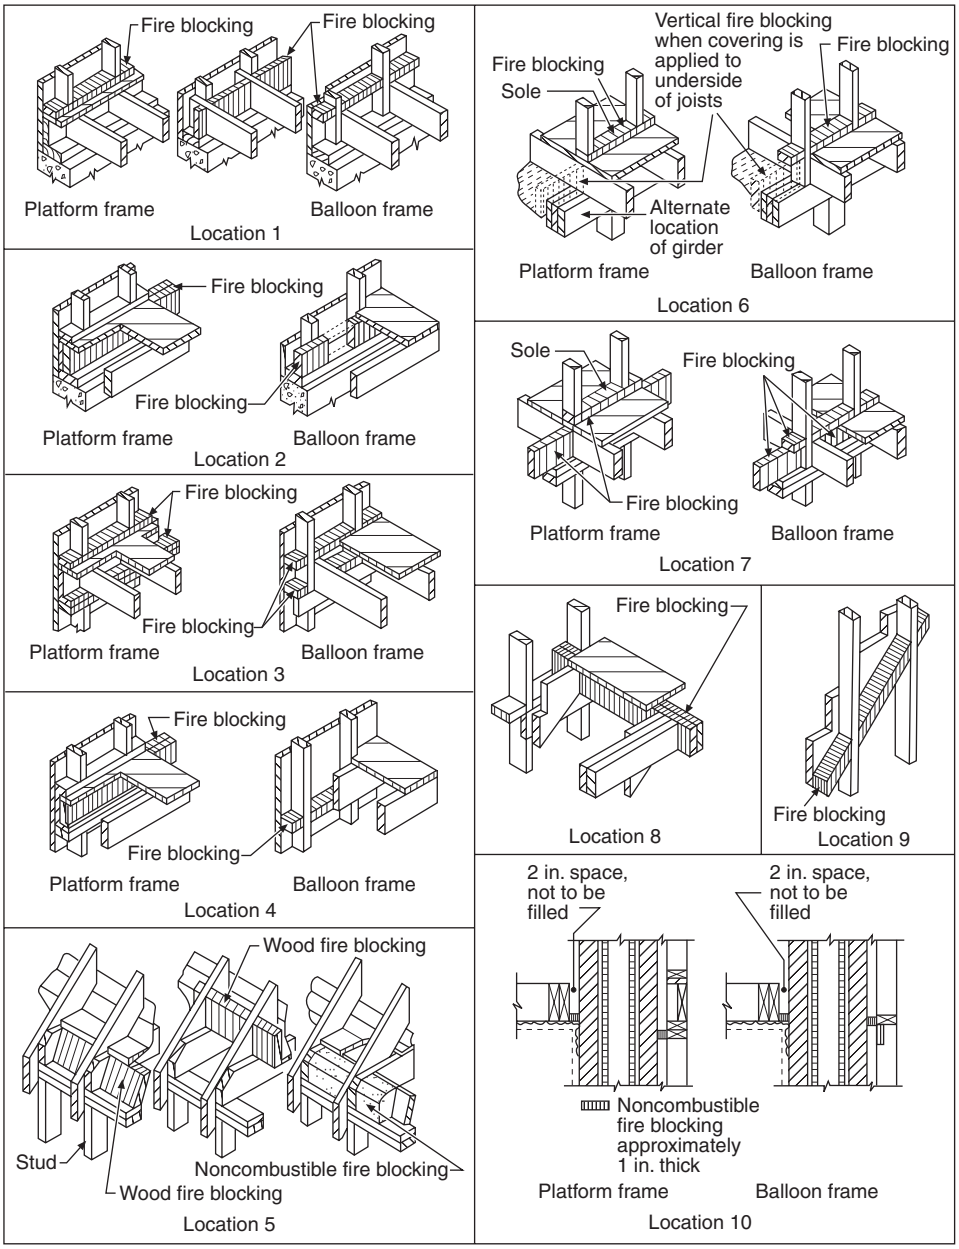

FIGURE 19.1.31 Details of the Application of Fire Blocking to Platform and Balloon Framing. Location numbers coincide with locations circled in Figures 19.1.29 and 19.1.30. For SI units: 1 in. = 25.4 mm.

Staggered Trusses

The staggered truss system is primarily intended for high-rise residential buildings. Typically, in a staggered truss design, story-high trusses span the full building width at alternate column lines on each floor. These trusses are supported only on the two rows of exterior columns. Thus, the interior of the building is column free; at any given elevation, floor construction is alternately supported on the top and bottom chords of adjacent trusses.

It is characteristic of staggered truss applications that these trusses are enclosed in wall construction that separates individual apartments or hotel/motel guest rooms. There may be a control opening in the truss that permits passage space for a corridor. Since staggered trusses are usually enclosed in walls, the entire wall assembly must have a fire resistance required for this condition.

Interstitial Trusses

The interstitial truss concept was first developed to solve the functional needs of hospitals. Although steel trusses in interstitial framing systems are quite deep (on the order of 8 ft [2.5 m]

in height), they do not extend from floor to floor as do staggered trusses. The top chords support the floor above, while the bottom chords support a suspended ceiling system and a walking surface for maintenance purposes. As such, interstitial trusses are analogous to very deep open-web steel joists.

The interstitial space thus created provides a convenient location for the complex mechanical and electrical systems that are necessary components of a modern hospital. Direct access for maintenance, renovation, and replacement of the various system components within these interfloor spaces is provided without significant interference with normal operations.

Because each interstitial truss supports only one floor, all three conventional fire protection methods for trusses are permitted by the model building codes. However, because of practical considerations, individual protection of each truss element or ceiling membrane protection are the methods most widely used.

FLOOR/CEILING ASSEMBLIES

Ceiling components are important elements in the performance of a fire-resistive floor/ceiling assembly. In the event of fire within a room, the ceiling acts as a barrier to protect the structural framing above it. The degree of protection, of course, depends on the type of material, its installation, and its completeness. Combustible ceilings or ceilings that do not remain in place when subjected to the pressures and temperatures of a fire do not provide a significant degree of protection. It is important to note that the membrane ceiling is one part of the floor/ceiling assembly. The entire assembly, acting together, provides the designated fire resistance. The ceiling itself has insufficient fire resistance.

Ceilings may be applied directly to or suspended from the underside of the floor framing. Figure 19.1.24 illustrates a ceiling connected directly to the floor framing system; Figure 19.1.20 shows a ceiling suspended from the floor slab. It is also common to apply a fire-protective material, such as a plaster or sprayed mixture, directly to the bottom surface of the floor slab. Figure 19.1.32 illustrates a floor slab with plaster applied directly to the steel floor deck.

There are several types of suspended membrane ceilings in common use. One type consists of a lay-in system in which the ceiling panels are supported by an exposed metal grid. Another common type of membrane has the metal grid concealed by recesses in the edges of the ceiling panels. Suspended membrane ceilings may also consist of traditional lath and plaster or permanently secured gypsum wallboard with finished joints. Both of these latter systems can be either suspended below or attached directly to the basic subflooring system.

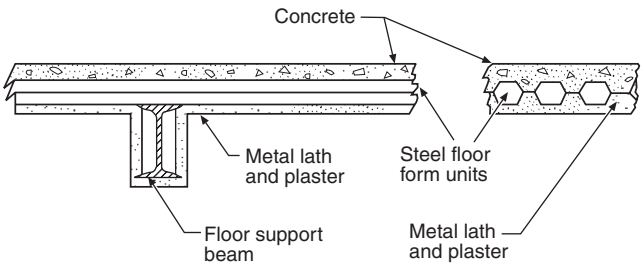

FIGURE 19.1.32 Plaster Applied Directly to Underside of Floor Slab Construction

In the variety of arrangements currently used, the space above the ceiling may be of combustible construction and may also contain other combustible materials, such as duct insulation, wire insulation, and vapor seals. Air-handling systems may use ducts or the void space itself (plenum) as a means of supplying, exhausting, or recirculating air, but associated materials must meet stringent requirements for combustibility and smoke evolution.

The material used for the membrane ceiling is important. Gypsum plaster and lath were a common construction of early membranes. Today special mineral tile formulations are generally used for acoustical panel systems that will not warp during fire exposure. The support framing is designed to accommodate thermal expansion with a minimum of distortion, so that the ceiling panels stay in place.

If lighting fixtures and duct openings are included in membrane ceilings that are part of fire-rated assemblies, they both must be of suitable design and properly spaced, and they often require shielding to reduce heat transmission into the ceiling space. Fire test performance is based on specific lighting fixtures and spacing, so indiscriminate substitution of lighting fixtures can cause premature failure. If air duct openings are installed in a membrane-type ceiling, they should be suitably protected or dampered, as determined by a fire test on the ceiling assembly that incorporates the air-handling components.

ROOF FRAMING

The design and construction of roof framing follow the general pattern for floor framing systems—both must support vertical loads and distribute these loads to walls or columns. Roof loads are usually smaller than floor loads. In addition, architectural considerations may demand longer spans than floor framing, and the shape of the roof need not be flat.

The roof deck and covering may be supported by steel or wood joists or by a truss where a longer span is needed. Roof trusses can be made to conform to any roof shape, whether flat, pitched, or curved.

Open-web steel or wood joists are often used in flat roof construction. An open-web joist is merely a lightweight, parallel chord truss. Open-web steel joists are typically used to support 1½-in. (38-mm) deep steel deck and are usually spaced about 6 ft (1.8 m) on center. This close spacing allows the roof deck to be designed to span between the joists. Figure 19.1.33 illustrates this type of roof framing.

In single-story buildings that require a large open space, rigid frames are sometimes used both as columns and roof supports. The portion spanning the roof is rigidly connected to columns on opposite sides of the building to form a single member. The frame itself may provide for a sloping roof. Figure 19.1.34 shows a rigid frame structure.

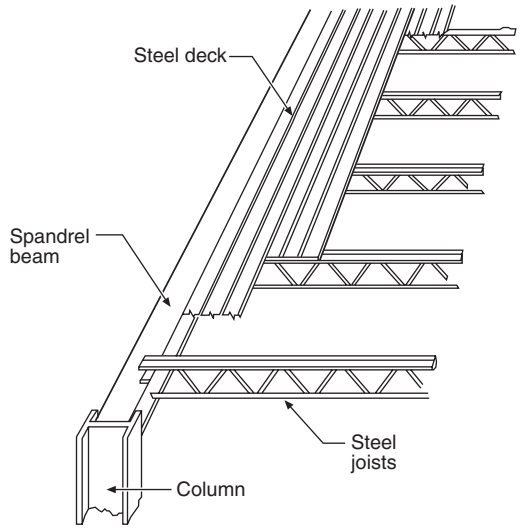

FIGURE 19.1.33 Long-Span Joist Framing

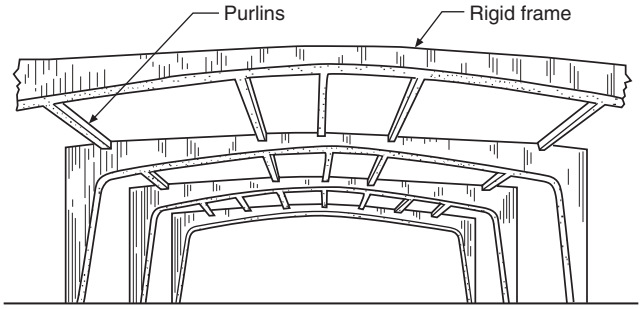

FIGURE 19.1.34 Rigid Frame

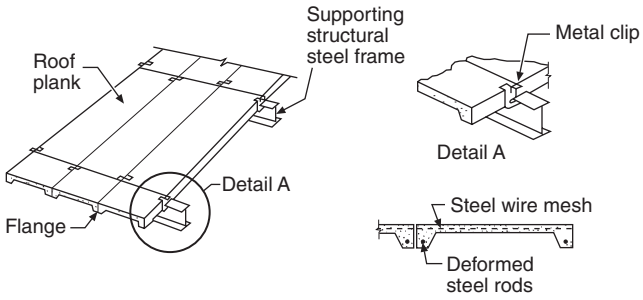
Flat slab and ribbed concrete slab systems may be used for roof construction in buildings in which that is the predominant type of framing. Other systems utilizing long-span prestressed concrete double-tee or channel sections are also common. These units serve both as support and as the deck (see Figure 19.1.24).

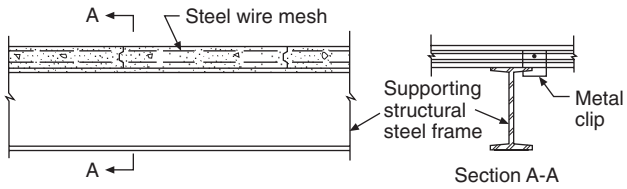
Roof decks may also consist of precast reinforced concrete planks fastened to the structural steel supports by galvanized metal clips, as shown in Figure 19.1.35. These planks are manufactured in three general shapes: (1) square edge, (2) channel slab, and (3) tongue and groove. To reduce weight they may be fabricated with aerated concrete using lightweight aggregates.

ROOF COVERINGS

In resistance to ignition and burning from exterior fire exposure, roof coverings range from combustible wood shingles with no fire-retardant treatment to built-up or prepared coverings that are effective against severe external fire exposure. Insofar as well-designed roof coverings can protect buildings from exposure fires, the likelihood of fire spread from one building to another can be reduced considerably.



Lightweight precast concrete channel roof plank



Lightweight tongue and groove concrete roof plank

FIGURE 19.1.35 Lightweight Precast Concrete Planks

Fire performance for any given roof assembly subjected to exterior fire exposure is not necessarily the same as that for interior fire exposure. The presence of pea stone gravel, large stone ballast, concrete paver blocks, or some coatings such as fibrated aluminum or asphalt emulsions on top of roof coverings can greatly enhance resistance to exterior fire exposure.

Fire-Retardant Roof Coverings

The test standard for roof coverings is NFPA 256, *Standard Methods of Fire Tests of Roof Coverings.* The three classes of roof coverings that rank resistance to exterior fire exposure are the following:

Class A Coverings. Class A coverings include roof coverings that are effective against severe fire exposures. These coverings are not readily flammable, do not carry or communicate fire, afford a fairly high degree of fire protection to the roof deck, do not slip from position, and possess no flying brand hazard.

Class B Coverings. Class B coverings include roof coverings that are effective against moderate fire exposures. These coverings are not readily flammable, do not readily carry or communicate fire, afford a moderate degree of fire protection to the roof deck, do not slip from position, and possess no flying brand hazard; however, they may require repairs to maintain their fire retardant properties.

Class C Coverings. Class C coverings include roof coverings that are effective against light fire exposure. These coverings are not readily flammable, afford at least a slight degree of fire protection to the roof decks, do not slip from position, and pos-

sess no flying brand hazard; however, they may require repairs or renewals to maintain their fire-retardant properties.

Building codes commonly require Class A or B coverings within the fire limits of cities or wherever fire-resistive construction is required. Class C roofing is appropriate for other buildings. Many cities specify Class C as the minimum standard for roofing. Fire testing laboratories classify metal deck roof assemblies by type of construction (Table 19.1.8).[4]

Built-Up and Prepared Coverings

Fire-retardant roof coverings fall within one of several groups. One is the built-up covering which, as the name implies, consists of several layers of materials applied or "built up" on the roof decks according to specifications. What is known as a "tar and gravel" roof is actually a built-up roof covering consisting of several layers of roofing felts and insulating panels or sheets bonded together by hot or cold cements and topped with roofing gravel (Figure 19.1.36).

Another group (prepared coverings) includes fire-retardant shingles and sheet coverings, which can be applied only to roof decks capable of receiving and retaining nails and which are sloped sufficiently to permit drainage (Figure 19.1.37). In some instances, however, the slope must not exceed a specified maximum in order to qualify for Class A, B, or C fire-retardant rating. Asphalt organic felt shingles (i.e., "composition" roofs) are a common example of prepared roof coverings and are frequently used on dwellings.

Prepared roof coverings also include such noncombustible coverings as brick, concrete, tile, and slate. Tables 19.1.8 and 19.1.9 list various types of prepared and built-up roof coverings, respectively, and their fire-retardant classifications. Any roof covering can be used for a less severe exposure than the one for which it is listed.

In addition to the built-up roof coverings described in Table 19.1.9, there are several other types consisting of organic felt, glass fiber, aluminum, steel, and tile applied in a special manner with special listed proprietary securements that are listed by testing laboratories. Single-ply membranes are a very popular type of roof covering. Exterior fire exposure ratings for these coverings are dependent on the type of material, whether it is fire retardant, the type of insulation directly below, and the presence of a coating or topping. Such classifications can be found in publications by fire testing laboratories.

Wood Shingles

Untreated wood shingles may be readily ignited by small sparks from chimneys or exposure fires, by radiated heat, or by burning brands. Burning shingles themselves also produce brands, which may be carried by the wind to start other fires. Age and humidity increase the susceptibility of wood-shingled roofs to ignition.

Treatment of wood shingles in place with fire-retardant coatings has not proved practical to date. Ordinary flame-resistant treatments lose their effectiveness with continued exposure to the weather. Wood shingles impregnated with a fire-retardant solution are more durable. Shingles of this type have been tested and carry a Class B or C rating.

Untreated wood shingle roofs are prohibited by law in the congested sections of practically all large cities, and a very large number of cities and towns prohibit their use altogether within municipal limits.

Metal roofing	12/unlimited	Sheet roofing of 16 oz copper or of 30 gauge steel or iron protected against corrosion—limited to noncombustible roof decks or noncombustible roof supports when no separate roof deck is provided	Sheet roofing of 16 oz copper or of 30 gauge steel or iron protected against corrosion or shingle-pattern roofings with underlay of one layer of Type 30 or two layers of Type 15 asphalt-saturated organic felt[b]	Sheet roofing of 16 oz copper or of 30 gauge steel or iron, protected against corrosion, or shingle-pattern roofings, either without underlay or with underlay of rosin-sized paper
	¼ (standing seam) or ½ (lap seam)/ unlimited	Standing or lap seam metal panel with glass fiber batts below on steel purling or joints		Zinc sheets or shingle roofings with an underlay of one layer of Type 30 or two layers of Type 15 asphalt-saturated organic felt[b]
Organic felt (previously referred to as *rag felt*) sheet coverings	¼/unlimited			Sheet coverings of asphalt organic felt either grit surfaced or aluminum surfaced
Organic felt (previously referred to as *rag felt*) shingle covering, with special coating	Sufficient to permit drainage[c]	Mineral surfaced, two or more thicknesses	Mineral surfaced, two or more thicknesses	
Organic felt (previously referred to as *rag felt*) shingle coverings	Sufficient to permit drainage[c]	Mineral surfaced, two or more thicknesses	Mineral surfaced, two or more thicknesses	Mineral surfaced shingles, one or more thicknesses

TABLE 19.1.8 Continued

Roof Covering[a]	*Minimum/ Maximum Roof Slope, in. per ft*	*Class A*	*Class B*	*Class C*
Asphalt glass fiber mat shingle coverings	Sufficient to permit drainage[c]	Mineral surfaced, two or more thicknesses	Mineral surfaced, one or more thicknesses	Mineral surfaced shingles, one or more thicknesses
Asphalt glass mat sheet covering	Sufficient to permit drainage[c]			Mineral surfaced
Fire-retardant treated red cedar wood shingles and shakes				Treated shingles or shakes, one or more thicknesses; shakes require at least one layer of Type 15 felt underlayment

Note: Roofing materials containing asbestos are no longer used in the United States; however, they may still be encountered in existing construction.

[a]Prepared roof coverings as classified as applied over square-edge wood sheathing of 1 in. nominal thickness, or the equivalent, unless otherwise specified. See footnotes (built-up roof coverings) to Table 19.1.9. Laid in accordance with instruction sheets accompanying package. Limited to decks capable of receiving and retaining nails. Prepared roofings are labeled by Underwriters' Laboratories to indicate the classification when applied in accordance with direction for application included in package.

[b]*End lap* means the overlapping length of the two units, one placed over the other. *Head lap* in shingle-type roofs is the distance a shingle in any course overlaps a shingle in the second course below it. However, with shingles laid by the Dutch-lap method, where no shingle overlaps a shingle in the second course below, the head lap is taken as the distance a shingle overlaps one in the next course below.

[c]Typically ¼ in. per ft.

For SI units: 1 in. = 25.4 mm; 1 ft = 0.305 m; 1 oz = 0.0284 kg; 1 lb = 0.454 kg.

ROOF DECK INSULATIONS AND VAPOR BARRIERS

Since the 1953 General Motors fire at Livonia, Michigan, major attention has been paid to the combustibility of insulated metal roof decks. In that fire, the asphalt mopping in the felt vapor barrier beneath the insulation on the 1,502,500 ft^2 (139,582 m^2) flat steel-deck roof melted and vaporized. Asphalt vapor under pressure entered the building through the joints in the steel deck and burned inside. As a result of this and similar fires, research was conducted to find a solution to the problem.

The combustibility of a roof was historically determined by the physical characteristics of the roof deck and its supporting structure, with no consideration given to the combustibility of the roof insulation and covering. Thus, combustible fiberboard insulation and asphalt-impregnated felt roof covering normally were not considered to affect the classification of a noncombustible roof deck on noncombustible supports. Large-scale fire tests, confirmed by actual fire experience, however, have shown that under certain conditions some metal deck assemblies can contribute to an interior fire.[4]

A series of full-scale tests was conducted in 1955 at Factory Mutual Research (FMR) testing facilities to compare the performance of various metal roof deck constructions with respect to fire propagation along the underside of the deck. The tests were run in cooperation with the Metal Roof Deck Technical Institute (now Steel Deck Institute) and the Insulation Board Institute, and the results were published in a technical report.[5] With the insulation or vapor barriers adhered to the metal deck with complete moppings of asphalt, it was shown that the asphalt contributed a significant amount of fuel when exposed to the heat of an intensive interior fire below the deck (Figure 19.1.38). The asphalt was vaporized by the heat of the fire below and, unable to escape upward through the roof covering, was forced down through the joints in the deck, when it ignited and contributed to the spread of fire under the roof deck. This type of assembly is called combustible or a Class 2 steel deck. Because of poor wind-loss experience, FM Global no longer recommends using adhesives to secure above-deck components to steel decks. However, other combinations of combustible above-deck components (such as vapor barriers, insulation, and roof covers) may create a Class 2 steel-deck assembly.

Recognized fire testing laboratories now list metal roof deck construction and components that will not contribute significantly to an interior fire and that meet certain performance standards. Such assemblies are called noncombustible, fire-classified, or Class 1 steel decks.

Metal roof deck constructions use both combustible and noncombustible insulation fastened with mechanical fasteners to the upper surface of the deck. Prior to the early 1980s, asphalt was accepted as an adhesive to secure certain insulation to steel decks if it was applied in strips (with a mechanical applicator), and if the total amount used between the deck and the insulation did not exceed 12 to 15 lb per 100 ft^2 (5.4 to 6.8 kg/9.3 m^2) of roof area.

There is no restriction on the use of asphalt in conventional built-up roofing used above the insulation. When a vapor

TABLE 19.1.9 Built-Up Roof Coverings

*Roof Covering**	*Minimum/ Maximum Roof Slope, in. per ft*	*Class A*	*Class B*	*Class C*
Asphalt organic felt, bonded with asphalt and surfaced with 400 lb of roofing gravel or crushed stone, or 300 lb of crushed slag per 100 ft^2 of roof surface, on coating of hot mopping asphalt	¼/2	4 (plain) or 5 (perforated) layers of Type 15 felt 1 layer of Type 30 felt and 2 layers of Type 15 felt 1 layer of Type 15 felt and 2 layers of Type 15 or 30 cap or base sheets 3 layers of Type 15 or 30 cap or base sheets 3 layers of Type 15 felt—limited to noncombustible decks	4 layers of perforated Type 15 felt 3 layers of Type 15 felt 2 layers of Type 15 or 30 cap or base sheets

Steep tar organic felt	¼/2	4 layers of Type 15 tar-saturated organic felt, bonded with steep coal-tar pitch, surfaced with 275 lb of ⅝ in. crushed slag per 100 ft^2 of roof surface on steep coal-tar pitch		
Asphalt organic felt, plain or perforated, bonded and surfaced with a cold application coating	¼/12			3 layers of Type 15 felt 1 layer of Type 30 felt and 1 layer of Type 15 felt 2 layers of Type 15 or 30 cap or base sheets 2 layers of Type 15 felt and 1 layer of Type 15 or 30 cap or base sheets

Note:

From the standpoint of relative effectiveness of the different types of wood sheathing, the tongue-and-groove boards and ¾ in. moisture-resistant plywood give better results in the brand and flame tests than square-edge sheathing with boards spaced about ¼ in. apart. For classifications based on square-edge sheathing, tongue-and-groove or plywood sheathing can be substituted. Square-edge sheathing boards should be butted together as closely as possible. Reference to ¼ in. spacing is to indicate fire test procedure intended to simulate actual conditions after shrinkage of boards due to age or other reasons.

The minimum weight of cementing material between separate layers of felt is considered to be 25 lb per 100 ft^2 of roof surface.

Types 15 and 30 felts are defined as saturated felts weighing a minimum of 14 lb and 28 lb per 100 ft^2 of the finished materials, respectively. Where saturated felts are referred to be weight, the weight is minimum and is expressed in pounds per 100 ft^2 of the finished material.

Materials intended for built-up roof coverings are labeled by Underwriters Laboratories. The classifications indicated are of generally accepted combinations.

*Built-up roof coverings are classified as applied over square-edge wood sheathing of 1 in. nominal thickness, or the equivalent, unless otherwise specified.

For SI units: 1 in. = 25.4 mm; 1 ft = 0.305 m; 1 ft^2 = 0.0929 m^2; 1 lb = 0.454 kg.

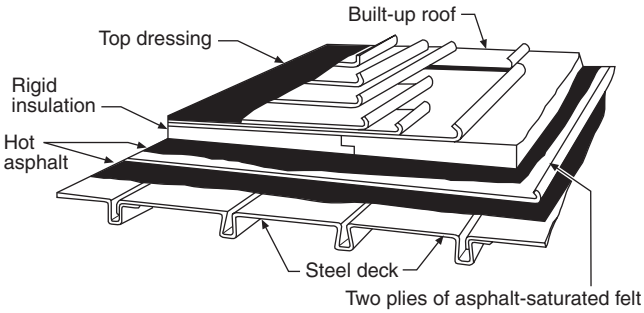

FIGURE 19.1.38 Typical Built-Up Roof Covering with a Combustible Vapor Barrier Adhered to the Roof Deck and to Roof Insulation by a Combustible Adhesive

barrier is used between the deck and the insulation, a listed, noncombustible, or material with limited fuel contribution is recommended. Testing laboratories list various manufacturers of acceptable vapor barriers and adhesives.

FM Global divides insulated metal deck roof assemblies into two classes. Class 1 construction is any insulated steel roof deck construction having a combination of above-deck components that will not contribute significantly to an interior fire and that will meet or equal FMR performance standards. Class 2 construction is any insulated metal roof deck construction using a combination of above-deck components which, when exposed to fire locally, will produce sufficient heat release to allow a self-propagating fire on the underside of an unprotected deck.

Constructions that are found acceptable to FM are listed by FM Global Research.[6] Underwriters Laboratories list those roof deck constructions that have been tested in the UL Building Construction Directory or online at http://database.ul.com.

SUMMARY

Building construction is classified based on the materials used for the structural elements and the degree of fire resistance afforded by each element. In the United States, construction is classified according to subtypes derived from five fundamental construction types: Type I, formerly referred to as fire-resistive construction; Type II, formerly referred to as noncombustible construction; Type III, formerly referred to as exterior protected combustible or ordinary construction; Type IV, formerly referred to as heavy-timber construction; and Type V, formerly referred to as wood-frame construction.

The classification of construction recommended by the MCSC and the BCMC comprises two major groups, noncombustible and combustible, with subtypes based on the fire resistance of the three basic elements of a building: the exterior wall, the primary structural frame, and the floor. The designs of exterior walls, interior walls and partitions, floor framing systems, trusses, floor/ceiling assemblies, roof framing, roof coverings, and roof deck insulations and vapor barriers also play an important role in the fire safety of a building.

Chapter 2

Structural Integrity During Fire

Revised by
Richard J. Davis

Chapter Contents

Fire Resistance Testing
Fire Resistance Tests of Structural Assemblies
Illustrative Fire Resistance Ratings for Structural Frame and Barrier Constructions
Calculating Fire Endurance
Structural Materials at Elevated Temperatures
Fire Behavior of Other Building Materials
Contemporary Trends in Structural Fire Protection

Key Terms

ceiling assembly, fire barrier, fire endurance, fire resistance, fire test, floor assembly, glass, gypsum, partition, prestressed concrete, reinforced concrete, roof assembly, structural assembly, structural frame, structural integrity, structural steel, timber, wall, wood

The selection of building materials and the design of the details of construction always play an important role in overall building fire safety. Two important fire safety considerations regarding the building structure are to minimize the likelihood of collapse of the structural frame during a fire and to ensure that fire barriers remain intact to prevent ignition and fire spread to adjoining spaces.

The following are the three general approaches to structural frame and barrier design for fire resistance that are in use or under development today:

1. Standard fire resistance testing combined with building code requirements
2. Analytical calculations to determine the resistance to a standard fire test exposure as a substitute for laboratory testing
3. Analytical structural fire engineering design methods based on real fire exposure characteristics

The traditional method of treating the structural aspects of fire protection is through building code requirements. Codes generally require structural frames and barrier assemblies to be selected based on ratings determined through standardized laboratory fire resistance tests (approaches 1 and 2 above).

Classification of building construction with regard to fire resistance requirements is an approach that has the principal advantage of being relatively easy to incorporate into the design process and to administer from a code enforcement viewpoint. It has a major disadvantage of being unable to represent the performance of the structural member or fire barrier under the broad range of "real world" fire loads. In other words, code compliance alone is not sufficient to ensure performance success of the barriers or structural frame in an actual fire. Studies that correlate building code requirements and fire test results with field performance need to be further pursued.

Although the century-old approach for determining fire resistance can be criticized for its shortcomings, it is the only method universally accepted in U.S. building codes today. The first part of this chapter describes the fire resistance test procedures common in building construction today. Latter parts of the chapter discuss methods of calculating fire-endurance (resistance) ratings and the behavior of building materials at elevated temperatures. The chapter concludes with a brief discussion of some of the more advanced approaches to designing for structural integrity in a fire.

For related topics, see Section 6, Chapter 3, "Concepts and Protocols of Fire Testing"; Section 18, Chapter 1,"Confinement of Fire in Buildings"; Section 19, Chapter 1, "Types of Building Construction"; Section 19, Chapter 4, "Analyzing Structural Fire Damage"; and Section 19, Chapter 5, "Approaches to Calculating Structural Fire Resistance."

Richard J. Davis, P.E., FSFPE, is an assistant vice-president and senior engineering technical specialist at FM Global in Norwood, Massachusetts, and is a member and retired chair of the NFPA Technical Committee on Construction and Demolition and a member of the NFPA Technical Committees on Building Construction; Structures, Construction and Materials; Fire Tests; and Smoke Management.

FIRE RESISTANCE TESTING

The fire resistance rating of the beams, girders, columns, and other members that comprise the structural frame and the fire resistance rating of the walls, partitions, floor/ceiling assemblies, and roof/ceiling assemblies that serve as fire barriers serve as the basis for classifying building construction and codifying frame and barrier capabilities. This part of the chapter describes the history and procedure for standardized fire testing and discusses the interpretation of laboratory fire test results.

History of Fire Resistance Tests

One review of fire test methods for building constructions refers to tests on metal and masonry conducted in Germany as early as 1884–1886.[1] The first large-scale fire tests in this country are reported to have been conducted on masonry arches in Denver, Colorado, in 1890. These were followed by tests in New York City in 1896.

Efforts to establish an acceptable test procedure were initiated by Professor Ira H. Woolson of Columbia University and Rudolph P. Miller, Chief Engineer, Building Bureau, New York City. Preliminary tests by the bureau, "necessitated by the rapid development of the skyscraper," led to the development of a test furnace (using railroad ties as fuel). This provided a means of establishing hourly fire ratings for floor constructions.

After the Baltimore, Maryland, conflagration of 1905, the American Society for Testing and Materials (ASTM) established a committee to standardize the test method, with Woolson as chairman and Miller as secretary. A test method for floor constructions was proposed in 1906 and adopted by ASTM in 1907. A procedure for testing wall and partition constructions was proposed in 1908 and adopted in 1909.[2]

These standards were presented to the NFPA Committee on Fire-Resistive Construction for consideration in 1914. In 1916, a joint committee composed of representatives from eleven engineering societies, including NFPA, was organized to revise and update the standard. This was done, and the revised standard test method controlled by a standard time-temperature curve was adopted subsequently by NFPA, ASTM, and the American Engineering Committee (now the American National Standards Institute [ANSI]). NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials,* was adopted by NFPA as a tentative standard in 1917 and advanced to official standard status in 1918. Time-temperature curves and testing procedures developed in other countries follow the same general pattern, with minor differences. See Section 19, Chapter 5, "Approaches to Calculating Structural Fire Resistance," for discussion of international approaches.

Fire Test Procedures

Fire test procedures usually require that columns, floors, partitions, walls, and other structural elements be loaded in a manner calculated to develop, as nearly as practicable, the theoretical working stresses expected by the structural design. Separate test procedures are provided for load-bearing and non-load-bearing arrangements and for arrangements involving restrained and unrestrained beams and girders.

The Appendices to NFPA 251 contains detailed specifications for test procedures, a guide to the determination of restraint required, if any, and a suggested report form. The standard specifies in detail the preparation and conditioning of the test specimens.

Acceptance criteria are specific for the assembly or structural element tested based on predetermined conditions of test (load or no load, restrained or unrestrained). The criteria include the following:

1. Failure to support load
2. Temperature increase on the unexposed surface 250°F (121°C) above ambient
3. Passage of heat or flame sufficient to ignite cotton waste
4. Excess temperature (as specified) on steel members
5. Failure under hose streams (walls and partitions)

The end restraint conditions during the fire test influence significantly the test results and, consequently, the ratings. Appendix E of NFPA 251 defines a restrained condition as one in which expansion at the supports of a load-carrying element is prevented during the test. A restrained condition is intended to account for some degree of rotational restraint at the ends of the element in addition to prestressing some parts of the assembly. An unrestrained condition is one in which the load-carrying element is free to expand and rotate at its supports.

One justification for incorporating two differing means of end restraint is to simulate simple (statically determinant) and continuous (statically indeterminant) conditions. Figure 19.2.1 illustrates simple and continuous arrangements. All else being

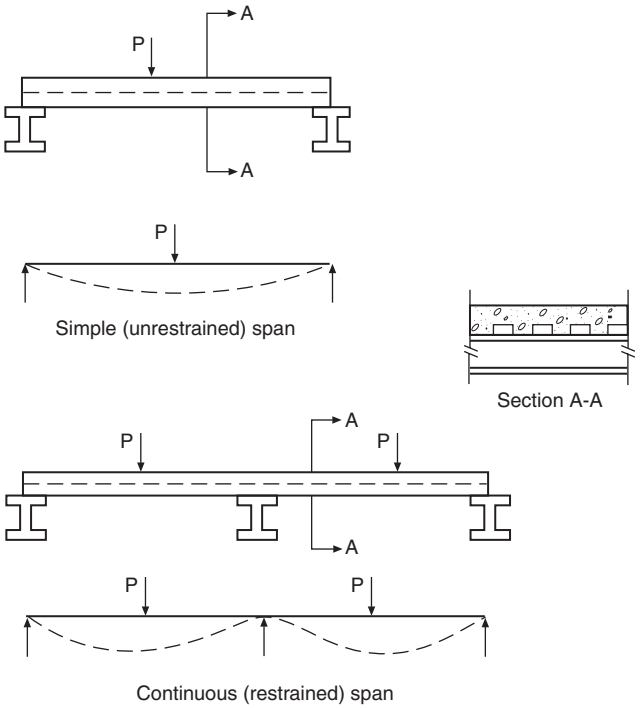

FIGURE 19.2.1 Influence of Structural Continuity on Collapse Mechanisms

equal, continuous span construction is inherently stronger than simple span construction. It is possible to calculate the increase in load-carrying capacity of statically indeterminant structural members. However, the amount of increased strength in an indeterminant structure can be quite variable, depending on the type of construction materials used, the location of structural members within the structure, the degree of indeterminance, the loading conditions, and the details of construction.

Requirements to evaluate structural members based on restrained and unrestrained conditions were introduced in standardized fire testing in 1970. The degree of restraint for structural members and assemblies tested and accepted for building construction prior to 1970 is unknown.

Fire Resistance Ratings

Fire resistance ratings represent the time duration the structural member or assembly withstood the fire test without failure. Although the actual time is recorded to the nearest integral minute, fire resistance ratings are given in standard intervals. The usual fire resistance ratings for all types of structural members and assemblies are 15 minutes, 20 minutes, 30 minutes, 45 minutes, 1 hour, 1½ hours, 2 hours, 3 hours, and 4 hours. Therefore, a 1 hour rating indicates that the assembly withstood the standard test for 1 hour or longer. A 2 hour rating indicates that the assembly withstood the standard test for a minimum of 2 hours without failure of any of the criteria listed in the fire test protocol.

Some agencies in the United States that test assemblies of building construction materials for fire resistance are Underwriters Laboratories Inc. (UL), Omega Point, Southwest Research Institute, and Intertek Testing. A number of other organizations have furnaces or equipment for conducting fire tests of various special assemblies. Some of these include the Forest Products Laboratory at Madison, Wisconsin; University of California at Berkeley; Armstrong Cork Co., Lancaster, Pennsylvania; and the National Gypsum Co., Buffalo, New York. Some of these test facilities may not conform to the specifications described in NFPA 251. Consequently, those facilities may be used more for research purposes rather than for establishing fire resistance ratings.

The results of fire tests conducted by Underwriters Laboratories Inc., Omega Point, Southwest Research Institute, and Intertek Testing are published in company directories, which are now available in electronic as well as in print formats. The *Fire Resistance Directory* is published by UL. Omega Point, Southwest Research Institute, and Intertek Testing each have their own *Directory of Listed Products.* FM Approvals has access to a facility to conduct the tests and publishes the results in its *Approval Guide.* These guides and directories have illustrations of building assemblies that have met the test criteria for specific fire resistance hourly ratings.

The results of fire tests conducted by governmental agencies have been published in various reports and technical papers. Those issued by the National Institute of Standards and Technology (NIST) may be consulted in many depository libraries, and lists of those available may be obtained from NIST. In Canada, there are facilities at the Underwriters Laboratories of Canada in Toronto and the Building Research Division of the National Research Council of Canada in Ottawa. Throughout the world, many well-equipped fire-testing laboratories are making significant contributions to the literature and to the development of international fire test standards.

In Europe, there are a number of public and private facilities available. Some of the facilities that have furnaces include the Centre Technique Industriel da la Construction, Metz, France; Netherlands Organization for Applied Scientific Research, Ja Delft, Netherlands; Danish Institute of Fire and Security Technology, Hvidovre, Denmark; Federal Institute for Materials Research and Testing, Berlin, Germany; University of Ghent, Ghent, Belgium; Warrington Fire Research Center, Warrington, UK; Timber Research and Development, Buckinghamshire, UK; Swedish National Testing and Research Institute, Borås, Sweden; VTT Technical Research Centre of Finland, Espoo, Finland; and The Foundation for Scientific and Industrial Research at the Norwegian Institute of Technology, Trondheim, Norway. The bulletins and reports of the British Ministry of Technology on the subject are obtainable by purchase from H. M. Stationery Office or the British Information Services, New York. Throughout the world, many well-equipped fire-testing laboratories are involved with determining structural fire resistance.

Building codes may include tabulations of construction assemblies that will be accepted as meeting code requirements for terms of fire test results and may include tabulations of construction forms that will be accepted as meeting code requirements for specific fire resistance ratings. Such tables are usually based upon fire test data, but some include ratings determined by experience, judgment, and extrapolation of specific test data.

Not included are the many useful data sheets and summaries published by trade associations of the building materials manufacturers. These sources are not cited because they are so numerous and because the information published either pertains to the products of a specific manufacturer or consists of tabulated ratings for a single type of construction material.

The number of test facilities in use today and the variety of published test results make it almost impossible to tabulate in a single useful form all the data on the various assemblies that have been tested. Users of this handbook are urged to consult the fire resistance directories and reports mentioned previously for the specifics on design specifications for assemblies that have been tested and for which fire resistance ratings have been assigned.

As a matter of information and to illustrate the scope of testing activities, tabular compilations of test results or representative assemblies will be found later in this chapter. They are included in this handbook to help give an understanding of basic requirements for test specimens and how the results of tests are recorded. In addition, the information contained in the tables can be useful in identifying, within reasonable limits, the fire resistance capabilities of assemblies as they are found in the field and for which precise data on their fire resistance are not available or are no longer available. The tables are not presented as references for design but to familiarize handbook users with the type of test information available.

Variations in Test Results

The standard fire test attempts to provide a relative measure of fire performance of comparable assemblies under uniform fire exposure conditions. It does not consider suitability for use after the fire. Many effects from fire tests are observed indirectly, if at all. For example, the temperature gradient through a wall or floor slab results in internal strains and deflections. The strains may cause spalling or other disruptions, and distortions may be severe enough to crack floor slabs and walls, sometimes leading to collapse or excessive heat transmission. The greater the area exposed, the more serious are the results of unequal expansion. General deterioration of the test specimen is not considered when determining the fire resistance rating, except when it contributes to the failure of the test specimen.

It should be recognized that the fire resistance rating is the amount of time the member of assembly withstood a standard laboratory fire test. It is not necessarily the time duration the assembly will perform without failure under actual fire conditions. For example, a 2 hour assembly can withstand failure for at least 2 hours when subjected to the standard fire test exposure. Under actual field conditions, the same assembly may fail in a considerable shorter or longer time duration. One of the major misconceptions in fire protection is the belief that an assembly rating indicates the time that the assembly will survive an actual fire. Rather, it is the time the assembly survived, without failure, the fire test exposure. Differences between the standard test and field conditions can be substantial.

The fact that test-time duration and field performance may be vastly different is not intended to demonstrate that fire resistance ratings do not have value or purpose. Over the years this procedure has resulted in improved fire performance of code-complying buildings. However, one must understand the limitations of the procedure so that unrealistic reliance is not placed on the construction.

Although the test standard specifies the preparation and conditioning of specimens, there are many opportunities for differences between a test specimen and an actual structural element in the field. The test specimen may be superior in both materials and workmanship to those found in the field; the test specimen is usually smaller than the construction assembly it represents. Restraints to thermal expansion may be of different magnitudes. Therefore, discretion in the interpretation of fire test results is in order. Differences in the results of fire tests on apparently equal test specimens of building constructions arise from many factors, such as undetermined differences in the quality of materials, workmanship, moisture content, and test procedures. While the standard method of test requires that materials in the specimen and the workmanship be representative of those in actual buildings, considerable variation in field practice can occur.

The test method permits the intensity of the fire exposure to deviate as much as 10 percent (formerly 15 percent) from that prescribed as standard and requires adjustment in the reported results to correct for such deviations only for tests of ½ hour duration or greater. The effects of several of the variables encountered in fire testing procedures are found in the technical reports listed in the bibliography at the end of the chapter.

The character and proportions of aggregates and binders have an important influence on the results of fire resistance tests. For example, gypsum plaster with lightweight aggregates, mixed with 2 to 3 ft^3 (0.057 to 0.085 m^3) to each 100 lb (45 kg) of gypsum, provides fire resistance from 10 to 70 percent greater than equal thicknesses of sanded gypsum plaster. The use of such aggregate in specific constructions should be adopted only after consulting the publication of ratings based on tests in which these aggregates have been used.

Vermiculite aggregate plaster, if too wet when applied, may be subject to shrinkage cracks. Such cracks, if they develop, are likely to occur within a short time. Some expanded perlite aggregates tend to absorb atmospheric moisture and may show destructive expansion after a few years. There may be considerable variation in this effect, as perlite is a natural volcanic glass or rock from many sources and varies in composition.

Finishing lime produced from dolomite contains magnesium oxide. That which is designated as "normal" finishing hydrate may not be sufficiently hydrated, and sometimes subsequent gradual hydration results in destructive expansion. Plasters containing such lime are subject to rapid destruction in the event of fire. This difficulty is avoided with lime hydrated under high temperature and pressure and known as "special" or "autoclaved" lime.

So-called stabilized gypsum plaster containing a small percentage of the normal hydrated lime may similarly be subject to deterioration with age and, in tests, may not provide the fire resistance to be expected from such constructions.

The effects mentioned are not such as to preclude the use of these materials where long life is not a factor or where adequate guarantees are provided. They are merely illustrations of the variability in test results that can occur as a result of differences in materials.

Although standard fire tests are made on fairly large specimens representative of building constructions or assemblies, they do not necessarily produce heat-expansion effects similar to those of fires in buildings having larger wall or floor areas. It may be necessary to specify thickness of construction or lateral support in addition to rated fire resistance to guard against the adverse effects of heat expansion or temperature gradients.

In addition to the material variation noted, construction differences may be even more significant. For example, a test does not provide full information on performance of assemblies constructed with components or lengths other than those tested. Performance is often reduced when the spans are increased. Also, approving "or equal" clauses in construction specifications need to be thoroughly evaluated. Sometimes substitutions in materials are approved for components that have not been listed with the assembly. Consideration also needs to be given to the connection methods used in constructing the various elements of the assembly.

The standard test does not incorporate information regarding the effect on fire resistance of conventional openings in the assembly, such as electrical receptacle outlets, pipe chases, and so on. Poke-through construction for electrical services or piping often is not patched properly. Transfer grilles, windows, and other penetrations are often incorporated into barriers without considering their impact on fire resistance.

The factors noted above, in addition to the many deviations to plans and specifications during and after construction,

significantly affect the fire resistance of members and assemblies. Often the code calls for—and the designer may think he or she is providing—a specified fire resistance, only to have that resistance reduced because of inattention to penetrations and important details of construction.

FIRE RESISTANCE TESTS OF STRUCTURAL ASSEMBLIES

Structural Frame Systems

The fire resistance rating of structural framing members, such as beams, girders, and columns, may be achieved in several ways. Generally, the members are protected by encasing them in a material with sufficient insulating qualities to prevent excessive thermal penetration or by providing a membrane protection that delays thermal penetration to the members. The general behavior of reinforced concrete, structural steel, and barrier assemblies are described in the following paragraphs. Illustrative fire resistance ratings are shown in tabular form later in this chapter.

Reinforced Concrete Systems

Reinforced concrete construction has exhibited good performance with regard to its ability to withstand structural collapse. Because concrete has a low thermal conductivity and a low thermal capacity, it provides an effective cover for reinforcing steel. For example, Figure 19.2.2 shows the temperature gradient in a 6 in. (152 mm) slab after a 2 hour fire exposure.[3] Although undoubtedly the moisture in the concrete greatly influences the values, the significant feature is the fact that the temperatures vary considerably throughout the thickness, even after a considerable time exposure.

This feature provides some insight into one reason that reinforced-concrete systems usually perform comparatively well during fire exposure. Consider, for example, a continuous, monolithic reinforced-concrete beam or slab, as shown in Figure 19.2.3. Considering the temperature gradient of Figure 19.2.2, it will take some time before the tension steel at midspan is affected. Even after the tension steel at midspan reaches its yield value, the steel reinforcement in the negative moment region near the top of the beam or slab over the supports has not been seriously affected because of the insulating effect of the concrete and the moisture.

Continuous (restrained) construction of this type has inherent capabilities far greater than statically determinant (simple unrestrained) construction. Considerable stress redistribution can take place before collapse will occur. It takes time before excessive rotation will develop at all the necessary locations, causing structural collapse of the restrained member. Although the member is weakened by the fire, structural stability against collapse will remain for a considerable period of time.

The level of stress in a reinforced-concrete member exposed to the elevated temperatures of a fire has a significant influence on its fire resistance. A series of tests was conducted on 15 in. × 15 in. (381 mm × 381 mm) columns with four number-nine reinforcing bars.[3] Each column was loaded at a different percentage of the design load. Table 19.2.1 illustrates the effects of stress level on the fire resistance of reinforced-concrete columns. It can be seen that the magnitude of stress during a fire causes significant reductions in capacity. This is attributed primarily to the reduction in the mechanical properties of steel and concrete at elevated temperatures.

Steel Construction

The popularity of steel-frame building construction is due to its high strength, ease of fabrication, and ensured uniformity of quality. Exposed structural steel, however, is vulnerable to fire

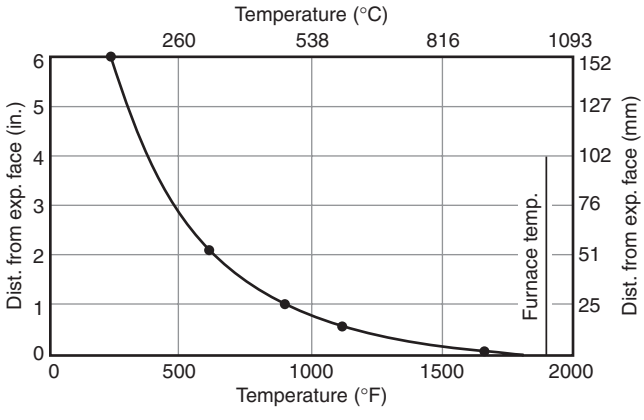

FIGURE 19.2.2 Thermal Gradient in a 6 in. Slab After 2 Hour Fire Exposure. For SI units: 1 in. = 25.4 mm; °C = ⅝ (°F – 32).

30	358

damage. In order to possess fire resistance, it must be protected from high temperatures encountered in fires with other materials. Protection for steel beams, girders, and columns, such as encasements of concrete, clay, tile, masonry, or gypsum blocks, has been generally superseded by plastered or sprayed-on applications applied either to a furred plaster base, such as expanded metal lath, or directly to the surface of the member to be protected. The applications may be conventional plasters of portland or gypsum cements combined with appropriate aggregates, or one of the many combinations of mineral fibers with binders. Gypsumboard encasement is a popular technique for protecting steel structural elements. Deliberate efforts must be taken to ensure that the materials used to protect the steel members from fire are maintained and not removed for the installation of hangers, supports, and other purposes.

Barrier Systems (Walls and Partitions)

Exterior walls, interior partitions, floors, and floor/ceiling assemblies are components that define the functional layout of rooms and spaces in a building. In the normal functional use of a building, these components are used to provide privacy, security, protection from the elements, and noise control. They can also provide fire protection by delaying or preventing heat and particles of combustion from spreading throughout the building.

The effectiveness of a barrier in preventing fire spread depends on several factors. One is fire severity, which is influenced by the fuel in the space, as well as the size and location of openings, the size of the room, and the thermal properties of the wall and ceiling construction. The fire severity represents the thermal load applied to the barrier surface. The performance of the barrier is affected by the materials of construction, as well as other factors such as the applied structural loads, the details at connections, and the dimensions. Of even greater importance is the effect of openings and penetrations in the barrier. The most common cause of fire spread from one room to an adjacent room is through unprotected openings in barriers. Information on protection of openings can be found in NFPA 80, *Standard for Fire Doors and Other Opening Protectives.* Often code requirements and expensive constructions are rendered ineffective because of lack of attention to the details of opening protection.

Building codes through construction classifications identify the fire resistance requirements of barriers. In addition, special locations, such as around vertical shafts, are required to provide specific resistances. Fire resistance ratings are determined by subjecting the barrier assembly to a standard fire test, as described in NFPA 251. The length of time the assembly withstands the laboratory fire without failure describes the fire resistance and is similar to how ratings are obtained for structural building elements. Both combustible and noncombustible barriers can obtain fire resistance ratings in the standard fire test.

The limitations expressed earlier in this chapter with regard to the interpretation of the fire resistance time durations also apply here. That is, the time durations reflect laboratory times and are not necessarily the values to be expected in a real fire. For example, one should not expect a 2 hour barrier assembly to withstand an actual building fire for 2 hours. Failure could occur earlier or later, depending on construction details.

Many fire tests are stopped arbitrarily before an end-point criterion has been attained. In some cases, the indications are that, had the test been continued, the construction would have qualified for a higher fire resistance rating than that assigned to it. For a more detailed discussion of fire barrier systems, see Section 18, Chapter 1, "Confinement of Fires in Buildings," NFPA 221, *Standard for High Challenge Fire Walls, Fire Walls, and Fire Barrier Walls,* and *NFPA 5000®, Building Construction and Safety Code®*.

Floor/Ceiling Assemblies

The fire resistance of floor/ceiling assemblies is important in the prevention of flame movement vertically from floor to floor. Fire resistance ratings from the standard fire test are determined from unpenetrated assemblies. The anticipated fire resistance may be reduced greatly or eliminated in building construction when holes and poke-throughs are not protected adequately or when details do not conform to the tested assembly.

The method of attaching ceilings is a major factor in determining the fire resistance of floors. For example, the nailing of gypsum lath, metal lath, or gypsum wallboards to the soffits of wood joists is often critical in plaster construction. The longer, thinner nails, particularly those with cement coatings, conduct less heat to char the wood surrounding them than do the common types of wire nails. Similarly, the integrity of suspended ceilings must be maintained to reduce the likelihood of premature failure on some assemblies. Details such as attention to expansion of the supporting framework are essential to preventing premature ceiling failures.

Self-tapping screws, made particularly for the attachment of gypsumboard, offer greater holding power and less damage to the core materials than do nails. Such screws can be used to attach wallboards to either wood or cold-rolled channels without previous drilling.

Consideration must also be given to the character of the plaster base with respect to loosening of plaster mixes from the base on application of heat sufficient to char combustible surfaces. The use of wire or, better yet, wire fabric to reinforce the plaster mixes applied to such plaster bases ensures increased fire resistance. Clearances for longitudinal expansion of metal furring members are required to prevent damage from buckling. The tendency of certain plaster bases and plaster mixes to expand or contract with changes in atmospheric humidity should also be given consideration where resultant cracking might affect the fire resistance of structures incorporating such plaster.

Suspended ceilings with openings for air diffusers and light troughs should be designed so that such openings are not points of vulnerability to fire. Continuous construction above recesses for lighting fixtures and properly designed self-closing dampers for air ducts provide protection.

Roof/Ceiling Assemblies

Roof/ceiling assemblies are tested and rated in a manner similar to the floor/ceiling assemblies. The results are generally comparable. However, it should be noted that roof assemblies often have a given thickness of insulation in place at the test. If ad-

ditional thicknesses of insulation are desired, the fire resistance rating may be reduced.

ILLUSTRATIVE FIRE RESISTANCE RATINGS FOR STRUCTURAL FRAME AND BARRIER CONSTRUCTIONS

Fire resistance testing has produced a large amount of performance data. To illustrate the effect of materials and construction materials on the fire resistance rating of assemblies and structural members, several graphs and tables are included. These graphs and tables can be used to give guidance on the needs to achieve fire resistance ratings and to provide a basis for interpretations of the fire resistance of construction encountered in field evaluations.

TABLE 19.2.2 Reinforced-Concrete Beams and Girders of Medium Size

Concrete Grade[a]	*Protective Cover of Reinforcement (in.)*	*Fire Resistance Rating*[b] *(hr)*
	¾	1
	1	2
1	1¼	3
	1½	4
	¾	½–1[c]
	1	1–2[c]
2	1½	2–3[c]
	2	2–4[c]

[a]For lightweight concrete having an oven-dried density of 110 pcf or less, the cover shown for concrete Grade 1 may be reduced 25 percent.
[b]May be increased if some bars are better protected by being away from corners or in an upper layer or if beam is large. Should be decreased if beam is small.
[c]Variable depending on spalling characteristics of aggregate. The use of mesh to hold cover in place will give ratings about as high as for concrete of Grade 1.
For SI units: 1 in. = 25.4 mm.

Reinforced-Concrete Members

The details of construction and the kind of aggregates affect the fire resistance of concrete structures. The fire resistance ratings for reinforced concrete beams are given in Table 19.2.2 and for prestressed concrete girders, beams, joists, and slabs in Table 19.2.3. As the cold-drawn, high-strength steel tendons used in prestressed concrete are more adversely affected by high temperatures than normal reinforcement steel, these tendons require a thicker protective cover than is required in conventional reinforced concrete. The fire resistance of reinforced concrete columns is shown in Table 19.2.4.

Structural Steel Members

As previously noted, fire resistance generally is provided for structural steel by encasing the members in concrete, lath and plaster, gypsumboard, or spray-applied cementitious or material fiber coatings. Another common method of providing fire resistance is by installing a membrane barrier to delay or prevent the heat from raising the temperature of the steel to critical failure temperatures. Table 19.2.5 gives minimum thicknesses of portland cement encasement for steel beams, whereas Tables 19.2.6 and 19.2.7 illustrate the influence on the fire resistance of columns for various methods of encasement. Figures 19.2.4 and 19.2.5 illustrate different methods of encasement for steel columns. Figure 19.2.6 provides a means to estimate the necessary encasing requirements for steel columns.

TABLE 19.2.3 Prestressed Concrete Girders, Beams, Joists, and Slabs (Grade 1 Concrete)

Type of Unit	*Condition of Restraint*	*Cross-Sectional Area (in.²)*[b]	Cover for Fire Rating Shown (in.)[a]			
			1 hr	*2 hr*	*3 hr*	*4 hr*
Girders, beams, and joists	Unrestrained	40 to 150	2	2.5	—	—
		150 to 300	1.5	2.5	3.5[c]	—
		Over 300	1.5	2.25	3[c]	4[c]
	Axially restrained	40 to 150	1.5	2	—	—
		150 to 300	1	1.5	2	—
		Over 300	1	1.5	1.5	2
Slabs, solid or covered, with flat undersurface	Unrestrained		1	1.5	2	2.5
	Biaxial restraint		0.75	1.25	1.5	2

Note: Data in this table are based on 67 standard ASTM fire tests.
[a]Cover for an individual steel tendon is measured to the nearest exposed surface. For several tendons in the same member having different concrete covers, the minimum cover may be reduced slightly. The covers shown may be reduced 25 percent for lightweight concrete having an over-dried density of 110 pcf or less. For Grade 2 concrete, the cover may need to be increased.
[b]In computing the cross-sectional area of joists, the area of the flange must be added to the area of the stem, but the total width of the flange so used must not exceed three times the width of the stem.
[c]Provide against spalling of the cover by means of a light, 2-in., U-shaped mesh, covered about 1 in.
For SI units: 1 in. = 25.4 mm; 1 in.^{2} = 645 mm^2.

TABLE 19.2.4 Fire Resistance of Reinforced-Concrete Columns*
