FIRE-GAS

مدرس ، طراح و مشاور سیستم های (آتش نشانی ، تهویه ، اگزاست و فشار مثبت)

دارای صلاحیت سازمان آتش نشانی

اخذ تاییده از سازمان آتش نشانی

اولین هند بوک سیستم اطفاء حریق و مدیریت دود در ایران

Handbook of Smoke Control Engineering

AUTHOR QUILL PEN

طراحی سیستم های اطفا آبی ، گازی و فوم Sprinkler ,FM200,CO2,Foam

طراحی ، انتخاب ، تست و راه اندازی پمپ های آتش نشانی مطابق NFPA20

طراحی سیستم های اگزاست و تهویه پارکینگ ، فشار مثبت راه پله - آسانسور وآتریوم ها

SOFTWARE

نرم افزار کانتم Contam

نرم افزار پایروسیم و پاس فیدر Pyrosim ,Pathfinder

نرم افزار اتواسپرینک Autosprink

نرم افزار انتخاب فن، دمپرهای دود و آتش Sodeca Quick Fan & RF Damper

Dedication

In recognition of his extraordinary service as founder and professor of the fire protection engineering program at the University of Maryland, as chairman of the NFPA Board of Directors, as chairman of the NFPA Standards Council, as leader and mentor, this handbook is dedicated to Dr. John L. Bryan.

Contents

Preface xv

Introduction xvii

SECTION 1
Safety in the Built Environment 1-1

1.1 Challenges to Safety in the Built Environment
■ *John R. Hall, Jr., and Erin R. Twomey* 1-3

1.2 Fundamentals of Structurally Safe Building Design ■ *Bonnie E. Manley* 1-31

1.3 Codes and Standards for the Built Environment
■ *Arthur E. Cote and Casey C. Grant* 1-51

1.4 Legal Issues for the Designer and Enforcer ■ *Arthur E. Schwartz* 1-73

1.5 Fire Prevention and Code Enforcement
■ *Ronald R. Farr and Steven F. Sawyer* 1-81

1.6 Premises Security ■ *Lauris V. Freidenfelds* 1-95

1.7 Protecting Against Extreme Events ■ *Brian J. Meacham and Carl Galioto* 1-109

1.8 Emergency Management and Business Continuity ■ *Donald L. Schmidt* 1-137

1.9 Systems Approach to Fire-Safe Building Design ■ *John M. Watts, Jr.* 1-157

SECTION 2
Basics of Fire and Fire Science 2-1

2.1 Physics and Chemistry of Fire ■ *Dougal Drysdale* 2-3

2.2 Physics of Fire Configuration ■ *Ronald L. Alpert* 2-21

2.3 Flammability Hazard of Materials
■ *Daniel Madrzykowski and David W. Stroup* 2-31

2.4 Dynamics of Compartment Fire Growth ■ *Richard L. P. Custer* 2-49

2.5 Basics of Fire Containment ■ *Marc L. Janssens* 2-59

2.6 Fundamentals of Fire Detection
■ *Richard L. P. Custer and James A. Milke* 2-75

2.7 Theory of Fire Extinguishment ■ *Hong-Zeng Yu and Jeffrey S. Newman* 2-79

2.8 Explosions ■ *Robert Zalosh* 2-93

SECTION 3
Information and Analysis for Fire Protection 3-1

3.1 An Overview of the Fire Problem and Fire Protection
■ *John R. Hall, Jr., and Arthur E. Cote* 3-3

3.2 Fire Loss Investigation ■ *Richard L. P. Custer and David T. Sheppard* 3-31

3.3 Fire Data Collection and Databases ■ *Marty Ahrens and Stan Stewart* 3-43

3.4 Use of Fire Incident Data and Statistics
■ *Marty Ahrens, Patricia Frazier, and Gayle Kelch* 3-61

3.5 Introduction to Fire Modeling
■ *Craig L. Beyler, Philip J. DiNenno, Douglas J. Carpenter, and John M. Watts, Jr.* 3-93

3.6 Applying Models to Fire Protection Engineering Problems and Fire Investigations ■ *Richard L. P. Custer, David T. Sheppard, and Christopher B. Wood* 3-111

3.7 Fire Hazard Analysis Techniques
■ *Morgan J. Hurley and Richard W. Bukowski* 3-121

3.8 Fire Risk Analysis ■ *John R. Hall, Jr., and John M. Watts, Jr.* 3-135

3.9 Closed Form Enclosure Fire Calculations
■ *Edward K. Budnick, Sean P. Hunt, and Mark T. Wright* 3-145

3.10 Performance-Based Codes and Standards for Fire Safety
■ *Milosh T. Puchovsky and Morgan J. Hurley* 3-167

3.11 Overview of Performance-Based Fire Protection Design
■ *Frederick W. Mowrer and Eric R. Rosenbaum* 3-183

SECTION 4
Human Factors in Emergencies 4-1

4.1 Human Behavior and Fire ■ *John L. Bryan* 4-3

4.2 Calculation Methods for Egress Prediction ■ *Rita F. Fahy* 4-49

4.3 Concepts of Egress Design ■ *James K. Lathrop* 4-69

4.4 Techniques of Crowd Management ■ *John J. Fruin* 4-93

4.5 Strategies for Occupant Evacuation During Emergencies
■ *Daniel J. O'Connor and Bert Cohn* 4-103

SECTION 5
Fire and Life Safety Education 5-1

5.1 Principles and Techniques of Fire and Life Safety Education
■ *Edward Kirtley* 5-3

5.2 Fire and Life Safety Education Messages
■ *Ernest Grant and Rodney Eksteen* 5-21

5.3 Disaster Preparedness Education ■ *Gerri Penney* 5-29
5.4 Media's Role in Fire and Life Safety Education ■ *Robin J. Adair* 5-45
5.5 Reaching High-Risk Groups ■ *Sharon Gamache* 5-63
5.6 Juvenile Firesetting ■ *Paul Schwartzman* 5-87
5.7 Using Data for Public Education Planning and Decision Making ■ *John R. Hall, Jr.* 5-103
5.8 Evaluation Techniques for Fire and Life Safety Education ■ *John R. Hall, Jr., and Michael W. Weller* 5-119

SECTION 6
Characteristics of Materials and Products **6-1**

6.1 Fire Hazards of Materials ■ *Robert P. Benedetti* 6-3
6.2 Combustion Products and Their Effects on Life Safety ■ *Richard G. Gann and Nelson P. Bryner* 6-11
6.3 Concepts and Protocols of Fire Testing ■ *Marcelo M. Hirschler* 6-35
6.4 Wood and Wood-Based Products ■ *John M. Cholin* 6-61
6.5 Fibers and Textiles ■ *Jeffrey O. Stull and Salvatore A. Chines* 6-75
6.6 Upholstered Furniture and Mattresses ■ *Vytenis Babrauskas* 6-103
6.7 Fire-Retardant and Flame-Resistant Treatment of Cellulosic Materials ■ *James R. Shaw* 6-129
6.8 Dusts ■ *Richard F. Schwab* 6-141
6.9 Metals ■ *Tom Christman* 6-153
6.10 Gases ■ *Theodore C. Lemoff* 6-165
6.11 Medical Gases ■ *Mark Allen* 6-187
6.12 Flammable and Combustible Liquids ■ *Orville M. Slye, Jr.* 6-197
6.13 Polymeric Materials ■ *Robert P. Benedetti and Guy R. Colonna* 6-209
6.14 Pesticides in the Workplace ■ *Fred Whitford* 6-233
6.15 Explosives and Blasting Agents ■ *Lon D. Santis* 6-247
6.16 Manufacture and Storage of Aerosol Products ■ *David L. Fredrickson* 6-257
6.17 Tables and Charts ■ *Vytenis Babrauskas* 6-269

SECTION 7
Storage and Handling of Materials **7-1**

7.1 Storage and Handling of Solid Fuels ■ *Kenneth W. Dungan* 7-3
7.2 Storage of Flammable and Combustible Liquids ■ *Anthony M. Ordile* 7-15
7.3 Storage of Gases ■ *Theodore C. Lemoff and Carl H. Rivkin* 7-35
7.4 Storage and Handling of Chemicals ■ *John A. Davenport* 7-43
7.5 Hazardous Waste Control ■ *Paul R. Severson* 7-57

SECTION 8
Special Equipment 8-1

8.1 Air-Moving Equipment ■ *Jane I. Lataille* 8-3
8.2 Chemical Processing Equipment ■ *Richard F. Schwab* 8-17
8.3 Materials-Handling Equipment ■ *John K. Bouchard* 8-31
8.4 Automated Equipment ■ *L. Jeffrey Mattern* 8-43
8.5 Lasers ■ *Fred P. Seeber* 8-51
8.6 Protection of Electronic Equipment ■ *Brian P. Rawson* 8-57
8.7 Heat Transfer Systems and Fluids ■ *John A. LeBlanc* 8-65
8.8 Industrial and Commercial Heat Utilization Equipment ■ *Raymond Ostrowski* 8-71
8.9 Oil Quenching and Molten Salt Baths ■ *Raymond Ostrowski* 8-93
8.10 Stationary Combustion Engines and Fuel Cells ■ *James B. Biggins* 8-105
8.11 Fluid Power Systems ■ *Paul K. Schacht* 8-113
8.12 Refrigeration Systems ■ *Henry L. Febo, Jr.* 8-117
8.13 Electrical Systems and Appliances ■ *Robert M. Milatovich* 8-127

SECTION 9
Processes and Facilities 9-1

9.1 Woodworking Facilities and Processes ■ *John M. Cholin* 9-3
9.2 Spray Finishing and Powder Coating ■ *Don R. Scarbrough* 9-27
9.3 Dipping and Coating Processes ■ *John Katunar III* 9-39
9.4 Plastics Industry and Related Process Hazards ■ *George Ouellette* 9-53
9.5 Metalworking Processes ■ *Paul G. Dobbs* 9-67
9.6 Welding, Cutting, and Other Hot Work ■ *August F. Manz and Mark E. Blank* 9-73
9.7 Storage and Handling of Grain Mill Products ■ *James E. Maness and Lee M. Sargent* 9-85
9.8 Protection of Records ■ *James A. Beals* 9-105
9.9 Semiconductor Manufacturing ■ *Vinnie DeGiorgio and Heron Peterkin* 9-119
9.10 Oilseed Solvent Extraction Plants ■ *C. Louis Kingsbaker* 9-131
9.11 Protection of Wastewater Treatment Plants ■ *James F. Wheeler* 9-141
9.12 Fire Protection of Laboratories Using Chemicals ■ *Richard R. Anderson* 9-157
9.13 Fire Protection of Telecommunications Facilities ■ *Ralph E. Transue* 9-167
9.14 Electric Generating Plants ■ *Daniel J. Sheridan* 9-179
9.15 Nuclear Facilities ■ *Wayne D. Holmes* 9-191
9.16 Mining and Mineral Processing ■ *Larry J. Moore* 9-203
9.17 Oxygen-Enriched Atmospheres ■ *Keisa Rosales and Joel M. Stoltzfus* 9-225

SECTION 10
Building Services 10-1

10.1 Emergency and Standby Power Supplies ■ *Dan Chisholm, Sr.* 10-3
10.2 Heating Systems and Appliances ■ *Peter J. Gore Willse* 10-9
10.3 Building Transportation Systems ■ *Edward A. Donoghue* 10-57
10.4 Air-Conditioning and Ventilating Systems ■ *William A. Webb* 10-69
10.5 Ventilation of Commercial Cooking Operations ■ *David P. Demers* 10-77
10.6 Boiler Furnaces ■ *L. Jeffrey Mattern, Eugene Catania, and Shelton Ehrlich* 10-91

SECTION 11
Fire Prevention Practices 11-1

11.1 Waste Handling and Control ■ *Lawrence G. Doucet and Sharon S. Gilyeat* 11-3
11.2 Housekeeping Practices ■ *L. Jeffrey Mattern* 11-27
11.3 Building and Site Planning for Fire Safety ■ *Albert M. Comly, Jr.* 11-39
11.4 Fire Hazards of Construction, Alteration, and Demolition of Buildings ■ *Richard J. Davis* 11-47
11.5 Control of Electrostatic Ignition Sources ■ *Don R. Scarbrough* 11-59
11.6 Lightning Protection Systems ■ *John M. Caloggero* 11-69

SECTION 12
Non-Emergency Fire Department Functions 12-1

12.1 Planning for Public Fire-Rescue Protection ■ *John A. Granito* 12-3
12.2 Organizational Benchmarking and Performance Evaluation ■ *Dorinda Cline* 12-23
12.3 Needs Assessment and Hazard Analysis ■ *William F. Jenaway* 12-41
12.4 Managing Fire-Rescue Departments ■ *Rebecca F. Denlinger* 12-51
12.5 Information Management and Computer Technology ■ *Brian P. Duggan* 12-79
12.6 Liability of Fire Service Organizations for Negligent Fire Fighting ■ *Maureen Brodoff* 12-99
12.7 Safety, Medical, and Health Issues and Programs ■ *Murrey E. Loflin* 12-107
12.8 Effect of Building Construction and Fire Protection Systems on Fire Fighter Safety ■ *Glenn P. Corbett* 12-127
12.9 Fire and Emergency Services Protective Clothing and Protective Equipment ■ *Bruce W. Teele* 12-143
12.10 Training Programs for Fire and Emergency Service Personnel ■ *Jerry W. Laughlin* 12-161
12.11 Industrial Fire Loss Prevention ■ *Michael Snyder* 12-177
12.12 Disaster Planning and Response Services ■ *William Van Helden and Terry Stewart* 12-199

12.13 GIS for Fire Station Locations and Response Protocols
■ *Russ Johnson and Mike Price* 12-215
12.14 Fire Rescue Stations and Fire Service Training Centers
■ *David J. Acomb and Roger M. LeBoeuf* 12-233
12.15 Public Emergency Services Alarm, Dispatch, and Communications Systems
■ *John M. Merklinger* 12-253
12.16 Fire Department Apparatus and Equipment ■ *Robert Tutterow* 12-267
12.17 Pre-Incident Planning for Industrial and Municipal Emergency Response
■ *Michael J. Serapiglia* 12-289
12.18 Pre-Incident Planning for Emergency Response ■ *John Norman* 12-299
12.19 Community Risk Reduction ■ *Edward Kirtley* 12-309

SECTION 13
Organizing for Public Sector Emergency Response 13-1

13.1 Fireground Operations ■ *Bernard J. Klaene and Russell Sanders* 13-3
13.2 Organizing Rescue Operations ■ *Richard Wright* 13-13
13.3 Fire Streams ■ *Michael A. Wieder* 13-23
13.4 Alternate Water Supplies ■ *Laurence J. Stewart* 13-37
13.5 Wildland Fire Management ■ *James C. Smalley* 13-53
13.6 Public Fire Protection and Hazmat Management
■ *Michael S. Hildebrand and Gregory G. Noll* 13-81
13.7 Aircraft Rescue and Fire Fighting (ARFF) ■ *Jack Kreckie* 13-99
13.8 Managing the Response to Hazardous Material Incidents
■ *Charles J. Wright* 13-117
13.9 Emergency Medical Services and the Fire Department ■ *Jack J. Krakeel* 13-145

SECTION 14
Detection and Alarm 14-1

14.1 Fire Alarm Systems ■ *Wayne D. Moore* 14-3
14.2 Automatic Fire Detectors ■ *Kenneth W. Dungan* 14-15
14.3 Notification Appliances ■ *Robert P. Schifiliti* 14-29
14.4 Fire Alarm System Interconnections ■ *Fred Leber* 14-39
14.5 Inspection, Testing, and Maintenance of Fire Alarm Systems
■ *John M. Cholin* 14-53
14.6 Household Fire-Warning Equipment ■ *Daniel T. Gottuk* 14-79
14.7 Fire Protection Surveillance and Security Services ■ *Lawrence J. Wenzel* 14-89
14.8 Gas and Vapor Detection Systems and Monitors ■ *John M. Cholin* 14-99
14.9 Carbon Monoxide Detection in Residential Occupancies ■ *Art Black* 14-113
14.10 Security and Intrusion Detection Systems ■ *Shane M. Clary* 14-119

SECTION 15
Water Supplies for Fixed Fire Protection 15-1

15.1 Fixed Water Storage Supplies for Fire Protection ■ *Bruce A. Edwards* 15-3
15.2 Water Supply Requirements for Public Supply Systems ■ *Lawrence J. Wenzel* 15-23
15.3 Hydraulics for Fire Protection ■ *Kenneth W. Linder* 15-35
15.4 Water Supplies for Sprinkler Systems ■ *Wayne M. Martin* 15-63
15.5 Microbiologically Influenced Corrosion in Fire Sprinkler Systems ■ *Bruce H. Clarke and Anthony M. Aguilera* 15-75
15.6 Water Distribution ■ *John D. Jensen* 15-85
15.7 Fire Pump Controllers and Power Supply Arrangements for Motor-Driven Fire Pumps ■ *James S. Nasby and John R. Kovacik* 15-105

SECTION 16
Water-Based Fire Suppression Equipment 16-1

16.1 Principles of Automatic Sprinkler System Performance ■ *Russell P. Fleming* 16-3
16.2 Automatic Sprinklers ■ *Kenneth E. Isman* 16-15
16.3 Automatic Sprinkler Systems ■ *Roland Huggins* 16-29
16.4 Hanging and Bracing of Water-Based Systems ■ *Russell P. Fleming* 16-55
16.5 Sprinkler Systems for Storage Facilities ■ *James E. Golinveaux* 16-71
16.6 Residential Sprinkler Systems ■ *Daniel Madrzykowski and Russell P. Fleming* 16-91
16.7 Ultra-High-Speed Water Spray Systems ■ *Robert M. Gagnon* 16-109
16.8 Water Mist Fire Suppression Systems ■ *Jack R. Mawhinney* 16-135
16.9 Water Spray Protection ■ *Kerry M. Bell* 16-181
16.10 Standpipe and Hose Systems ■ *David R. Hague* 16-191
16.11 Care and Maintenance of Water-Based Extinguishing Systems ■ *David R. Hague* 16-205

SECTION 17
Fire Suppression Systems and Portable Fire Extinguishers 17-1

17.1 Carbon Dioxide and Application Systems ■ *Thomas J. Wysocki* 17-3
17.2 Chemical Extinguishing Agents and Application Systems ■ *James D. Lake* 17-17
17.3 Characteristics and Hazards of Water and Water Additives for Fire Suppression ■ *John A. Frank* 17-31
17.4 Foam Extinguishing Agents and Systems ■ *Joseph L. Scheffey* 17-45
17.5 Fire Extinguisher Use and Maintenance ■ *Mark T. Conroy* 17-71

17.6 Halon and Halon Replacement Agents and Systems
■ *Philip J. DiNenno and Gary M. Taylor* 17-93
17.7 Application of Gaseous Agents to Special Hazards Fire Protection
■ *Jeff L. Harrington* 17-123
17.8 Explosion Prevention and Protection ■ *Erdem A. Ural and Henry W. Garzia* 17-141

SECTION 18
Confining Fires **18-1**

18.1 Confinement of Fire in Buildings ■ *Hossein Davoodi* 18-3
18.2 Interior Finish ■ *Marcelo M. Hirschler* 18-23
18.3 Smoke Movement in Buildings ■ *James A. Milke and John H. Klote* 18-43
18.4 Venting Practices ■ *Gunnar Heskestad* 18-57
18.5 Penetration Sealing ■ *John E. Kampmeyer* 18-73
18.6 Deflagration (Explosion) Venting ■ *Richard F. Schwab* 18-79

SECTION 19
Structural Fire Protection **19-1**

19.1 Types of Building Construction ■ *Peter J. Gore Willse* 19-3
19.2 Structural Integrity During Fire ■ *Richard J. Davis* 19-29
19.3 Structural Fire Safety in One- and Two-Family Dwellings
■ *Kuma Sumathipala* 19-59
19.4 Analyzing Structural Fire Damage ■ *Stephen Pessiki* 19-65
19.5 Approaches to Calculating Structural Fire Resistance ■ *Barbara Lane* 19-77

SECTION 20
Protecting Occupancies **20-1**

20.1 Assessing Life Safety in Buildings ■ *John M. Watts, Jr.* 20-3
20.2 Board and Care Facilities ■ *Philip R. Jose* 20-15
20.3 Hotels and University Housing
■ *April Berkol, Byron Briese, and Ed Comeau* 20-23
20.4 Apartment Buildings ■ *Kenneth Bush* 20-37
20.5 Lodging or Rooming Houses ■ *Richard R. Anderson* 20-49
20.6 One- and Two-Family Dwellings ■ *James K. Lathrop* 20-55
20.7 Manufactured Housing ■ *Kirsten M. Paoletti* 20-63
20.8 High-Rise Buildings ■ *James R. Quiter* 20-73
20.9 Assembly Occupancies ■ *Gregory Miller and Edward Roether* 20-85
20.10 Mercantile Occupancies ■ *Ed Schultz* 20-97
20.11 Business Occupancies ■ *Brian L. Marburger* 20-105
20.12 Educational Occupancies ■ *Alex L. Szachnowicz* 20-115

20.13 Day-Care Occupancies ■ *Catherine L. Stashak* 20-123
20.14 Detention and Correctional Occupancies ■ *Thomas W. Jaeger* 20-129
20.15 Health Care Occupancies ■ *Daniel J. O'Connor* 20-139
20.16 Storage Occupancies ■ *Jeffrey Moore* 20-157
20.17 Library and Museum Collections ■ *Danny L. McDaniel* 20-179
20.18 Industrial Occupancies ■ *David P. Demers* 20-203
20.19 Motion Picture and Television Studios and Soundstages ■ *Raymond A. Grill* 20-211
20.20 Occupancies in Special Structures ■ *Wayne D. Holmes* 20-217

SECTION 21
Transportation Fire Safety **21-1**

21.1 Passenger Vehicle Fires ■ *R. T. Long, Jr., Jeff D. Colwell, Rose Ray, Helene L. Grossman, Ben Thomas, and Robert Strassburger* 21-3
21.2 Fire Safety in Commercial Vehicles ■ *Brian Routhier* 21-15
21.3 Automotive and Marine Service Station Operations ■ *Carl H. Rivkin* 21-29
21.4 Vehicle Fueling Using Gaseous Fuels ■ *Carl H. Rivkin* 21-41
21.5 Fuel Cell Vehicles ■ *Glenn W. Scheffler and William P. Collins* 21-77
21.6 Recreational Vehicles ■ *Bruce A. Hopkins* 21-91
21.7 Fixed Guideway Transit and Light Rail Systems ■ *Tom Peacock* 21-101
21.8 Rail Transportation Systems ■ *Charles J. Wright* 21-109
21.9 Aviation ■ *Brian Boucher* 21-135
21.10 Marine Vessels ■ *Randall Eberly* 21-151
21.11 Road Tunnels and Bridges ■ *Arthur G. Bendelius* 21-187

Index I-1

Preface

The *Fire Protection Handbook*®—there is no other fire protection reference quite like it. For more than a century, the *FPH*™ has been *the* compilation of fire protection data and best practices. This 20th edition honors the traditions of thoroughness and accuracy that make this handbook so central to any fire protection library. At the same time, this edition includes new and expanded information throughout. For example, there are 25 new chapters and more than 500 new figures and tables. The pool of authors grew from 247 in the 19th edition to our current 260.

FPH users face a unique challenge: navigating quickly though such a wealth of information. This edition includes several new features to make it easier for readers to find the information they need. The most obvious change is the use of a second color to highlight important information such as subheads and expanded cross references to related chapters.

Other changes include the following:

- The addition of new features such as "Key Terms" and "Chapter Contents"—tools to help make the information easier to find
- The reorganization of the sections, so that each section contains fewer chapters

Clearly, a big team participated in creating the *FPH*. The authors are at the center of that team—and I'm particularly grateful for the evening and weekend time they devoted to their chapters. The authors were unfailingly cheerful and were marvelous at fitting the *FPH* into their busy lives and careers.

The section editors recruited authors, reviewed draft material, and resolved technical differences. They were simultaneously diplomats and technical taskmasters responsible for as many as 24 chapters. Their job was far from simple. The three associate editors completed a particularly important job in reviewing new chapters.

Special places in heaven are reserved for my colleagues, Robine Andrau (who timed her retirement to accommodate the *FPH* schedule), Betsey Henkels, and Michael Gammell. They faced a huge manuscript—a stack of paper and electronic files equivalent to 12,000 pages and 2,500 illustrations—and tamed it, one page at a time.

Many other people contributed to this handbook in large and small ways. We all share a simple goal of making our world a bit safer. I tip my hat to you all.

Pam Powell
Managing Editor and Senior Product Manager

Introduction

This is the 20th edition of the *Fire Protection Handbook*®. It has changed significantly since its inception in 1896 as the *Handbook of the Underwriter's Bureau of New England.*

The original author, Everett U. Crosby, was manager of the Underwriter's Bureau and one of the stock fire insurance company executives who came together to develop a consistent set of sprinkler rules in 1895 that led to the formation of NFPA. He also became the first secretary of NFPA, serving from 1896 to 1903, and was chairman of the executive committee from 1903 to 1907. Henry A. Fiske, who later succeeded Crosby as manager of the Underwriter's Bureau, joined Crosby as co-editor of the second edition in 1901. The third edition in 1904 was called the *Handbook of Fire Protection for Improved Risks,* and the fourth edition in 1909 became known as the *Crosby-Fiske Handbook of Fire Protection,* the title used until the 10th edition in 1948. H. Walter Forster, chair of NFPA's Safety to Life Committee, joined the editorial team in 1918 and became an editor for the sixth edition in 1921.

In 1935, Crosby, Fiske, and Forster donated all rights to their handbook to NFPA, which published the eighth and all subsequent editions. By the 11th edition, in 1954, the work was entitled the *NFPA Handbook of Fire Protection.* From the 12th edition in 1962 to this 20th edition, the handbook has been known simply as the *Fire Protection Handbook.*

The explosion of fire-related technology and fire protection knowledge during the last quarter of the twentieth century and into the beginning of the twenty-first century has driven exhaustive changes in the format and content of the *FPH*™. The original 5" × 7" pocket handbook is now a two-volume 8½" × 11" set.

As the most pressing concerns of fire protection have evolved—from property protection concerns of the late 1800s, through life safety concerns for public occupancies in the beginning of the 1900s, to the computer-modeled, risk assessment–based systems approach in use today—the number of subjects covered by the *FPH* has increased greatly.

Creation of the *Fire Protection Handbook* through 20 editions and 111 years has involved literally thousands of fire protection experts from within and without NFPA. It is their expertise that has established the *Fire Protection Handbook* as *the* reference source for fire protection practitioners worldwide.

Every effort has been made to make the content consistent with the best available information on current fire protection practices. If readers discover errors or omissions, the editors would appreciate those shortcomings being called to their attention. In offering this edition of the *Fire Protection Handbook,* the editors solicit suggestions for improvements to make future editions increasingly useful.

Arthur E. Cote, P.E., FSPE
Editor-in-Chief
NFPA Executive Vice-President and Chief Engineer (retired)

Safety in the Built Environment

Robert E. Solomon

1.1 Challenges to Safety in the Built Environment
1.2 Fundamentals of Structurally Safe Building Design
1.3 Codes and Standards for the Built Environment
1.4 Legal Issues for the Designer and Enforcer
1.5 Fire Prevention and Code Enforcement
1.6 Premises Security
1.7 Protecting Against Extreme Events
1.8 Emergency Management and Business Continuity
1.9 Systems Approach to Fire-Safe Building Design

The term *built environment* has come into widespread use to describe all human-made structures, systems, components, and features that surround us. With the exception of one chapter on wildland fire management, the entire *Fire Protection Handbook*® focuses on the built environment. However, building encroachment into the wildland/urban interface can affect certain wildland mitigation strategies and tactics as they relate to the built environment.

The built environment includes more than simply land-based buildings, and safety in the built environment addresses much more than fire safety. The built environment includes all human-made structures, whether or not they are intended for human habitation. Furthermore, the structures are not limited to fixed structures, nor are structures limited to relatively conventional structures. Structures, in fact, can range from submarines to luxury passenger ships to aircraft, and from underground mines to nuclear facilities and transportation infrastructure such as bridges and tunnels.

Regardless of their configuration, these structures face an astonishing array of challenges to make them perform efficiently as well as safely. The purpose of this section is to introduce a wide ranging array of safety issues related to the built environment. Some of these subjects are more traditional, such as the ever-present subject of fire safety; some are newer, such as consideration for extreme or extraordinary design events; and some are a newer and more formalized way of looking at existing issues, such as business continuity.

Chapter 1, "Challenges to Safety in the Built Environment," provides statistical information on the long-term trends in building performance and safety-related problems as well as short-term trends and patterns that help to show the relative importance of various mitigation strategies. Among other topics, Chapter 1 addresses natural disasters and the importance of all-hazard education.

Chapter 2, "Fundamentals of Structurally Safe Building Design," focuses on current building design theories and concepts, concentrating on safety issues within the context of building design. In addition to defining building terms, the chapter introduces design loads and forces, basic building systems and components, fundamental design concepts, and basic design methodology.

Chapter 3, "Codes and Standards for the Built Environment," provides an overview of building codes and standards from their origins nearly 4000 years ago to the documents in use today. The chapter explains the differences between codes, standards, and other regulatory documents, and how these documents differ around the world.

The next two chapters explore the legal and administrative context in which codes and standards for the built environment operate. Chapter 4, "Legal Issues for the Designer and Enforcer," is new to this handbook and covers topics such as the legal implication and adoption of codes, key legal concepts for the engineer and enforcer, the engineer and negligence, and liability concerns associated with building design. Chapter 5, "Fire Prevention and Code Enforcement," introduces the functions of various fire prevention personnel before discussing inspection, enforcement, and plan review activities.

Robert E. Solomon, P.E., is assistant vice-president of building fire protection and life safety at the National Fire Protection Association.

The section's next three chapters are all new and focus on the emerging concerns of security, extreme events, and emergency management. Chapter 6, "Premises Security," explains types of security threats and various building configuration, layout, design, system, and program strategies to mitigate those threats. The aim of Chapter 7, "Protecting Against Extreme Events," is to outline a variety of measures available to help protect buildings and their occupants against the impacts of extreme hazard events. These design events are beyond the realm of the normal or expected hazards that a building is expected to encounter during its life cycle. Chapter 8, "Emergency Management and Business Continuity," defines the essential elements of an emergency management and business continuity program and a process for developing and implementing such programs. Business interruption can come in many forms—fire, earthquake, cyber, and pandemic, among others—and strategies for dealing with each one are considered.

The section concludes with a return to what, for many readers, will be more familiar territory: an exploration of a "Systems Approach to Fire-Safe Building Design" (Chapter 9). The chapter covers the Fire Safety Concepts Tree and its fire protection mitigation strategies.

Falls
Natural Disasters
Fatalities Involving Hazardous Environments

Key Terms

all-hazard education, built environment, Consumer Product Safety Commission (CPSC), hazard, International Classification of Diseases (ICD), *Remembering When,* risk, *Risk Watch*®

We expect a great deal of our built environments. We expect that they protect us from hazards arising from objects we bring into the environments and from the components of the structure itself. We expect that our built environment itself will not be harmful and will provide a protective envelope to shield us from harm arising outside the built environment. We expect it to keep us secure and comfortable and to provide conveniences for the time we spend in it. We expect a lot from our built environments in addition to functionality, usability, attractive appearance, affordability of construction and operation, and a host of other nonsafety goals and objectives.

The first step in evaluating the challenges to safety in the built environment is to classify the types of harm encountered. This chapter examines several perils causing harm to people and property in the built environment.

See also, Section 1, Chapter 7, "Protecting Against Extreme Events"; and Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection."

DEFINING THE CHALLENGES TO SAFETY

Any harm that occurs inside a built environment could theoretically have been prevented or mitigated, at least in some very small way, by some feasible modification to the built environment. However, that definition of challenges to safety is far too sweeping to be useful. A built-in visual and motion building monitoring system might provide enough surveillance to reduce the fraction of heart attacks or strokes that prove fatal by detecting collapse or other actions indicating a person in distress, but if our purpose is to track the effectiveness of our current typical code and design choices, it would not be helpful to have tracking statistics dominated by the large number of heart attacks simply because it is technically feasible to build a structure that would help on some of them.

Any harm that occurs as a direct result of some failure in the built environment under conditions anticipated by the code is the type of event that should be tallied as an indicator of performance. However, that definition of challenges to safety is far too narrow to capture what good design can accomplish in the way of preventing or reducing harm. The narrow definition is more appropriate for assigning legal liability than for evaluating overall effectiveness and impact.

Also of concern is any harm that occurs as a result of conditions that were not anticipated by the code but that should have been, and would have been, anticipated with better information or better understanding of the factors driving perilous events and the performance of the built environment to challenges those events represent. The sometimes delicate and emotional debate if the codes should consider and provide design criterion for hostile acts or terrorism is a relatively new and highly complex subject. These events are neither predictable nor quantifiable. Although databases of such events exist, there is no return interval or probabilistic data to support a hard and fast design approach that could realistically be included in our design codes and standards to address these events. See also Section 1, Chapter 7, "Protecting Against Extreme Events."

John R. Hall, Jr., Ph.D., is NFPA's assistant vice-president for fire analysis and research.

Erin R. Twomey was a research analyst for fire analysis and research at NFPA during 2005–2006.

General crime deterrence and security measures, such as those covered by NFPA 730, *Guide for Premises Security,* do have a place in the types of harmful hazards that our codes and standards should address.

Options for Data

Natural disasters—including major wildfires but excluding other major fires—involve probabilistically occurring natural hazard–event triggers, whose probabilities vary by location (e.g., coastal location) and by characteristics (e.g., soil conditions) that themselves vary by location. Therefore, risk assessment for the hazards can be set up using risk maps for the triggering events, and codes can control design choices by specifying building performance in response to specified severities of these triggering events (analogous to fire scenarios used in performance-based design). The actual data on these natural disasters—and the losses they cause, which reflect both the event of severity and the building performance in resisting damage from the event—are what we track in order to gain insight into both the challenges to buildings and the performance of different building materials and designs in response to those challenges.

In the area of fire safety, the instances of harm occur in well-defined incidents, most of which lead to an encounter with an official body (e.g., a fire department) and the creation of an official record (e.g., incident report). These reported incidents are represented by the large or small samples of incidents captured by one or another international database. At least in the United States, these databases provide a baseline for surveillance of the magnitude of the harm proper design is intended to prevent or reduce. These databases provide information on the size of the problem, answering many, but far from all, of the questions we have about the effect of design choices and code language on resulting harm.

It is true that the database encompasses instances in which other parties are far more responsible than the builders and managers of built environments for the harm, instances that could not have been prevented or mitigated by even the most expansive, and often times expensive, of design standards. Nevertheless, the overall database can be used to identify candidate areas for targeted safety improvement, to estimate the magnitude of improved safety achievable by proposed design changes, and to monitor the changes in loss magnitudes associated with the implementation of design changes.

The databases available for monitoring, tracking, and surveillance of other types of harm within the built environment are not so well developed, except for major natural disasters, which are sufficiently few in number that they can be individually documented in great detail. For other instances of harm that do not involve fire or a natural disaster, there is less ability to develop statistics by type of harm and physical object creating the hazard (and thereby distinguishing between those that are part of the built environment and those that are not).

A notable exception may be criminal activity for which there are police crime and arrest databases. Deterrent systems comprised of metal detectors, screening processes, limited access doors, and overall procedural policies are examples of design changes to a built environment that could address this type of challenge.

Data are needed that can support a comprehensive analysis of all forms of harm associated with built environments, leading to a more focused analysis of options for action to address that harm and supported after actions are taken by follow-up monitoring of the impact of those actions in practice. This sequence corresponds to what is sometimes called program analysis and, after actions have been taken, program evaluation. Engineers and economists both apply risk assessment, which includes these steps as well, even though risk has different meanings to both.

Questions Involved in Safety Decisions

Conducting analysis in support of safety decisions requires detailed answers to a series of questions pertaining to the overall risk. Discussion of the following questions is the starting point for analysis.

- *Is this a significant risk?* Use readily available data to conduct a primary risk estimate. In this first triage phase, risks are identified and justifications are made as to whether or not the risk needs further examination.
- *What are the risk details?* Describe the circumstances of all probable scenarios of the risk, so an understanding of an overall developmental process of the risk can be created. During this process of risk factor identification, the potential impact of candidate strategies is determined. In this second triage phase, risks are deemed to be significant or not.
- *What are the best ways for dealing with this risk?* Identify candidate strategies, considering one or more options within each of several general approaches, such as prevention, mitigation, and separation. The options may be interventions, programs, or risk control techniques. In this treatment selection phase, a risk is considered and one or more ways are selected to address it. The risk is judged to be significant enough to focus on and conventional enough to change.
- *What is the best way to implement the strategy?* In this service delivery strategy phase, the cost-effectiveness of implementing one or more strategies that show promise is addressed.

The goal of this chapter is to provide readily available information that bears on the first question of establishing whether a risk is significant but not much on the subsequent questions. This chapter represents more of a starting point than a full overview of the challenges to safety in the built environment. A structure will be provided, and details will be filled in to the extent possible. It is the authors' intention that this starting point will be a first step in the development of more complete databases, providing answers to a wider range of safety questions about the built environment.

RELEVANT MAJOR SOCIETAL TRENDS

Growth in Older Population

For every form of fatal injury in a built environment, except for poisonings by solids or liquids and unintentional firearms injuries, older adults are at higher risk.[1] This part of the population is also the fastest-growing segment of the population, not only in the United States but also throughout the economically developed world.[2]

The United States has a death rate (8.3 per 1000 population) that is lower than its birthrate (14.1 per 1000 population). Annual population growth from 2000 to 2005 was 1.03 percent, and older adults defined as age 65 and older represent 12.4 percent of the total population. The United States must deal with both a need for more buildings to house a growing population and a need to remake the building stock to address the special needs of a rapidly growing older population.

Growth in High-Risk Areas

The U.S. population has been growing specifically in those regions where the likelihood of certain natural disasters is higher. Although population growth in coastal communities nationwide has actually been slower than in the rest of the country,[2] the state of Florida ranked third highest in number of people added in the 1990s, and Florida has by far the highest frequency of hurricane incidence of any state.[2,3] The geography of Florida is such that even population increases away from the coast can add to the people likely to be affected by hurricane-force winds and rain. The state that added the largest number of people was California, which also has by far the most people living in areas of frequent seismic activity.[2,3]

Whether growth in high-risk areas is disproportionately large or only proportional to growth elsewhere, it means the same perilous event will cause more deaths and damage more value in property, unless the increased exposure has been offset by improvements in protection.

MAJOR DATABASES

Even though 90 to 95 percent of all unwanted fires are unreported to fire departments, the ones that are reported number nearly 2 million a year, and they represent most of the deaths and property damage.[4] For every other type of harm, there is no analogous database with comparable breadth of scope and detail.

Major individual incidents, involving multiple deaths or millions of dollars of loss, are more likely to be extensively documented, and the more severe the harm caused by an incident, the more likely it is that a case study report on the incident will be published. It is, therefore, possible to develop lists and pattern analyses of these incidents. However, these large incidents generally account for only a small fraction of total harm to people, either by deaths or by nonfatal injuries. Such large incidents may account for a large share of damage to property, but for many forms of harm, like fire, they do not.

Database of Death Certificates

The national database of death certificates provides useful details on deaths due to injury.[5] The International Classification of Diseases (ICD) is designed for the classification of morbidity and mortality information for statistical purposes and for indexing of hospital records by disease and operations for data storage and retrieval.[5] The ICD has been revised approximately every 10 years since 1900 in order to reflect changes in understanding of disease mechanisms and in disease terminology.[5]

ICD-9 and ICD-10 were used to compile data tables for this chapter. However, although the traditional ICD structure has been retained, an alphanumeric coding scheme (ICD-10) replaces the previous numeric one (ICD-9).[5] This does provide a larger coding frame to leave room for future revision, but some categories of the previous edition have been left out of the latest revision. The data tables in the chapter will represent those changes.

Illnesses are generally not coded to indicate the involvement of or relevance of components of the built environment. This is an important gap, because it means we cannot really isolate and identify relevant illnesses, such as waterborne illness due to backflow or cross-connections in a plumbing system, Legionnaire's disease due to cultivating of bacteria or viruses in poorly designed or poorly operating air-circulation systems, and the kind of airborne illnesses associated with indoor air pollution. However, the statistics presented in this chapter will focus on fatal and nonfatal injuries, not illnesses.

The database of death certificates codes unintentional injuries as V01–X89, Y85–Y86. Deaths in which the injury was intentional (e.g., homicide, suicide) or where it the intent was unknown (codes X60–Y89) are largely excluded from the chapter. Deaths involving transportation or vehicles (codes V01–V99, Y85) are excluded from this chapter as being outside the definition of the built environment. Also excluded are injuries arising from medical problems (e.g., poisonings by drugs, medical malpractice), as these (codes X40–X49, Y4–Y84, Y88.0–Y88.3) are also deemed to be outside the definition of the built environment. Finally, statistics presented in the chapter exclude unintentional firearm injuries (codes X93–X95), radiation (codes W88–W91), and overexertion (codes X50–X57).

Databases on Injuries and Property Damage

Nonfatal injuries are not routinely captured, but there are three exceptions (in addition to the injury component of the fire incident databases). Occupational injuries are captured by the U.S. Department of Labor if they meet a severity threshold.[6] Injuries involving a trip to the hospital emergency room and associated with a consumer product are reported in a U.S. Consumer Product Safety Commission database.[7] (Recent changes mean that all emergency room injuries will be captured in the near future.) And the injuries people suffer that go unreported to any medical or other entity are tracked through an in-home sample survey as part of the National Health Interview Survey.[8] The database on occupational injuries uses approximately the same structure as the death certificate codes with additional detail in some places.

Apart from any natural disasters and fires, property damage is tracked only by the insurance industry and, for storms, by the National Weather Service.[9,10] Their published information has some useful detail, and it is possible that their unpublished coded data will in time permit more detailed analysis.

Influence of Major Incidents

Many issues in building codes and other codes for the built environment have historically been addressed not on the basis of number, rates, or percentages of fires or statistically derived indicators such as risk values, but rather on the basis of individual major incidents that indicate a specific type of hazard or

type of built-environment performance problem not previously encountered. For example, the Northridge earthquake of 1994 showed some problems with brittle fracture of structural steel that, although not necessarily significant in the loss in that incident, were nevertheless unexpected, leading to new research and code-change proposals. For this reason, this chapter includes not only statistics but also lists of deadliest or costliest incidents, where such lists are meaningful and potentially useful. There is an extended discussion in Section 2, Chapter 1, "Physics and Chemistry of Fire," of the past century of progress in fire safety, by major occupancy type, in which trigger events were often individual fires but progress could be measured statistically.

OVERVIEW OF TYPES OF PERIL CAUSING HARM

Table 1.1.1 provides a first-level classification of types of peril causing harm to people (deaths, injuries, and illnesses) and to property (including potential business interruption or other interference with mission continuity), cultural or historical value damage, and environmental damage. Direct and indirect perils causing harm are both of interest. Fire, burns, and electric shock; falls; natural disasters; water or storms; and harmful environments are the main types of peril causing harm in the built environment.

Fire is as a rapid, persistent, chemical reaction that releases heat and light.[11] In the built environment, fire is combined with explosions, electric shock, scalds, and other types of burns. The majority of harm to property by fire is from thermal or corrosive effects.

Falls are the most common type of peril causing harm in the built environment and include injuries caused by the fall and injuries due to objects falling on other people. Types of falls in the built environment include the following:

- Falls from or on stairs and steps
- Falls from or on ladders or scaffolding
- Falls out of structures
- Falls from one level to another
- Falling objects

Falling objects may be a direct result of structural collapse caused by another type of peril harming the built environment.

TABLE 1.1.1 Typology of Types of Peril Causing Harm to People and Property in the Built Environment

Peril Causing Harm	*Harm to People*	*Harm to Property**
Fire, burns, and electrical shock	Burns from fire, hot surfaces, steam, or other hot objects Electrical shock Injury from structural failure resulting from fire Explosions Injury from inhaled toxic products Injury from oxygen deprivation resulting from fire	Direct harm from thermal or corrosive effects of fire Damage from structural failure resulting from fire
Falls	Injuries due to fall Injuries due to objects falling on people	Structural collapse
Natural disasters (e.g., earthquakes, landslides, hurricanes, tornadoes)	Injury from structural failure resulting from natural disaster Fire injuries Injuries due to falling objects or objects in motion Fall injuries Postevent harmful environment (e.g., disease, exposure) Postevent electrical shock	Damage from structural failure resulting from natural disaster Fire Wind and water damage
Water (e.g., floods, storms)	Injuries due to falling objects or objects in motion Drowning Postevent electrical shock Postevent harmful environment	Damage due to wind, water, or storm loads (e.g., snow or hail) Flooding Water damage
Harmful environment	Poisoning by solid, liquid, or gas Mechanical suffocation Water-borne or airborne disease Adverse health effects of excessive heat or cold, insufficient or poor lighting, excessive noise or vibration, or radiation exposure (e.g., radon)	Corrosive or other damaging effects of moisture Damage due to heat or cold Damage due to noise or vibration Radiation damage

Note: The categories in this table are not taken from any published source and are not in general use. They are proposed only as a basis for organizing the material in this chapter. Some performance issues for the built environment are excluded from this typology, including all issues of amenities and issues of access, such as those addressed by the Americans with Disabilities Act (ADA). Vehicles and outdoor settings not involving structures are excluded from consideration here, even though most of those environments can be regarded as built.

*Includes business interruption, other functionality damage, and damage to heritage.

Natural disasters are created by natural processes and as disasters effect society and the built environment. Earthquakes, hurricanes, and tornadoes all contribute to structural damage and may produce serious types of harm such as fire, electric shock, and fall injuries, all of which can be fatal.

Water from storms and floods has the potential to create major property losses, although most of the deaths in this category are not associated with catastrophic events.

A harmful environment refers to an environment in which people are exposed to harmful substances, such as airborne disease and poisonous gases. The built environment serves as a barrier to protect people from harm. Like people, it is susceptible to any type of peril causing harm. Harmful environments can exist alone or as the result of another type of peril. Sick building syndrome, which can result from mold or release of volatile organic compounds (VOCs) from synthetic materials, may cause illness in some occupants.

The degree of harm depends on exposure and the relative vulnerability of the built environment to a particular peril. Both exposure and vulnerability depend considerably on the location chosen for the structure. Soil type, rainfall, geography, and wind speed are examples of factors contributing to the degree of harm on the built environment.

FIRE, BURNS, AND ELECTRIC SHOCK

This chapter will provide a few fire statistics in context with other hazards, with nonfire-thermal-related injuries addressed at greater length, because the fire loss experience including magnitudes, trends, and patterns is extensively discussed in Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection."

Fire Losses and Injuries

Tables 1.1.2 and 1.1.3 provide overviews of U.S. fire deaths and related property damage, respectively. Table 1.1.2 compares fire deaths as estimated by the NFPA survey with those recorded by the primary fire-related X-codes in the national death certificate database. Table 1.1.3 excludes transportation and vehicle-related fires, which is why those statistics track more closely with NFPA survey data on structure fires alone and are also provided in Table 1.1.2. Death certificate counts from these X-codes can also exclude some incendiary fire deaths but should do so only if the fatal injury was itself known to have been intended, in which case it qualifies as a homicide or suicide and is classified there for primary categorization. It appears that few such fire deaths are so classified.

The NFPA survey can miss deaths occurring outside a reported fire. Clothing ignitions are the classic example, but the death certificate database tracks clothing ignition deaths separately, and such deaths total less than 200 per year, some of which will be reported to fire departments. The NFPA survey is also subject to some sampling variation. The estimate of total fire deaths, for example, is subject to a 95 percent confidence interval of plus or minus just under 400 deaths, which is a more typical difference between the structure fire death estimate and the death certificate tally.

TABLE 1.1.2 Tracking U.S. Fire Deaths Based on NFPA Survey

Year	*Total*	*Structure Fire Only*	*Based on Death Certificate Coding X00–X09 Only*
1993	4,635	3,980	3,914
1994	4,275	3,590	3,999
1995	4,585	3,985	3,768
1996	4,990	4,220	3,748
1997	4,050	3,510	3,502
1998	4,035	3,420	3,263
1999	3,570	3,040	3,348
2000	4,045	3,535	3,377
2001*	6,196	5,671	3,309
2002	3,380	2,775	3,159

*2,451 of these deaths occurred due to the events of 9/11/01.

Source: NFPA survey, National Safety Council (NSC), and National Center for Health Statistics (NCHS) Vital Statistics System provided data for the number of deaths.

TABLE 1.1.3 Tracking U.S. Property Loss to Fire

Year	*Based on NFPA Survey (in Billions of Dollars)*	*Estimated by Insurance Services Office (in Billions of Dollars)*
1993	8.546	11.331
1994	8.151	12.778
1995	8.918	11.887
1996	9.406	12.544
1997	8.525	12.940
1998	8.629	11.510
1999	10.024	12.428
2000	11.207	13.457
2001	44.023	17.118
2002	10.337	17.586

Note: NFPA survey figures are estimates by fire officers, sometimes with the benefit of information on insurance estimates. ISO estimates include actual home insurance claims and estimates and losses in uninsured or underinsured properties.

Sources: NFPA survey; Insurance Information Institute, *The I.I.I. Insurance Fact Book 2006,* New York: Insurance Information Institute, 2006.

Similarly, there are a number of possible reasons for the modest but growing gap between the NFPA estimates of direct property damage and the Insurance Services Office estimates of fire loss, as shown in Table 1.1.3. The insurance industry estimate may include indirect losses (e.g., reimbursement for temporary housing or business interruption) and may overadjust for losses in uninsured or underinsured properties. The fire department–based NFPA estimate will miss losses in unreported fires even if they result in insurance claims. The insurance industry estimate is a mix of detailed observations by highly trained loss appraisers and self-reported losses as adjusted in response

to comments from appraisers who have not personally observed the fire scene. It is hard to say whether such estimates will be higher or lower, more or less accurate, than estimates by fire officers, who lack the same loss-estimation training but sometimes have access to insurance appraisals of the same fires and experience in other occupations, which give them the insight into what things cost.

Although the NFPA survey estimates are the best measures of fire loss, when fire is considered by itself, the available statistics on other hazards and types of harm are most comparable to the death certificate data and the insurance industry estimates for fire.

Burns and Electric Shock

Table 1.1.4 provides available information on total U.S. burn injuries, based on in-home surveys conducted by the U.S. Department of Health and Human Services. The samples are sufficiently small that the estimates of burn injuries are subject to considerable uncertainty. (For example, the estimate of a quarter million bed-disabling burn injuries per year in or during 1980 to 1981 is subject to relative error of more than 30%.) This uncertainty is also the reason why published analyses of the survey data do not always address burns and, when they do, use 2- or 3-year averages to reduce error to an acceptable level. The principal finding of Table 1.1.4 is that total U.S. burn injuries declined from roughly 2 million in 1980 to 1981 (and for at least two decades) to roughly 1 million in 1991 to 1993.

Table 1.1.5 provides a 10-year trend on pressure vessel explosions. Explosions involving pressurized tires, pipes, or hoses make up the largest share of fatal injuries, whereas boiler injuries make up the smallest share. Note that gas cylinders are a category under pressure vessels. This can point to a rough separation of natural gas (excluding pressure vessels) and LP-gas (gas cylinder explosion), although each of these is part of a category that can include other various situations and gases. Within the "explosion of other specified pressurized device" there is a roughly even split that tilts somewhat toward the unknowns.

Table 1.1.6 provides a 10-year trend on deaths due to injuries from hot objects. Figure 1.1.1 indicates 67 percent of those fatal injuries involve hot tap water, drinks, food, fats, or cooking oil, whereas 22 percent of those fatal injuries are caused by steam or other hot liquid or vapor. Figure 1.1.2 provides an overview of the death rates per million population by age-group for deaths due to injury by steam or other hot liquid or vapor. These rates are a measure of the differences in risk of death from this type of harm for different age-groups. As with fire deaths, the very young and older adults are the two high-risk age-groups, but unlike fire, the very young are not that much more at risk

TABLE 1.1.4 U.S. Burn Injuries Based on Responses to National Health Interview (In-Home) Survey

Measure	*1980–1981*	*1985–1987*	*1991–1993*
Burn injuries (per year)	2,130,000	1,735,000	1,129,000
Burn injuries per 100 population (per year)	1.0	0.7	0.4
Medically attended burn injuries	1,615,000	1,614,000	1,073,000
Restricted-activity burn injuries	1,213,000	810,000	445,000
Bed-disability burn injuries	244,000*	399,000	124,000
Average number of days of restricted activity per restricted-activity burn injury	6.1	8.8	NA
Average number of days of bed disability per bed-disability burn injury	5.7	8.1	NA

*Relative standard error of estimate exceeds 30 percent.
NA = Not available or not yet available.

2001	114
2002	102

Note: Involved corrosive substances and steam. Data prior to 1999 listed as Death Certificate Code E924. Post-1999 data listed as Death Certificate Codes X10–X19.

Sources: National Safety Council, *Accident Facts* and *Injury Facts,* Itasca, IL: National Safety Council, 1992–2006; 2002 data from CDC/NCHS website, http://www.cdc.gov/ncipc/osp/data.htm.

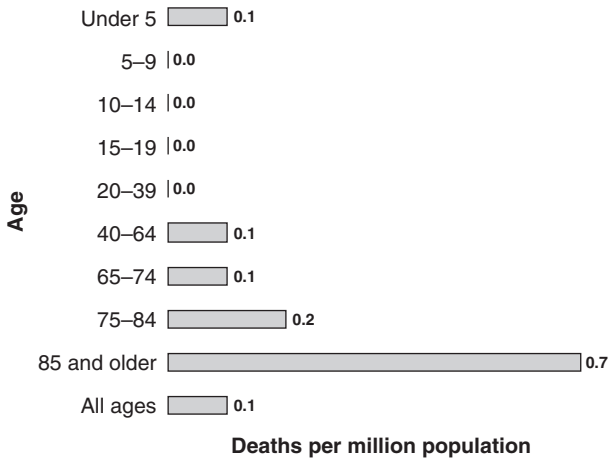

FIGURE 1.1.2 Deaths Due to Steam or Other Hot Liquid or Vapor, by Age, 1999–2002 (Source: CDC/NCHS, National Vital Statistics System, Mortality, http://www.cdc.gov/nchs/datawh/statab/unpubd/mortabs/gmwki10.htm)

than the all-ages average, and the older adults have risks much higher than those for the very young.

Table 1.1.7 provides a 10-year trend for the available components of deaths due to unintentional injury by electrical current. The largest share of fatal injuries due to electrical current falls into the "other or unknown" category. This table reflects the revision of the ICD. Home equipment, industrial equipment, and generating plants or distribution categories were discontinued in the tenth revision. However, data from 1999 to 2002 also demonstrate that the largest share of fatal injuries falls into the "other specified" category.

According to data prior to 1999, injuries involving home or industrial equipment have been declining substantially. Those involving generating plants or distribution equipment have not. As a result, deaths from electric current associated with generating plants or distribution now routinely outnumber those associated with home equipment by a large margin.

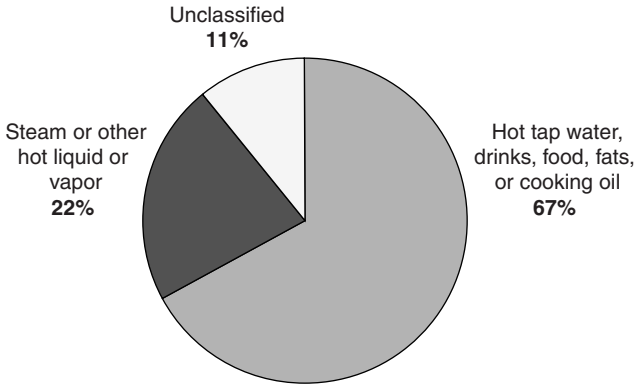

FIGURE 1.1.1 Deaths Due to Hot Object, by Type of Object, 1999–2002 (Source: CDC/NCHS, National Vital Statistics System, Mortality, http://www.cdc.gov/nchs/datawh/statab/unpubd/mortabs/gmwki10.htm)

FALLS

Falling People

Falls account for by far the largest number of fatal injuries among all the types of injuries that can occur in the built environment. Table 1.1.8 provides 10 years of data pertaining to deaths due to falls for the major types of falls. The "other or unknown-type" category contains the largest share of deaths, whereas the category for falls on the same level from collision, pushing, or shoving has the smallest share of deaths. Nearly half of these types of falls occur in sports and the rest involve other or unknown-type activities.

Falls from or on Stairs or Steps. Note that deaths due to falls from or on stairs or steps—the major category of falls most clearly linked to the design of the built environment—have been increasing over the period analyzed and are up by about 20 percent in the most recent decade analyzed. This is a larger increase than can be explained by the growth in total population, but it might be better explained by an age-adjusted analysis, which would factor in not only the growth in the total population but also the growth in the older-adult share of the population.

Figure 1.1.3 provides an overview of deaths per million population, by age, for fatal falls from or on stairs or steps. The risk is negligible for children, even children under age 5, but rises rapidly among older adults. Half of all deaths from falls from or on stairs or steps are people age 75 and older. This risk for adults age 85 or older is roughly 14 times the all-ages risk and 65 times the risk for younger adults.

Falls from or on Ladders or Scaffolding. Table 1.1.9 shows the total number of falls on or from ladders or scaffolding, as

2002	11,382	1,598	406	557	NA	509	646	12	7,654

Source: National Safety Council, *Injury Facts* and *Accident Facts,* Itasca, IL: National Safety Council, 1992–2002; 2002 statistics from the CDC/NCHS website, http://www.cdc.gov/ncipc/osp/data.htm.

well as both components. Falls on or from ladders contains the largest share of fatal injuries. Falls involving ladders dominate by 4 to 1. Figure 1.1.4 provides an overview of deaths per million population for fatal falls from or onto ladders, by age of victim. The risk is highest by far for older adults. A majority (55%) of the deaths are adults age 65 or older.

Falls out of Structures. Figure 1.1.5 provides an overview of deaths per million population for fatal falls out of a building or structure, by age of victim. There has been considerable publicity surrounding preschool children falling out of buildings, resulting in a recent push for bars on windows, which, if installed incorrectly, can become a deadly barrier preventing safe escape from a fire in the building. However, as with every type of fatal fall examined so far, the higher risks are faced by older adults. The risk for adults age 85 and over is five times the all-ages risk.

Falls from One Level to Another. Table 1.1.10 provides a breakdown of the different types of fatal falls from one level to another. Falls from playground equipment are a negligible share of the total. Falls from cliffs are an important component

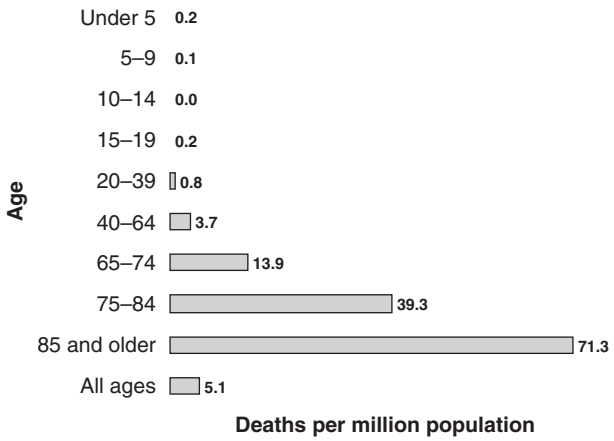

FIGURE 1.1.3 Deaths Due to Falls on or from Stairs or Steps, by Age, 1999–2002 (Source: CDC/NCHS, National Vital Statistics System, Mortality, http://www.cdc.gov/nchs/datawh/statab/unpubd/mortabs/gmwki10.htm)

but one that has been declining sharply. Falls from chairs or beds compose the largest share of fatal falls from one level to another, and those deaths have not been declining.

Figure 1.1.6 shows that differences in this risk by age are the largest yet seen in this chapter. Adults age 85 or older have more than 30 times the all-ages risk of suffering a fatal fall from a chair or bed. This age group accounted for roughly half (49%) of all deaths from this type of fall. Young children have a higher risk than older children but much less risk than older adults.

The category of "other" falls from one level to another shows a very different profile than that for falls from chairs and beds. The age profile more closely resembles that for deaths due to falls involving cliffs, which means it would be inappropriate and possibly misleading to treat these underspecified falls as if

TABLE 1.1.9 Unintentional Injury Deaths Due to Falls from Ladders Versus Scaffolding, Deaths Coded on U.S. Death Certificates

Year	*Total Falls on or from Ladders or Scaffolding*	*Falls on or from Ladders*	*Falls on or from Scaffolding*

Sources: National Safety Council, *Accident Facts* and *Injury Facts,* 1992–2004 editions, Itasca, IL: National Safety Council, 1992–2004; 2002 data from CDC/NCHS website, http://www.cdc.gov/ncipc/osp/data.htm.

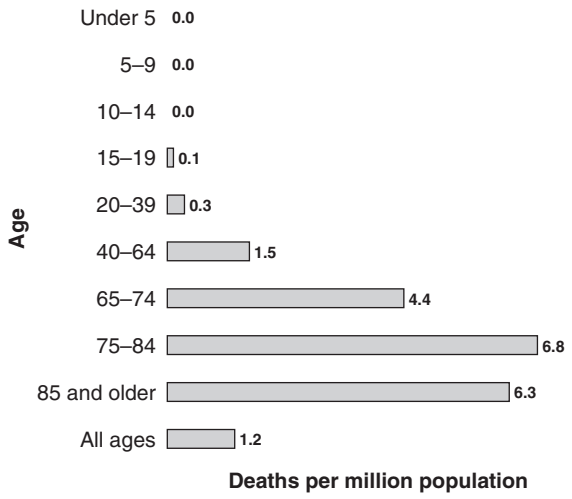

FIGURE 1.1.4 Deaths Due to Falls on or from Ladders, by Age, 1999–2002 (Source: CDC/NCHS, National Vital Statistics System, Mortality, http://www.cdc.gov/nchs/datawh/statab/unpubd/mortabs/gmwki10.htm)

they were similar to falls from chairs and beds. The age profile for these falls looks more like one might expect from falls off roofs, but it seems unlikely that this specific scenario would account for such a large death toll.

Nonfatal Falls. Table 1.1.11 illustrates the number of nonfatal falls based on responses to the government's in-home survey of health problems. The nonfatal fall injuries in Table 1.1.11 outnumber the fatal fall injuries in Table 1.1.8 by nearly a thousand to one. The relative importance of various types of falls is different, reflecting in part the fact that some types of falls—for example, from stairs or steps, or out of a building structure—are more likely to be fatal than some other types of falls.

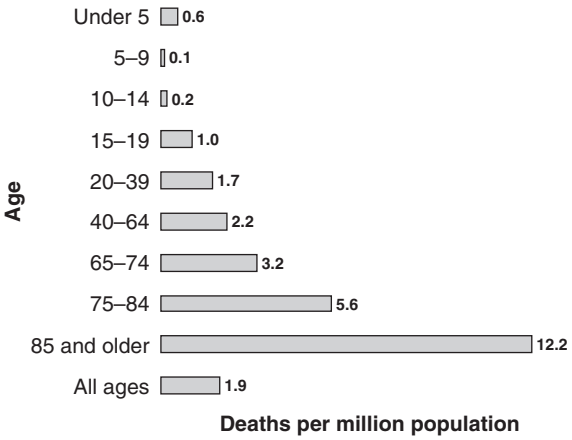

FIGURE 1.1.5 Deaths Due to Falls out of Building or Structure, by Age, 1999–2002 (Source: CDC/NCHS, National Vital Statistics System, Mortality, http://www.cdc.gov/nchs/datawh/statab/unpubd/mortabs/gmwki10.htm)

International Perspective on Falls. Table 1.1.12 illustrates the unintentional injury death rates due to falls at the international level. The table shows the averages of available 2000–2002 fatal fall rates for different countries. Unlike the case with fire deaths, the U.S. rate of fall deaths per million population is one of the lowest; Argentina has the lowest rate among all the countries listed.

An analysis of the international differences would need to begin with an examination of differences in age distributions, which could make a large difference in light of the enormous differences in risk of death from falls among age groups. Also, it would be useful to know how much variation in heights of surfaces normally encountered by people exists from place to place. Certainly, high-rise buildings are more common in some countries than others, but it is unlikely that this is a major factor in the overall statistics. Other differences, such as the average heights of beds or sleeping surfaces (e.g., futons), might exist, however, and might be important. Differences in contributing risk factors, such as the use of alcohol, could be important. And the possibility of differences in definitions used in practice or in data collection should also be considered.

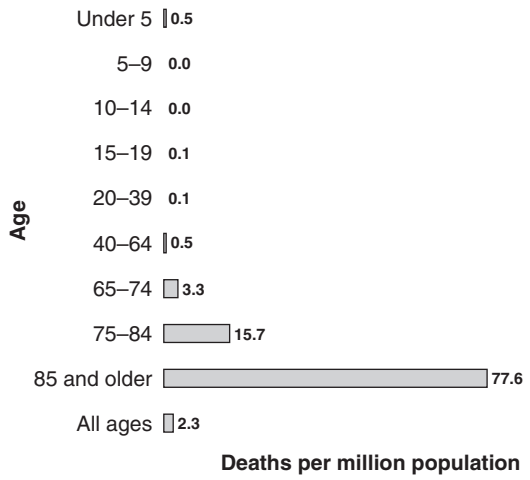

FIGURE 1.1.6 Deaths from Falls from Chairs or Beds, by Age, 1999–2002 (Source: CDC/NCHS, National Vital Statistics System, Mortality, http://www.cdc.gov/nchs/datawh/statab/unpubd/mortabs/gmwki10.htm)

Falling Objects

Deaths due to falling objects are the kinds of deaths that might include a significant share that can be related to the design and operating decisions of the built environment. Unfortunately, the coding provides no details on the kinds of falling objects involved. Whatever the objects may be, the toll from objects has

TABLE 1.1.11 U.S. Nonfatal Fall Injuries Based on Responses to National Health Interview (In-Home) Survey

Type of Fall	*Estimated 1997 Injuries*
Total fall episodes	11,306,000
Total types of falls mentioned*	12,285,000
Onto floor or level ground	4,158,000
From or onto stairs or steps	1,296,000
From or onto curb or sidewalk	1,162,000
From or onto chair, bed, sofa, or other furniture	807,000
From or onto playground equipment	493,000
From ladder or scaffolding	447,000
Into hole or other opening	382,000
From or onto escalator, building or other structure, tree, toilet, bathtub, or pool	610,000
Unreported type	2,793,000
Refused to give type or did not know	135,000

Note: Sum may not equal total because of rounding error.
*More fall types are mentioned than there were fall episodes because respondents could specify up to two types.

shown little decline. Table 1.1.13 illustrates the number of fatal injuries caused by falling objects.

Striking or Being Struck by Falling Objects

Within the category of people striking against or being struck by objects, it is possible to distinguish deaths due to people striking other people in a crowd, as in a hurried or rushed evacuation or when a crowd presses someone against a stationary barrier. Instances that might fit within this category might also be coded somewhere else. A good example would be a crowd-crushing situation that would be considered not to fit the "struck by" label.

Table 1.1.14 provides a breakdown of 2004 occupational injuries and illnesses by event or exposure, overall and for each of three groups of objects that are entirely or mostly recognizable as components of the built environment—floors, walkways, and ground surfaces; furniture and fixtures; and machinery.

NATURAL DISASTERS

Earthquakes

An earthquake is the vibration of the Earth's surface by the rapid release of energy. Most earthquakes are caused by slippage along a geologic fault in the Earth's crust.[12] The energy released during an earthquake is measured by the Richter scale (Table 1.1.15). Each unit of Richter magnitude equates to roughly a 32-fold energy increase. With each increase in magnitude comes the increased probability for loss of life and property damage. Earthquakes include many of the deadliest and costliest incidents in history.[13] Approximately 6200 earthquakes detectable by human beings occur every year.

Deadliest U.S. Earthquakes. Table 1.1.16 lists the 10 deadliest U.S. earthquakes of all time, leading with the 1906 San Francisco earthquake, which caused the costliest U.S. fire of all time. Six out of the 10 earthquakes occurred in California, and two others were offshore earthquakes near Alaska that produced tsunamis that resulted in the deaths of many. Since earthquakes have the ability to produce major postevent disasters such as fire, tsunamis, flooding, and landslides, these events could be listed as a multiperil incident. Reliable death tolls are hard to come by for older events, and property loss totals are even rarer, regardless of reliability. Therefore, it is possible that some of these incidents do not belong on the lists and other events, no longer even cited in general references, do belong.

Table 1.1.17 lists the 10 deadliest world earthquakes of all time, with the top earthquake occurring in China. This earthquake resulted in 830,000 estimated deaths and is possibly the greatest natural disaster of all time. The following earthquakes are estimated to have resulted in over 100,000 deaths each.

Costliest U.S. Earthquakes. Table 1.1.18 lists the 10 costliest U.S. earthquakes of all time, based on adjustment to 2004 dollars. The 1994 Northridge, California, earthquake and the 1989 Loma Prieta earthquake lead the list by a substantial margin, with the 1964 Anchorage, Alaska, earthquake ranking third. All but one of the costliest earthquakes occurred in California.

Landslides

Landslides are the downslope movement of rock and soil under the influence of gravity.[12] All material resting on a slope is considered to have an angle of repose, that is, an angle at which the material will remain stable.[13] Gravity is the controlling force of landslides, but several factors play an important role in creating downslope movement.

Factors Triggering Landslides. Landslides are sometimes triggered when periods of heavy rains or periods of snowmelt saturate surface materials. Oversteepening of slopes is another important trigger of landslides, whereas removal of vegetation allows for the enhancement of landslides. If the slopes are steep and water is plentiful, a landslide can easily occur.[12] Landslides commonly occur in connection with other major natural disasters such as earthquakes, wildfires, and floods.[14]

Landslides constitute a major geologic hazard because they cause $1–$2 billion in damages and more than 25 fatalities each year.[14] Landslides pose serious threats to the built environment in many parts of the country. Expansion of urban and recreational developments into hillside areas results in increasing numbers of residential and commercial properties in danger of landslides.

Deadliest Landslides Worldwide. Table 1.1.19 lists the 10 deadliest landslides of all time, six of which were caused by an earthquake. The most recent major landslide occurred in 1990 in Iran. A magnitude 7.7 earthquake shook the nation, triggering major landslides that claimed the lives of over 40,000 people. Two of the landslides making the list were triggered by consecutive days of torrential rains.

Hurricanes, Cyclones, and Tornadoes

A hurricane is a tropical cyclonic storm having winds in excess of 74 miles per hour. Hurricanes most often develop in late summer when water temperatures have reached 80°F or higher and, thus, are able to provide the necessary heat and moisture to the air. Based on the study of past hurricanes, the Saffir-Simpson

TABLE 1.1.16 Deadliest U.S. Earthquakes of All Time

Location	Richter Scale Magnitude	Year	Estimated Deaths	Comments
1. San Francisco, CA	7.7	1906	~3000	Fires caused extensive damage and deaths
2. Unimak Island, AK	8.1	1946	165	Tsunami: 159 Hawaii, 5 Alaska, 1 California
3. Prince William Sound, AK	9.2	1964	131	Tsunami: 98 Alaska, 11 California, 1 Oregon
4. Long Beach, CA	6.2	1933	115	Property damage estimated at $40 million
5. Ka'u District, Island of Hawaii	7.9	1868	77	Tsunami, landslide; largest earthquake in HI
6. San Fernando, CA	6.6	1971	65	Property damage estimated at $505 million
7. Loma Prieta, CA	6.9	1989	63	Estimated $6 billion in property damage
8. Northridge, CA	6.8	1994	61	Damages in excess of $40 billion
9. Charleston, SC	6.6	1886	60	Greatest historical earthquake in eastern United States
10. San Juan Capistrano, CA	7.5	1812	40	Damage estimate unknown

scale (Table 1.1.20) was established to rank the relative intensities of hurricanes. Predictions of hurricane severity and damage are expressed in terms of this scale.[12]

Deadliest U.S. Hurricanes. Table 1.1.21 lists the 10 deadliest U.S. hurricanes of all time. Eight of the deadliest hurricanes occurred before the convention of assigning names to hurricanes that began after World War II. Poor record keeping prior to the twentieth century and the fact that some hurricanes wiped out all life on isolated or island communities may mean that some hurricanes with true death tolls high enough to justify inclusion are not recognized as such. This also explains the considerable variation in estimated death tolls for some of these storms from one source to another.

The most recent hurricane to appear on the list of the 10 deadliest is Hurricane Katrina in 2005. Hurricane Katrina struck the Gulf Coast as a strong category 3 hurricane, resulting in severe storm surge damage along the Louisiana, Mississippi, and Alabama coasts and extensive wind damage. Secondary events, including severe urban flooding as a result of failure of parts of the levee system in New Orleans, resulted in over 1300 deaths.[15]

Deadliest Cyclones Worldwide. A *cyclone* (the term includes hurricanes and typhoons) is a low-pressure center characterized by a counterclockwise flow of air in the Northern Hemisphere (and a clockwise flow in the Southern Hemisphere). The terms *hurricane* and *typhoon* are regional names, with hurricane being the common choice for cyclones east of North and Central America.[12] Table 1.1.22 lists the five deadliest cyclones of all time. Four of the five occurred on the Indian subcontinent, and the deadliest one of all—the 1970 cyclone in what was then

TABLE 1.1.18 Costliest U.S. Earthquakes of All Time

East Pakistan—triggered the most extreme response to ineffective emergency response in world history, namely, the creation of the breakaway nation of Bangladesh.

Costliest U.S. Hurricanes. Table 1.1.23 lists the 10 costliest U.S. hurricanes of all time. The list is comprised mainly of hurricanes from 2004 and 2005. The 2004 Atlantic hurricane season caused an estimated $22.9 billion in insured losses according to ISO's Property Claim Services unit, the highest amount ever recorded in a single year up to the 2005 season.[9] The 2005 hurricane season was the worst on record, with 26 named storms, 14 of which became hurricanes and more than $46 billion in insured losses, resulting in a record high.[9] The season produced Katrina in August, the most costly hurricane in U.S. history. The losses from Hurricane Katrina doubled the losses of Hurricane Andrew in 1992.

Tornadoes. A tornado is a small, very intensive cyclonic storm with exceedingly high winds. Tornadoes form in association with severe thunderstorms that produce high winds, heavy rainfall, and hail. Their sporadic nature and violent winds cause many deaths each year. One commonly used guide to measure tornado intensity is the Fujita intensity scale (Table 1.1.24). Because tornado winds cannot be directly measured, a rating on the Fujita scale is determined by assessing the worst damage produced by a storm.[12]

Table 1.1.25 lists the number of tornadoes and associated deaths for the past 10 years. Table 1.1.26 lists the 10 deadliest U.S. tornado incidents of all time and in a contiguous region. The three single-tornado incidents on the list all occurred in the nineteenth century.

Tornado incidents rarely produce combined property losses in excess of $1 billion and, possibly for that reason, there were not enough tornado incidents with documented high property losses to justify preparing a list of the 10 costliest tornado incidents.

Water or Storms

Deaths in the water certainly occur as a consequence of a natural disaster. However, most of the deaths in the water or storms group do not involve catastrophic events. They involve drownings or submersions in more everyday situations, typically associated with swimming or diving. Table 1.1.27 provides an overview of these water- and storm-related fatal injuries.

Drownings in bathtubs come closest to involving design options for the built environment. Figure 1.1.7 shows that this

TABLE 1.1.23 Costliest U.S. Hurricanes of All Time

risk targets the very young and very old, much as fire does. Children under age 5 have roughly three times the all-ages risk, a higher relative risk than the same age children have for death from fire. Older adults show a lower relative risk for drowning in bathtubs than they do for death from fire.

Storms

Types of Storms. Storm data collected by the National Weather Service[10] show significant annual averages of damage (including both property and crop damage) in 2000 to 2004 from three types of storms:

- *Hail storms* average $0.97 billion per year
- *Thunderstorms (including wind)* average $0.33 billion per year
- *Winter storms* average $0.52 billion per year

Four other types of storms or storm effects—lightning, coastal storms, tsunamis, and ice storms—are not shown in the preceding list because each type averages much less damage per year in 2000 to 2004 than do the listed types. Clearly, this will not be true of 2005, when losses from the December Asian tsunami are included.

TABLE 1.1.24 Fujita Intensity Scale

Scale	Wind Speed (mph)	Damage
F0	<72	Light damage
F1	72–112	Moderate damage
F2	113–157	Considerable damage
F3	158–206	Severe damage
F4	207–260	Devastating damage
F5	>260	Incredible damage

Winter Storms. Available references do not cite a sufficient number of very costly individual winter storms, ice storms, hail, storms, or freezes to generate comparable lists. It also is not clear how much of the reported loss for such storms is relevant to such an assessments of impact on the built environment. For example, crop damage and snow removal costs would not be relevant to such an assessment. Damage due to snow loading is not separately tabulated in any published data, which would be the most relevant form of damage.

It can be noted that the highest U.S. property loss discovered for a winter storm was the 1993 blizzard dubbed the "Storm of the Century," with losses estimated at $3 to $6 billion, including $1.75 billion in insured loss. In the 1990s, however, at least three European winter storms, code named Daria, Lothar, and Vivian, each accounted for at least $4 billion in insured losses. The Storm of the Century also would rank second on a list of the 10 deadliest U.S. winter storms, accounting for an estimated 200 to 270 deaths, second only to an 1888 storm in the Northeast, in which 400 to 800 people were estimated to have died. A 1956 winter storm in Europe had the highest worldwide death toll identified at 1000 killed.

TABLE 1.1.27 Deaths Due to Drownings, Submersions, Storms, or Floods, Deaths Coded on U.S. Death Certificates

Year	*Cataclysmic Storms or Floods**	*Total Drownings and Submersions*	*Drownings in Bathtubs*	*Other or Unknown Type Drowning During Sport or Recreation*	*Drowning or Submersion Including Swimming or Diving Not for Sport or Recreation*

Estimating Property Loss from Natural Disasters

Table 1.1.28 represents an attempt to estimate property loss not limited to catastrophes for major sources of such loss. The table is limited to insured loss and to loss covered under homeowner policies. The table combines published data on shares of premium dollars that go toward compensation for losses with published data on the share of losses accounted for by each of several major hazard groups.

The fire and lightning losses in Table 1.1.28 should be comparable to NFPA statistics on property damage to in-home fires, and, in fact, the figures are reasonably close. This encourages optimism that the figures on wind and hail and on water damage and freezing are also comparable.

TABLE 1.1.28 Estimated Insured Property Damage Under Homeowners Multiple-Peril Policies

	Estimated Loss (in Billions of Dollars)		
Year	*Fire, Lightning, and Debris Removal*	*Wind and Hail*	*Water Damage and Freezing*
1994	5.2	2.0	4.7
1995	5.9	4.0	2.9
1996	5.4	5.0	3.6
1997	6.7	3.2	3.1
1998	6.5	6.3	3.3
1999	7.2	5.6	4.4
2000	9.1	4.5	4.9
2001	8.3	5.8	5.9
2002	8.4	5.3	5.6
2003	8.3	6.6	5.7
2004	6.2	13.4	4.6

Source: *The I.I.I. Insurance Fact Book 2003–2006,* New York: Insurance Information Institute, 2003–2006.

It has already been noted that fire losses in individual large loss fires do not dominate total property losses due to fire. In the majority of the years shown in Table 1.1.28, losses due to hurricanes—the large-loss windstorms—would dominate total property damage due to wind and hail. However, losses due to major flood events do not appear to dominate the total water damage and freezing values. In any event, most home insurance policies exclude damage due to major floods from coverage, which is why the Federal Emergency Management Agency's National Flood Insurance Program (NFIP) was created. The plumbing failures and ordinary rainstorms that probably account for most or all of the loss under water damage and freezing should constitute challenges that design for the built environment is meant to address.

Floods

Deadliest U.S. Floods. Table 1.1.29 lists the 10 deadliest U.S. floods of all time. The well-known Johnstown, Pennsylvania, flood of 1889 has by far the highest death toll on the list. The most recent flood to appear on the list was the 1972 Rapid City, South Dakota, flash flood. Like the classic Johnstown flood, a dam collapse was a critical event in the large loss. The other floods primarily involved rising waters swollen by rain and are more in keeping with the use of flood plain maps as a device for quantifying risk by location. Half of the floods on this list involved locations in the Mississippi River valley.

Deadliest Floods Worldwide. Table 1.1.30 lists the five deadliest floods of all time worldwide. All of them occurred in China. Two of the incidents, occurring three centuries apart, were initiated or worsened by deliberate acts in a wartime setting. One involved the destruction of river dikes by rebels, and the other involved flooding crops already ravaged by destruction by troops. In general, lists in this handbook of deadliest or costliest incidents exclude wartime incidents, which would account for many of the deadliest fires and avalanches* of all time, to name just two examples. The exception is made here only because there are so few incidents known to involve death tolls on the scale of incidents in Table 1.1.26 that the alternative to including these incidents would have been to shorten or exclude this list.

Costliest U.S. Floods. Table 1.1.31 lists the 10 costliest U.S. floods of all time. Even though all loss figures have been adjusted for inflation, half of the listed floods are from the last decade of the twentieth century. The costliest incident of all resulted in as much loss as the next two costliest floods combined. Four of the 10 floods involved the Mississippi River valley. The last three floods on the list were due in whole or in part to rivers swollen by melting snow, a scenario that did not contribute to any of the 10 deadliest floods.

Table 1.1.32 provides an overview of death tolls and losses from U.S. floods for the five most recent years available based on the storm data tracking done by the National Weather Service of the U.S. National Oceanic and Atmospheric Administration.

*An avalanche is a type of landslide distinguished by usually rapid movement of a newly detached segment of earth.[12] This definition is useful for *Fire Protection Handbook* Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection."

TABLE 1.1.29 Deadliest U.S. Floods of All Time

Flash floods always dominate river floods as causes of death and in most years also dominate as causes of property loss, but the damage caused by river floods in the exceptional years is more than enough to dominate multiyear statistics.

FATALITIES INVOLVING HAZARDOUS ENVIRONMENTS

The broader notion of a hazardous environment is that, as people move about within the built environment, they are exposed in some manner to hazards with the potential to cause harm. An atmosphere contaminated by deadly carbon monoxide is an obvious example. Most other examples of hazardous environments involve hazards that are less pervasive and more avoidable.

Carbon Monoxide and Other Poisonings by Gases and Vapors

Table 1.1.33 gives a 10-year overview of trends in poisonings by gases and vapors. The two major components are motor vehicle exhaust gas and other utility gas or carbon monoxide.

TABLE 1.1.30 World's Deadliest Floods of All Time

Rank	*Flood*	*Year*	*Estimated Deaths*
1	Huang He (Yellow) River, China	1931	3,700,000
2	Huang He (Yellow) River, China	1887	900,000
3	Kaifeng, China Dikes were destroyed by rebels	1642	300,000
4	Northern China Crops flooded and also destroyed by government, causing famine	1939	200,000

8	California Flooding was due to snow melt after blizzard	1996	3.0	3.1
9	Northeast to Mid-Atlantic United States Flooding was due to snow melt after blizzard	1996	3.0	3.1
10	Northwestern United States Snow melt and heavy rain led to flooding	1996–1997	2.0–3.0	2.43–3.65

Sources: National Safety Council, *Injury Facts 2000,* Itasca, IL: National Safety Council, 2000; *World Almanac Book of Facts 2006,* New York: World Almanac Education Group, Inc., 2006; James Cornell, *The Great International Disaster Book,* New York: Pocket Books, 1979; Lee Davis, *Natural Disasters,* New York: Facts on File, 1992.

Table 1.1.34 provides a five-year trend overview of the latter, for which half the deaths are attributed to carbon monoxide with no other details reported. The two largest components with details known are LP-gas from portable containers, for which deaths appear to be declining, and carbon monoxide from incomplete combustion of domestic fuels, for which no clear trend is apparent.

Tables 1.1.35 and 1.1.36 provide eight-year trends of deaths from carbon monoxide associated with unvented releases from heating and cooking equipment, respectively. Gas-fueled heating equipment dominates these figures, particularly in recent years. Deaths from carbon monoxide from charcoal grills include, and are probably dominated by, deaths from improper indoor use of these grills.

1998	3	16
1999	6	17
2000	11	8
2001	10	12
2002	3	10

Sources: John R. Hall, Jr., *Burns and Toxic Gases in Non-Fire Situations,* National Fire Protection Association, 2005; 2002 data taken from Debra S. Ascone and Natalie Marcy, *Non-Fire Carbon Monoxide Deaths Associated with the Use of Consumer Products, 2002 Annual Estimates,* July 2005, Table 1.

Carbon Monoxide Detectors. In 2002, 29 percent of households had at least one carbon monoxide detector. As had happened at this point per home smoke alarms, usage is higher for affluent households (34% of households with annual incomes of at least $50,000). Unlike smoke alarms, carbon monoxide detectors have been adopted in single-family dwellings (35%) far more than in apartments (17%), modular or manufactured homes (16%), and duplexes and townhouses (21%). Interestingly, carbon monoxide detectors are far more common in houses that use some type of fuel for central heating (38% for gas, 29% for fuel oil) than in homes that use electric power for central heating (13%). It appears that homes with significant potential sources of unvented carbon monoxide are understandably more motivated to obtain carbon monoxide detectors.[16]

For context, Table 1.1.37 provides statistics on suicide deaths due to gas or vapor and on related deaths when it was not determined whether the death was intentional or not. Suicides are far more numerous than unintentional injury deaths by the same mechanism of gas or vapor. Note that all these death tolls have been declining significantly with the possible exception of suicide by gas or vapor other than motor vehicle exhaust.

Poisonings

Table 1.1.38 provides a 10-year overview of other hazardous environment deaths involving specific objects. The first three columns are for poisonings by various solids or liquids. Cleaners and paints are shown separately because that category includes substances that might be encountered in components of the built environment. Fumes from cleaners and flaked-off lead paint are examples. Corrosives and caustics are shown separately because they also have the potential, although probably less than with cleaners and paints, to be encountered after application of substances to components of the built environment.

More often, these substances cause fatal poisonings because they are accessed in stored form and then ingested. The

TABLE 1.1.37 Deaths Due to Poisoning by Gases and Vapors, 1993–2002

Year	Unintentional Injury*	Intentional Injury (Homicide or Suicide)*	Undetermined Whether Unintentional or Deliberate*
1993	660	2092	107
1994	685	2044	84
1995	611	2095	107
1996	638	2007	118
1997	576	1918	77
1998	546	1726	82
1999	597 (63)	1618 (64)	89 (9)
2000	631 (38)	1521 (65)	87 (12)
2001	656 (63)	1519 (61)	89 (10)
2002	691 (51)	1485 (51)	85 (14)

Notes: Prior to 1999, suicides were distinguished by motor vehicle exhaust versus other gas. In the early 1980s, motor vehicle exhaust suicides outnumbered suicides by other gases by nearly 5 to 1. In the late 1990s, the ratio had declined to only 3 to 1.

*Beginning in 1999, only organic solvents and halogenated hydrocarbons and their vapors are distinguishable, and their totals are shown in parentheses.

Sources: John R. Hall, Jr., *Burns and Toxic Gases in Non-Fire Situations,* National Fire Protection Association, 2005; National Safety Council, *Injury Facts and Accident Facts,* Itasca, IL: National Safety Council, 2005–2006; 2002 data from the CDC/NCHS website, http://www.cdc.gov/ncipc/osp/data.htm.

separately listed cleaners, paints, corrosives, and caustics are a very small part of the overall category of poisonings by solids and liquids, as the third column demonstrates. Most of this category consists of alcohol products.

Machinery and Instruments

The fourth column of Table 1.1.38 tabulates deaths occurring when someone is caught in or between two objects. The fifth tabulates deaths involving machinery, more than half of which involve agricultural machinery, pointing to the high risks involved in farming. The sixth column tabulates deaths caused by cutting or piercing instruments and objects.

Almost none of the deaths shown in Table 1.1.38 can be said to arise from hazards of the built environment. However, there may be significant indirect effects. Specifically, the design of the built environment may make access to hazardous products, by small children or other people with reduced capacity to make sound risk judgments, more or less difficult. The design, through ergonomics or a lack thereof, may make interaction with machinery or other large objects more or less likely to cause injury. More likely, Table 1.1.38 is relevant in setting priorities and tracking progress for more general safety programs as opposed to choices involving the built environment.

Suffocation

The same is true of Table 1.1.39, which provides a 10-year overview of deaths due to suffocation or inhaling foreign objects.

TABLE 1.1.38 Other Hazardous Environment Deaths, Deaths Coded on U.S. Death Certificates

Year	Poisoning by Cleaner or Paint	Poisoning by Corrosive or Caustic	Other and Unknown-Type Poisoning by Solids or Liquids[a]	Caught in or Between Objects	Caused by Machinery[b]	Caused by Cutting or Piercing Instrument or Object

1998	10	5	402	118	1018	121
1999[c]	—	—	—	74	622	93
2000	—	—	—	85	676	84
2001	—	—	—	85	648	116
2002	—	—	—	109	652	115

Note: The ICD is revised periodically, and these revisions can affect the classifications of death certificate code categories. The tenth revision completely revised the categories effective with 1999 data.
[a]Includes alcohol or petroleum products, agricultural products, chemical or pharmaceutical products, and foods or plants. Alcohol products dominate.
[b]Majority of deaths caused by machinery are specifically caused by agricultural machinery.
[c]Categories with dashes were discontinued after 1998.
Source: National Safety Council, *Injury Facts,* Itasca, IL: National Safety Council, 2002–2006; 1999–2002 data from the CDC/NCHS website, http://www.cdc.gov/ncipc/osp/data.htm.

Only mechanical suffocation has identified components that could relate to the built environment, and they are shown in detail in the 4-year overview of Table 1.1.40.

Suffocation in a bed or cradle accounts for hundreds of deaths annually, and a bed is a sufficiently large piece of furniture that it can be treated as part of the specification of a built environment, even though codes for the built environment rarely set requirements for contents and furnishings, particularly in private homes, which is where most of the suffocation deaths in beds and cradles probably occur. Nevertheless, Figure 1.1.8 provides an overview of differences in risk of such suffocation by age of victim. Crib deaths of very young children clearly dominate.

Excessive Temperatures

Deaths due to excessive heat and cold vary considerably from year to year. Death certificate data from 1993 to 2002 in Table 1.1.41 show that, in most years, cold is the dominant killer. Storm data for 2000 to 2004, collected by the National Weather Service, shows just the opposite, with excessive heat the leading killer in four of the five years, usually by a wide margin. When

detailed circumstances are known and reported, most of the death certificate excessive temperature deaths are specifically attributed to weather as the cause of the extreme temperatures.

Excessive heat or cold, as a cause of death that can be essentially eliminated by a properly designed and operated building, provides the connection to the built environment, although mostly indirectly. Homelessness creates exposure to these potentially lethal conditions, as does the absence of effective and affordable climate control, principally heat for the winter. These problems are not really problems in the design of the building—although the cost of heating and the extent of natural cooling can vary considerably as a function of design—but are always problems arising from our efforts to live in environments of our own making.

Figure 1.1.9 provides a breakdown of deaths due to hunger, thirst, exposure, or neglect. Nearly half involve exposure to harsh weather, so they belong with the deaths shown on Table 1.1.41 as due to excessive heat or excessive cold.

SUMMARY

If we are guided by the relative magnitude of real harm done to real people—either direct harm to people or damage to their property—then the statistics presented here would appear to give us five priority areas for future attention, aimed at improved safety:

- Fire, burns, or shock because of harm to both people and property
- Falls because of harm to people

- Natural disasters because of harm to both people and property
- Water or storms because of harm to property more than people
- Harmful environment because of harm to people

Except for natural disasters, these priority areas primarily center around harm occurring in homes—dwellings, duplexes, manufactured homes, and apartments—which are traditionally the places where strict control by codes stops. Even if you allow for the fact that more time is spent at home than anywhere else, the risks from falls, fires, and water are higher at home than elsewhere. In terms of the first triage question—is this a big enough problem to worry about?—the answer for these four is yes. The next question asked how much of a difference can be made through changes in your built environments. To answer that question, it helps to distinguish among the five types in terms of the relative safety focus each has received in recent decades.

Fire has been the primary focus of NFPA for more than a century. Natural disasters are the focus of emergency managers at all levels of government and have been a focus of much of the insurance industry for some time. Water damage due to plumbing problems has been a focus of plumbing codes for some time.

Falls are the odd group in that they so clearly dominate any characterization of deaths in the built environment but have never been the primary focus of any major national organization or governmental agency.

Fatal falls can be made less likely through three distinct elements of design in the built environment. First, a variety of design decisions can make footing either more or less precarious. The dimensions of steps and stairs have long been controlled through codes, but there are other design elements, such as flooring angles, that may not have received much attention. Illumination levels at walking surfaces can also influence the safe use of the stairs. Also, the "slipperiness" or slip resistance of various surfaces, ranging from the aptly named "throw rug" or highly polished wood floor at one extreme to thick carpet or grooved concrete at the other extreme, has a bearing on the probability that a fall will occur.

Second, there is the effect of the surface's ability to absorb the impact of a fall without causing harm, or at least not fatal harm. Different flooring products certainly vary in this regard, but there is also a potential influence from lower walls, hard corners, protruding sharp or hard edges, and so forth.

Finally, there is the presence or absence, effectiveness or ineffectiveness, of physical aids to stabilization, such as handrails. These are all the design elements that compensate for the dangers created by walking surfaces or that permit an incipient fall to be interrupted or minimized on impact.

With so many opportunities to intervene via design in the number one cause of unintentional injury and deaths in the built environment, it is remarkable that falls have not emerged previously as a point of focus. The broad interception of the goals of NFPA *101®*, *Life Safety Code®,* has provided a limited basis for focus on falls by some of the technical committee volunteers working with NFPA. More recently, the U.S. Centers for Disease Control and Prevention has identified falls by older adults as a priority focus for its work, and NFPA's Center for High Risk Outreach has given preventative education regarding falls in the *Remembering When* program. Falls among children age 14 and under are one of the risk areas addressed in NFPA's school-based injury prevention program, *Risk Watch®*. Notwithstanding these serious and worthwhile programs, there is still a niche to be filled in focusing on code provisions to shape design of the built environment to reduce fatal falls.

Chapter 2

Fundamentals of Structurally Safe Building Design

Revised by
Bonnie E. Manley

Chapter Contents

Challenges to the Built Environment
Design Loads and Forces
Basic Building Systems and Components
Fundamental Design Concepts
Basic Design Methodology

Key Terms

building code, building envelope, built environment, dead load, design load, earthquake force, horizontal load, live load, load and resistance factor design, load-path concept, occupancy type, overstress, performance level, performance-based design, snow and ice load, stress design, structural integrity, structural system, vertical load, wind force

Engineers sometimes joke that structural design is "the art of molding materials we do not wholly understand, into shapes we cannot precisely analyze, to withstand forces we cannot really assess, in such a way that the community at large has no reason to suspect the extent of our ignorance." Although overstated, this saying contains truth. The structure design and construction process contains many inherent uncertainties.

Despite these uncertainties, it is possible to provide relatively uniform levels of safety and reliability by starting with a design that meets the basic requirements of the adopted building code and then ensuring that, as it is built, the structure conforms to the approved design documents—the plans and specifications. For help, owners, architects, engineers, building officials, and contractors turn to the building code, not only to help define their roles, but also to provide the minimum standards for design and construction quality.

From a structural standpoint, today's model building codes scope the general building requirements for given occupancies, including such items as height and area limitations, construction types, basic building configurations, and construction techniques. Additionally, the building codes adopt, by reference, design load standards that define the minimum permissible strengths to resist floor loads and other unique environmental forces due to wind, snow, water, and earthquakes. Material design standards, which also tend to be adopted by reference in the building codes, define material strengths, properties, and specific design methods that can be used by engineers with reasonable safety. Some minimum standards for construction quality are also specified in the building codes. For the purposes of this chapter, the many codes and standards that affect the structural design and construction of buildings are collectively referred to as "building codes." This collection of codes and myriad referenced standards work to provide a safe, functional, and appealing structure at the end of the design and construction process.

Operating within this environment of codes and standards, the structural engineer must optimize the design in such a manner that the building provides acceptable levels of safety and serviceability while being economical to construct. One approach to "optimum" building design says that if a structure is loaded to the slightest fraction beyond its strength limit, all elements should simultaneously fail and the entire structure collapse. This approach is seldom used. Instead, most structures are designed such that if they are overloaded, they are able to deform and give some warning to occupants prior to failure, so that evacuation and perhaps shoring can occur.

See also Section 1, Chapter 1, "Challenges to Safety in the Built Environment"; Section 1, Chapter 3, "Codes and Standards for the Built Environment"; and Section 1, Chapter 4, "Legal Issues for the Designer and Enforcer."

CHALLENGES TO THE BUILT ENVIRONMENT

The total complex of houses, factories, offices, schools, and so on in which we live and work is referred to as the "built environment." Each year, lives and property are lost due to building

Bonnie E. Manley, P.E., is a regional director of the American Iron and Steel Institute.

failures. Mostly, hurricanes or other high winds, earthquakes, floods, and other dramatic events precipitate these building failures. Much less often, failures are precipitated by minor events or even ordinary loads and conditions due to inadequate design and construction, lack of proper code enforcement, simple neglect, or decay. Although building codes are intended to protect lives, clearly there are instances where they have not done so. Problems occur for both existing buildings and new construction.

Existing Buildings

Modern construction materials are very different from those used in the past. In some respects they are better, and in others, worse. However, the methods and details that are used to combine these materials into finished buildings have improved significantly with time. Building codes and construction methods change with time, incorporating new materials and methods of construction and "lessons learned" from various failures induced by disasters such as fires, earthquakes, and hurricanes. Because of continual improvements in building codes, most buildings designed and constructed today are considered safer and more reliable than buildings that were designed using older building codes. Building loss investigations, the ability to do more analysis, and widespread use of various hazard simulation models—all benefit the design and construction process.

In most communities, new building construction in any year represents less than 2 percent of the total number of buildings.* There are two exceptions to this general rule. The first is a new, fast growth/development community. The second involves massive rebuilding efforts following a natural disaster or postwar period. Consider the status of many communities in Louisiana, Mississippi, and Alabama that had a high percentage of their commercial and residential structures destroyed beyond repair as a result of Hurricane Katrina in August 2005. Jurisdictions that had little or no significant construction since the 1970s are now undergoing a tremendous rebuilding effort.

However, given the general 2 percent rate of new buildings, at any one time at least 50 percent of the building population is likely to be more than 30 years in age. For many communities, this percentage is actually much greater. Because of continual improvements in building codes and building technology, older buildings designed to the standards and codes of 30 or more years ago are by some measures considered unsafe in comparison to current standards. Therefore, it is likely that every community contains a significant number of buildings that could be unsafe if exposed to major events that newly constructed buildings could better survive.

Existing buildings are typically replaced only when either a better financial use is found for the property or because the physical condition of the building becomes so poor as to preclude further use. Once a building is constructed, and an occupancy permit issued, building codes contain few restrictions on the building's continued use. In general, the following apply:

- The owner is required to meet certain zoning restrictions in terms of types of use or contents.
- Major additions, alterations, or changes in use may trigger improvements to meet newer building codes. However, these requirements may be circumvented by physical separation of the new and existing construction or by other negotiated means.
- If the local building official becomes aware of an obviously unsafe condition, the official has the power to condemn a building. However, such actions are quite rare and typically occur only after a damaging event or failure.
- Some codes, like NFPA *101*®, *Life Safety Code*®, and some regulations, like the Americans with Disabilities Act, impose requirements on existing buildings, and some of these provide for enforcement of retroactive requirements, regardless of whether any other work efforts are undertaken.

As a result, many existing buildings contain latent risks due to deterioration, owner-initiated changes that were not done in accordance with the permitting process, deferred maintenance, or basic details of construction that would not be found in newer construction.

New Buildings

Every building is unique in some ways and without prototype. To be safe and serviceable, it is vital that the construction be in accordance with the approved design documents. This requires that all parties involved in the construction process—code developers, owners, architects, the insurance community, engineers, code officials, and contractors—each exercise the skill and responsibility necessary to make certain that their part of the project is done in conformance with the intended requirements, while still meeting the limitations of project schedules and budgets.

A common challenge to this process is communication—for contractors and building officials to be able to correctly interpret the architect's and engineer's intent from their drawings and specifications, and for the architects and engineers to be able to interpret the intent of code developers from the building codes.

Another challenge of new construction is for engineers and code developers to predict the types and magnitudes of forces and events that a building may experience during its existence, and to define design loading conditions within building codes that are sufficient to withstand those conditions, without undue financial penalties. Ongoing debate—since 2001—involves the need to carefully analyze the design assumptions as they may relate to certain extreme events, most notably terrorism and hostile acts. The cadre of codes and standards simply cannot strive for "more" safety or "ultimate" safety, but rather they need to provide an "appropriate" level of safety.

DESIGN LOADS AND FORCES

Basic Types of Loads and Forces

Building codes define the following basic types of loads and forces as a basis for structural design. These loads and forces include the following:

*The conservative estimate of 2 percent is based on assessor's data for the county of Orange, California, an area of high growth. The annual development in Orange County between 1972 and 1994 added an average of 3 percent annually to the cumulative number of developed parcels.

- Dead load
- Live load
- Snow and ice loads
- Wind forces
- Earthquake forces

Dead Load. Dead load is the weight of the building itself. It includes the weight of all permanent fixed items, such as floor framing, walls, ceilings, roofing, and major fixed service equipment, but excludes loads from variable items, such as furnishings, people, traffic, and equipment, that change constantly throughout the building's life. Dead load is the easiest to predict and can be known with the most certainty, although there can still be some variation between dead load estimated by the engineer and the actual as-constructed weight.

Live Load. Live load is the weight of items such as furnishings, people, traffic, and equipment related to the use or occupancy of the building. This weight is generally known with little certainty, as it can vary over time. Building codes include tables of minimum required design live loads for various occupancy types, which are sometimes posted on signs within buildings. These design live loads represent reasonable maximum bounds on the amount of weight from these variable items that may be placed on a floor or roof during its life. It is extremely unlikely, except in certain types of occupancies such as warehouses, that all areas of floors and roofs would simultaneously be loaded to the design levels at the same time. Hence, building codes include "live load reduction factors" that account for the low likelihood of simultaneous heavy loading of large portions of the building and allow the design load to be reduced for building elements that support larger areas. Thus, an individual floor beam might be designed to support a larger floor load (on a pounds per square foot basis) than a column that supports many beams.

Snow and Ice Loads. Snow and ice loads are the design weights required by building codes to be considered for accumulation of snow and ice. Building codes define snow load in terms of "ground snow loads" that represent a weight of snow having a 2 percent annual probability of being exceeded (50 year mean recurrence)[1]—that is, such heavy loads are anticipated to occur only every 50 years or so. The building codes include maps that specify minimum design snow loads for various regions of the country. However, snow depths can be highly variable, particularly within mountainous regions, where local building officials often specify "standard" ground snow loads within their jurisdictions that are different from those indicated in the maps.

The ground snow load, contained on building code maps and enforced by building officials, is not the same load that is actually used to design buildings. Design snow loads are calculated based on the ground snow load, but require modifications to account for the effects of roof slope, thermal conditions (heated versus unheated), wind conditions that can cause snow to drift across roofs, and building shape or geometry conditions, which may cause drifts or snowfalls from adjacent higher roofs to accumulate. Design load standards are used to translate the basic ground snow loads into specific design weights that vary over the roof surface.

Wind Forces. Design wind forces are determined using horizontal wind pressures associated with a design wind velocity that is specified for a location. Just as with snow loads, building codes include maps of design wind velocity values for most areas (Figures 1.2.1 through 1.2.4). However, these maps exclude some "special wind regions" in which local terrain conditions produce occasional high wind conditions. In those areas, the building official is required to specify the design wind velocity.

Prior to 1998, the commonly accepted definition of design wind velocity was based on the "fastest-mile" wind speed, which was the wind speed based on the time required for a mile-long sample of air to pass a fixed point. Around 1998, U.S. building codes redefined the design wind velocity as the mean wind speed averaged over 3 seconds, measured at 33 feet above grade, over relatively open terrain.[2] The resulting wind velocity maps are generally based on a 50-year wind speed.[2] However, in hurricane-prone regions, wind velocity maps have been modified to include an adjusted value based on both hurricane simulation techniques and 500-year wind speed records. This "3 second gust" method is an improvement over the earlier method in that the fastest mile did not account as well for the effect of short duration gusts. Also, the older codes did not include the more severe winds anticipated in hurricane-prone regions.

The mapped wind velocity is not directly used to design buildings. Instead, the mapped wind values are modified depending on terrain conditions, elevation, and topographic effects such as hills or ridges that can cause local high-velocity conditions to occur. The design forces are calculated from these site-modified wind velocities, considering the building's shape, its flexibility, the quantity of openings that can allow fluctuating wind pressures to enter the building, and the total building area that may be subjected to locally varying wind gust pressures. Design load standards provide guidance to engineers on how to determine the appropriate pressures to design building components for relatively regular and normal looking buildings. Buildings that are very tall, flexible, or unusual in shape sometimes require special wind-tunnel testing using scale models in order to determine appropriate design wind pressures. In fact, more extensive use of, and reference to, wind tunnel testing techniques are the subject of one of the 30 recommendations of the NIST study of the World Trade Center disaster.[3]

Earthquake Forces. Earthquakes do not directly exert forces on buildings. Rather, they produce ground accelerations and deformations that vary with time. The response of the building to these ground movements results in stresses and deformations throughout the building. The severity of these effects depends on the event magnitude, its distance from the structure, local soil conditions, and the weight and stiffness characteristics of the building structure itself. Building codes provide procedures that allow engineers to determine the design forces. These are calculated as pseudo-inertial forces equal to the building mass times specified design accelerations. These design accelerations are determined from mapped values of design ground accelerations found in building codes, modified to account for the building's structural characteristics (Figure 1.2.5).

As with wind loads, the definition of the design ground acceleration used in building codes has evolved. Until 1991, building codes included maps that presented design ground motions

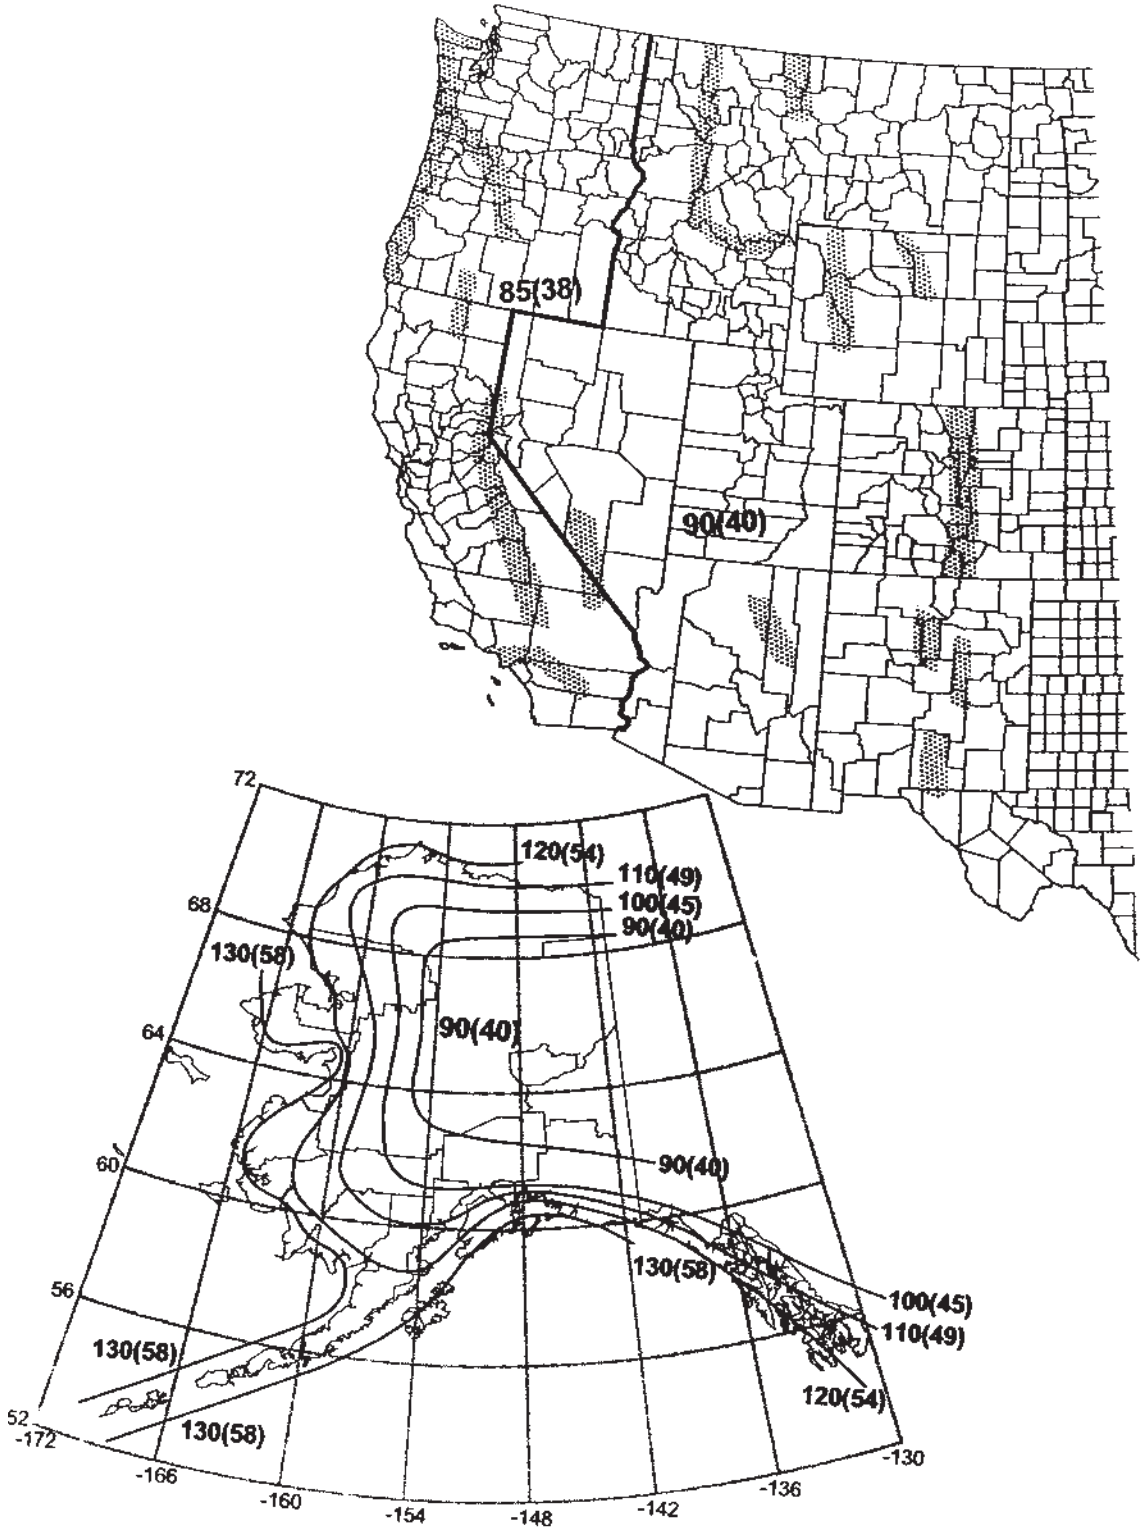

FIGURE 1.2.1 Basic Wind Speed (Source: Reprinted with permission from ASCE/SEI 7)

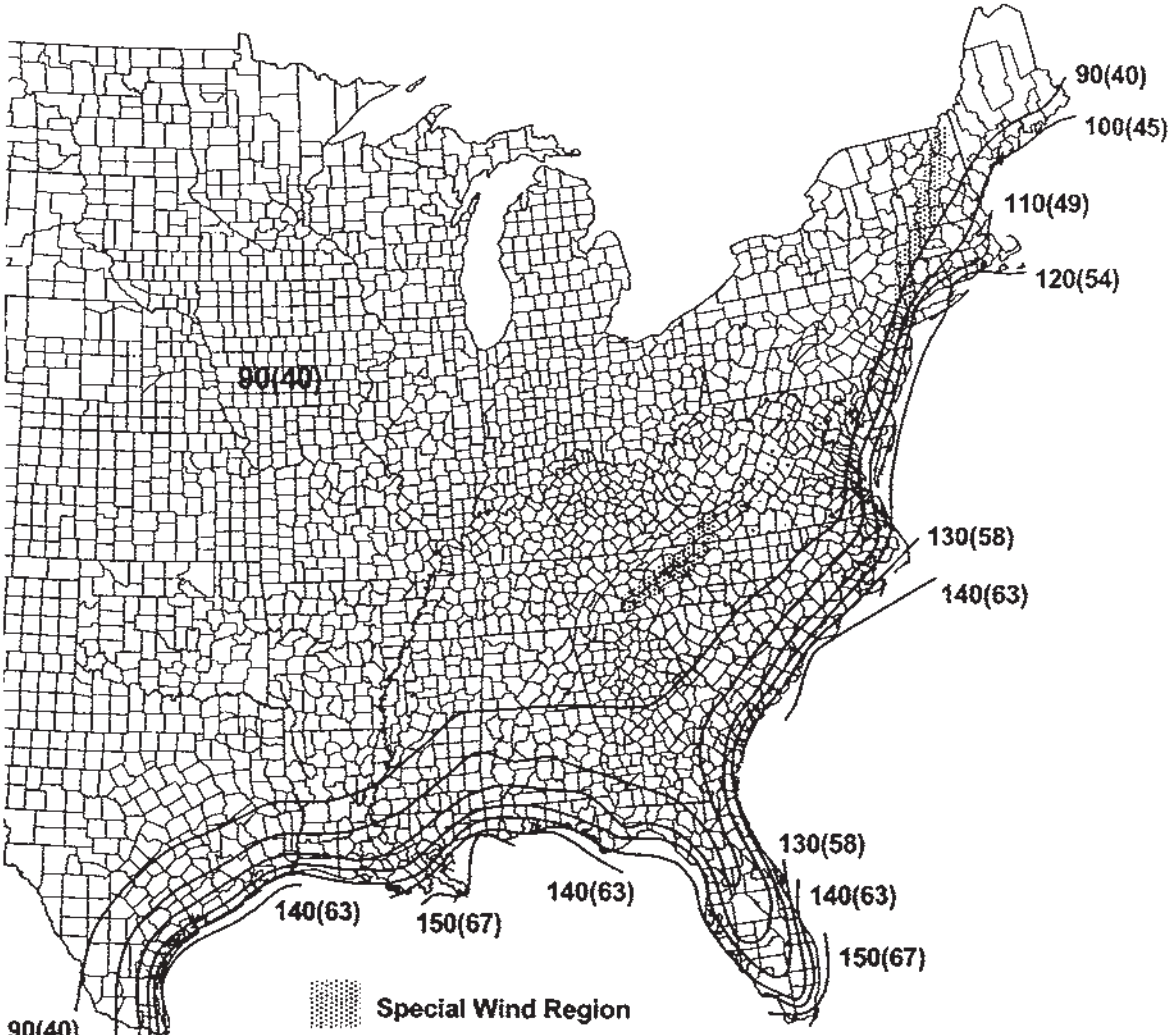
in the form of seismic zones. The seismic zones covered broad geographic regions, often encompassing several states. Within each seismic zone, the building codes specified earthquake acceleration values that approximately represented the most severe shaking likely to occur in any 500 year period—in statistical terms, having a 10 percent chance of being exceeded in 50 years. The use of broad geographic seismic "zones" resulted in these accelerations being very approximate.



Notes:
1. Values are nominal design 3-second gust wind speeds in miles per hour (m/sec) at 33 ft (10 m) above ground for Exposure C category.
2. Linear interpolation between wind contours is permitted.
3. Islands and coastal areas outside the last contour shall use the last wind speed contour of the coastal area.
4. Mountainous terrain, gorges, ocean promontories, and special wind regions shall be examined for unusual wind conditions.

FIGURE 1.2.1 Continued

Starting in 1991, codes began to abandon seismic zones and present design ground motions on maps in the form of ground motion "contours" that more precisely presented the likely levels of ground motion at any given site. Using these maps, each site location has a unique value of design ground acceleration depending on its location relative to known faults and seismic source zones. The newer mapped earthquake acceleration contours also represent a more unlikely event, corresponding to

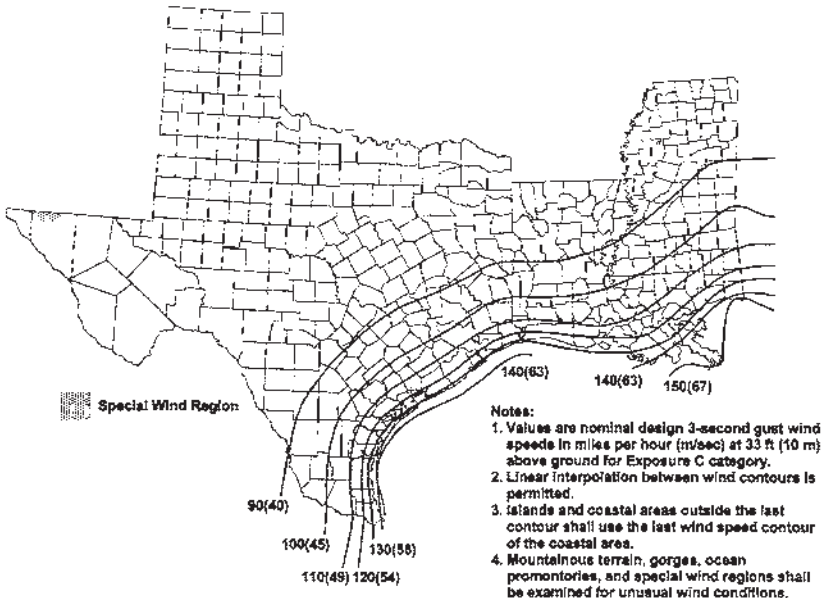


FIGURE 1.2.2 Basic Wind Speed: Western Gulf of Mexico Hurricane Coastline (Source: Reprinted with permission from ASCE/SEI 7)

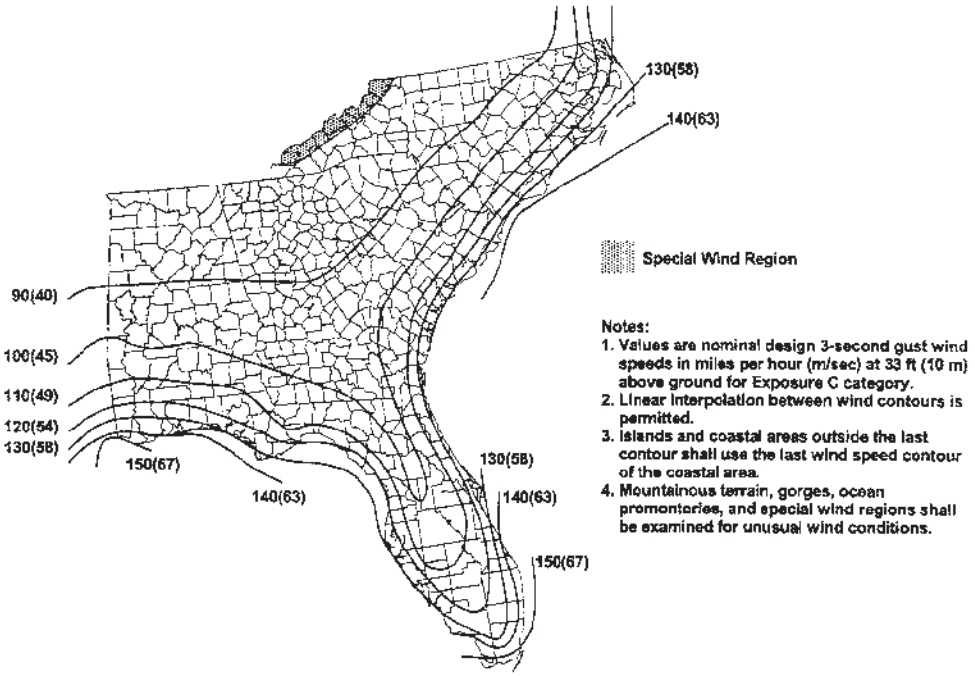

FIGURE 1.2.3 Basic Wind Speed: Eastern Gulf of Mexico Southeastern U.S. Hurricane Coastline (Source: Reprinted with permission from ASCE/SEI 7)

a 2500 year event, or one having a 2 percent chance of being exceeded in 50 years. This rather rare event is more appropriate for sites in the eastern United States, for example, where large earthquakes occur infrequently, and does not significantly increase the hazard in the western United States, where destructive ground shaking occurs more often. The intent of the newer building code regulations is to prevent structural collapse for these 2500 year events. However, actual design is based on providing a less severe level of damage for design ground accelerations taken as two-thirds of the mapped values.

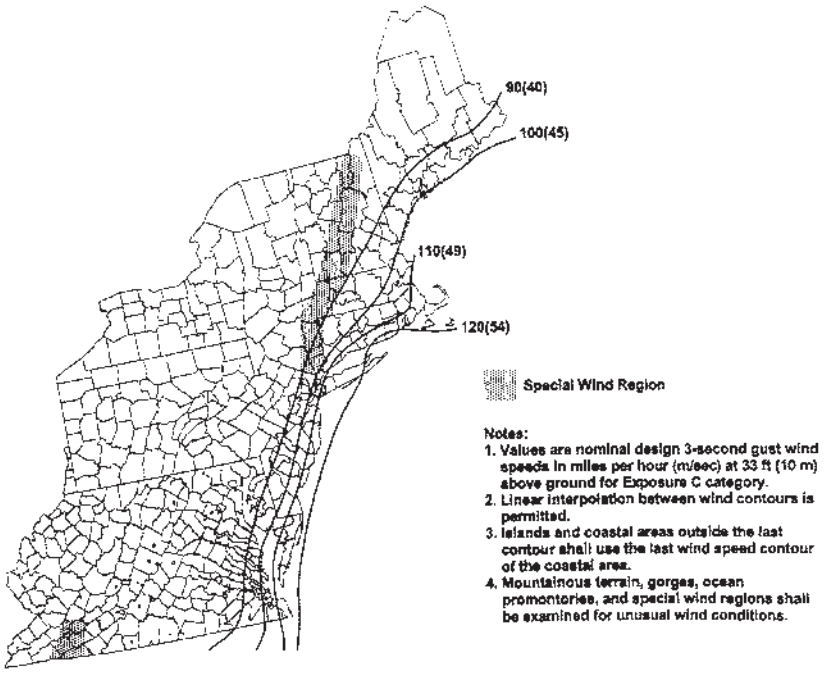

FIGURE 1.2.4 Basic Wind Speed: Mid- and Northern Atlantic Hurricane Coastline (Source: Reprinted with permission from ASCE/SEI 7)

In regions with moderate or strong earthquake potential, design ground acceleration values are so large that engineers cannot economically design ordinary buildings to resist the full acceleration values without also permitting some degree of damage. In fact, most buildings are designed to crack and yield when affected by design level shaking, ultimately holding together and not collapsing. The intent of the earthquake code provisions for ordinary buildings is to perform for and protect "life safety," but not protect property investments. In order to accomplish this, design forces are calculated using special reduction factors R that reduce the predicted ground accelerations into artificial design values. These R values are specified in the building codes, based on the type of structural system used and the historical performance of various systems.

In addition to specification of minimum design forces, building code provisions for earthquake resistance also include prescriptive detailing requirements intended to provide sufficient toughness to hold buildings together as they deform. The prescriptive provisions regulate the types of connections and reinforcements that are used in different types of construction and also the configuration (geometric shape) of the building and its elements. In addition, in locations where stronger accelerations may occur, some types of construction, such as unreinforced masonry, are not permitted.

Other Loads. Building codes and design load standards also include provisions for other common types of loading, including flood loads, soil loads, hydrostatic pressure, impact, and forces caused by thermal expansion and contraction or impact. However, building codes have either very limited provisions or no provisions at all for some very unusual types of loads such as those induced by tornadoes, blasts, or explosions. Industry-specific design standards, such as those developed by the military, the U.S. General Services Administration, the Department of State, or the Department of Energy, are typically used for the design methods of structures that must resist such load conditions.

Combining Design Loads. Once the individual design forces have been determined, they must be combined to consider the effects of simultaneous application; for example, the occurrence of high wind loads and occupancy-related loads such as furnishings and equipment. When combining loads of different types, the probability that loads occur concurrently is considered and loads that occur infrequently are typically not combined together. For instance, a full design snow load would not be combined with a full design wind or earthquake event, although some portion of the design snow might be considered. Building codes include equations for required combinations of loading that must be considered in building design. Some special types of structures also use load combinations defined in industry-specific standards. As an example, tanks are designed for earthquake inertial forces in conjunction with forces caused by earthquake-induced sloshing of tank contents.

Actual Versus Design Loads

Building codes deal with the uncertainties associated with predicting design loads through the use of probability and statistics. For example, building codes define a 50 year wind, or a 2500 year earthquake event. However, the resulting design maps correspond only to a statistical representation of the

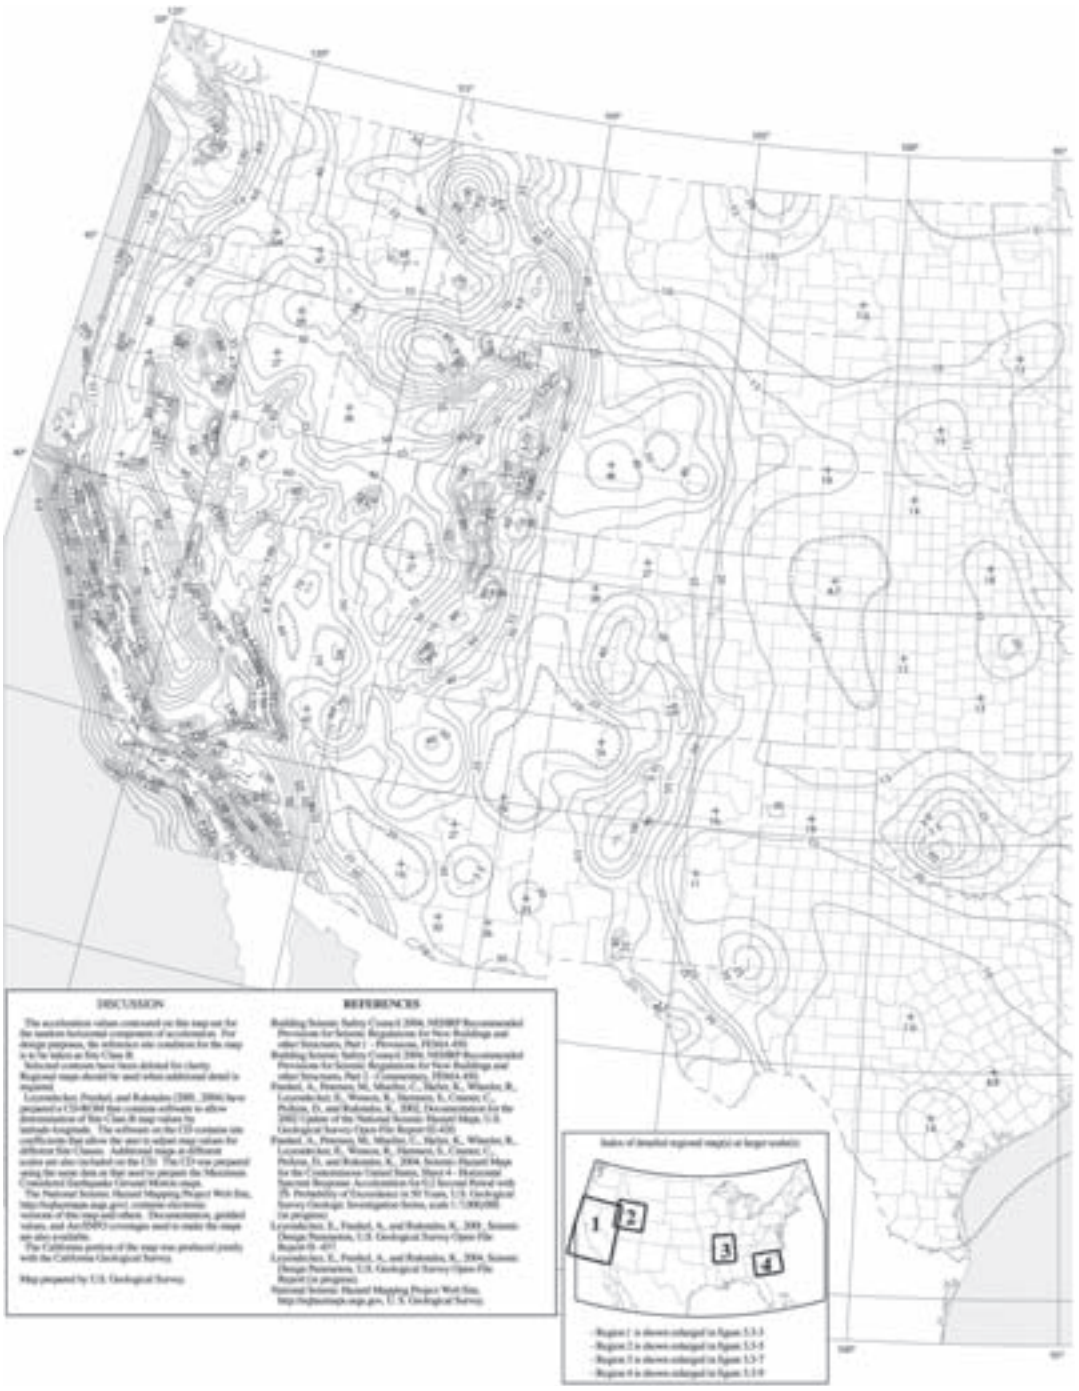

FIGURE 1.2.5 Maximum Considered Earthquake Ground Motion for the Conterminous United States of 0.2 Second Spectral Response Acceleration (5% of Critical Damping), Site Class B (Source: National Earthquake Hazards Reduction Program Recommended Provisions for Seismic Regulations for New Buildings and Other Structures, FEMA 450, 2003, Figure 3.3-1)

probabilities, based in part on the historical record and also in part on the experience and judgment of the code developers. Because neither can completely predict the future, it is possible that code-specified design loads will be exceeded. For example, earthquakes sometimes occur on previously undiscovered fault lines, or changes in global climatic patterns can result in increased wind or snow hazards that are not accounted for by the building codes.

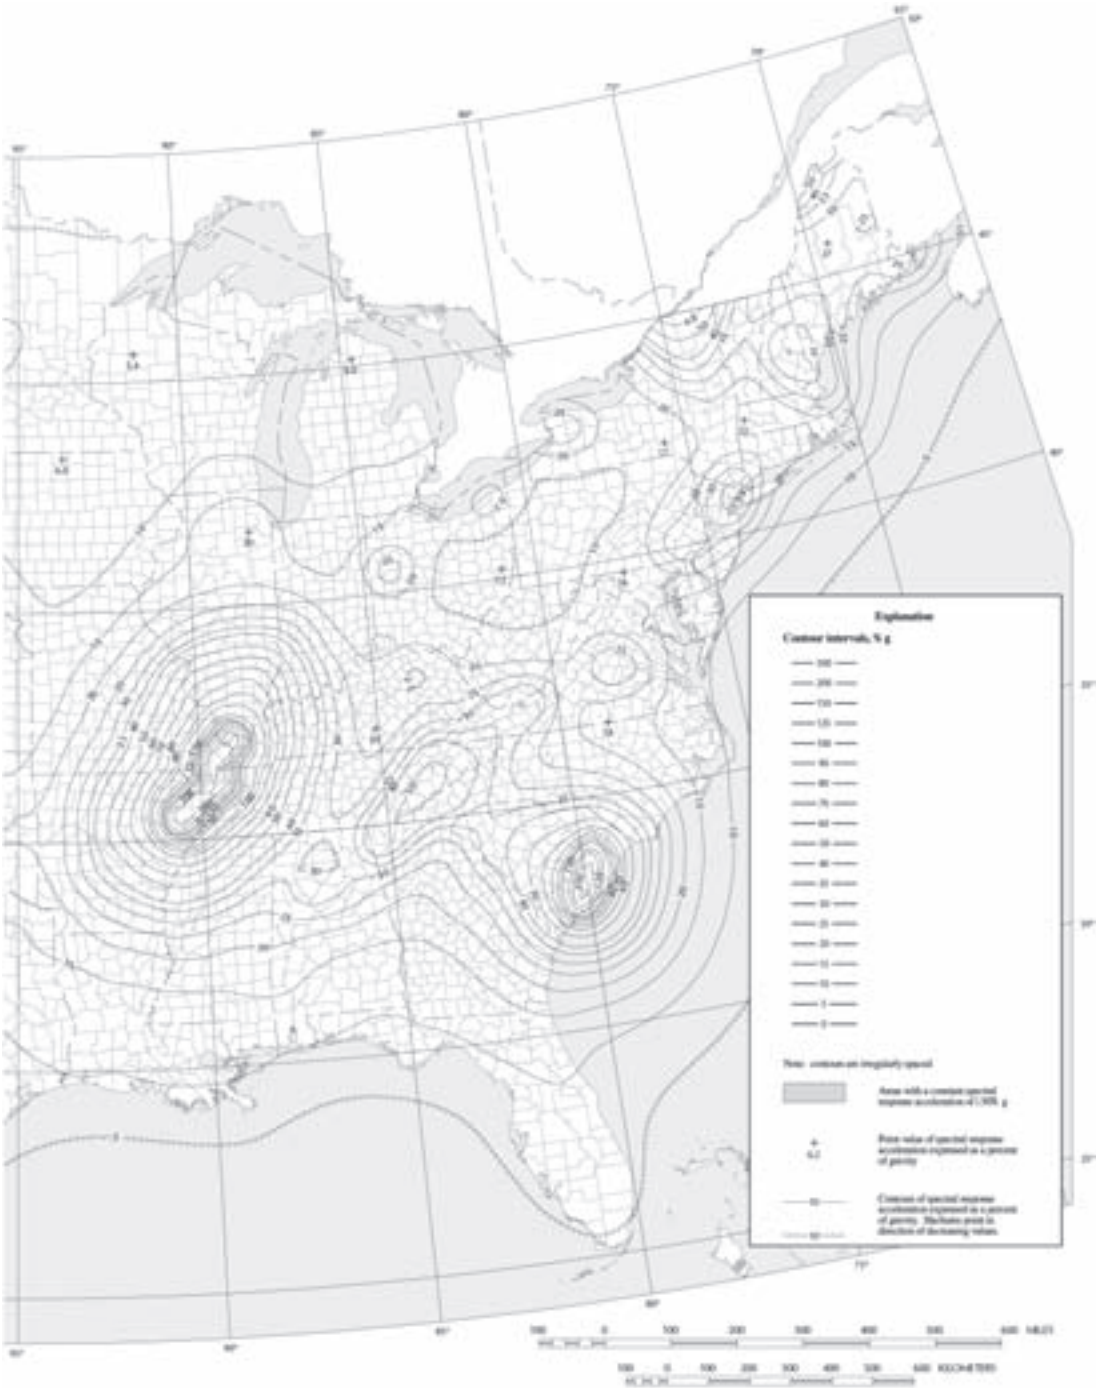

FIGURE 1.2.5 Continued

External Versus Internal Forces

Building codes define loads and forces such as dead, live, and snow loads, and wind or earthquake forces that are considered externally applied, in that they act upon the structure. When these forces and loads are applied on a structure, they result in movement (deflection) of the structure and also the development of internal forces or stresses within the individual structural elements. The building's structural elements, such as floors, beams, columns, or walls, are designed to control the magnitude of these deflections and stresses. Engineers must therefore use the external forces specified by the building code to calculate the distribution of internal forces and deflections in each building element. Although such calculations can be performed using manual methods, today elaborate computer programs are commonly used to assist the engineer in this task.

Internal forces calculated in individual elements include tension, compression, shearing, and bending forces (or bending "moments"). After the engineer determines these forces, they are compared against maximum permitted material strengths that are defined in building codes to verify the adequacy of each proposed design.

BASIC BUILDING SYSTEMS AND COMPONENTS

Basic Building Systems

Basic building systems include the building envelope system, the structural system, the foundation system, the plumbing system, mechanical systems (such as heating, ventilating, and air-conditioning systems), and the electrical system. Other critical building systems include the fire protection system and the security system, for example.

This chapter focuses primarily on the building envelope system and the structural system and briefly addresses the foundation system. The building envelope and structural systems enable a building to withstand the loads and forces placed on it. Stated another way, the building envelope and structural systems keep the building intact and standing; the skin and skeleton fulfill similar functions in human anatomy.

Building Envelope System

The building envelope has been described as being composed of "several building components that work together to protect the building's structure and its contents from the elements."[4] The building envelope consists of building elements such as windows, precast or similar nonstructural wall panels, and like elements that enclose and protect the building and create the finished appearance.

Basic Structural Systems

To resist both vertical loads such as dead weight and snow, and lateral forces such as those produced by winds or seismic effects, any stable building or structure requires two distinct structural systems: a vertical support system and a lateral force-resisting system. Each system consists of a series of structural components (beams, columns, walls, etc.) that combine to provide resistance against either vertical or lateral loading. These structural components can consist of individual elements, such as columns, or they may consist of combinations of elements that connect to produce subsystems, such as shear walls, moment-frames, braced frames, and so on.

Vertical Support System. Basic structural components that combine to form the vertical support system include roof and floor framing systems, columns, bearing walls, and foundations. All structures must have complete and sound vertical load-supporting systems or they would collapse under their own weight and that of their contents. This is in contrast to structures with missing or inadequate lateral force-resisting systems that could conceivably stand indefinitely, because extreme lateral loading events (high winds and earthquakes, for example) are quite rare.

Lateral Force-Resisting System. Basic structural components that provide lateral force-resistance include shear walls, braced frames, and moment-resisting frames, as well as diaphragms (such as roof decks, floor slabs, or horizontal bracing systems) and foundations. Depending on the type, use, and geometry of the structure in each application, these components can be combined to form a structural system.

Comparison of Vertical Support and Lateral-Force Resisting Systems. Frequently, there is little visible difference between the frames, bearing walls, and so on, used to provide vertical support, and the similar frames, shear walls, and so on, used to resist lateral forces. The basic distinction that exists between vertical support and lateral-force-resisting systems arises from the following factors:

- All loads applied to a structure tend to be resisted first by the structural components that have the greatest rigidity (relative to other components) in the direction of load. Thus, vertical loads supported by an elevated floor slab tend to be borne by the closest adjacent columns. On the other hand, lateral forces applied against a floor diaphragm may span entirely past interior support columns (which provide little or no lateral rigidity) and be resisted by more distant (but very rigid) walls or braced frames.
- The connections used to fasten components must provide adequate strength to resist the imposed forces and deflections. In addition, the various components that form a structure must be designed considering the likely deflection and rigidity of adjacent elements. Where the design assumptions require a rigid or inflexible link between lateral load resisting components, the connection must impart rigidity; however, where independent motion is more appropriate, the connection must provide adequate flexibility to accommodate structure deformations without impact or binding.

Structures must be able to resist forces that are imposed from any direction. Most structures are therefore designed with two separate lateral-force-resisting systems, one for each of two orthogonal axes of the building. When forces are applied about either orthogonal axis of the structure, some of the resisting elements are aligned parallel to the forces. Wall and bracing elements have high relative rigidity in-plane and thus provide substantial lateral support. However, walls or bracing systems have low relative strength and rigidity when aligned perpendicular to the direction of load, and thus must be properly attached to and supported by structural components that are parallel to the forces.

Types of Basic Structural Systems. Building codes define certain standard structural systems, called basic structural systems. In essence, basic structural systems are those that resist vertical and lateral loads. These basic structural systems are the following:

- *Bearing wall system.* Any structure in which vertical walls and/or diagonally braced frames simultaneously support both the weight of the structure and resist lateral loads.

- *Building frame system.* System in which the weight of the structure is completely supported by beams and columns. Resistance to lateral loads is independently provided either by walls, termed shear walls, and/or diagonally braced frames.
- *Moment-resisting frame system.* This structure is composed of beams and columns that are rigidly interconnected into moment-resisting frames to provide resistance to both vertical loads and lateral forces, without assistance from walls or diagonal braces.
- *Dual system.* System that provides two independent lateral-force-resisting systems, each capable of resisting all or part of the total lateral design forces. One system must always be a moment-frame system; the other can consist of either reinforced shear walls or braced frames that are added at selected locations.
- *Special systems.* Special systems include base-isolated systems or guyed systems, which do not fit the previous descriptions. A base-isolated system is a special type of seismic-resistant construction in which the structure is mounted on rubber bearing or sliding steel plates. A guyed system is a structure that is braced by guy wires, such as a radio-transmission tower.

Diaphragm Systems. Diaphragms are horizontal-spanning systems that tie vertical walls and columns together, provide stability to walls and other vertical elements, prevent excessive torsional (plane) deformations, and transfer forces to shear walls or frames below. Lateral forces resisted by diaphragms originate from wind forces applied against exterior walls, from seismic inertial forces, or from forces transmitted from shear walls or frames above.

The use of building floor and roof systems as diaphragm systems can be very efficient, because most of the structural elements required for diaphragm action are also required for these systems. Horizontal bracing systems provide diaphragm-like performance for applications where solid-surface construction cannot be used or is not required.

Building Foundation Systems

Foundation systems are used to transfer vertical and horizontal loads from the aboveground structure into the underlying soils. Common foundation types include piles, piers, caissons, spread footings, and mats. Piles, piers, and caissons are deep foundation systems designed to support heavy buildings on soft, compressible surface soils. Spread footings and mats are shallow foundation systems designed to support light buildings or heavier buildings on stiffer, stronger surface soils (Figure 1.2.6)

Basic Building Components

Basic structural components that collect loads from roof and floor levels and transfer them to foundations include moment-resisting frames, vertical walls, diagonally braced frames, and diaphragms and horizontal bracing. These underlying structures are surrounded and protected from the environment by the building envelope. Critical structural design considerations for the building envelope include resistance to lateral pressure or impact, accommodation of transient building movements, and accommodation of long-term building movement.

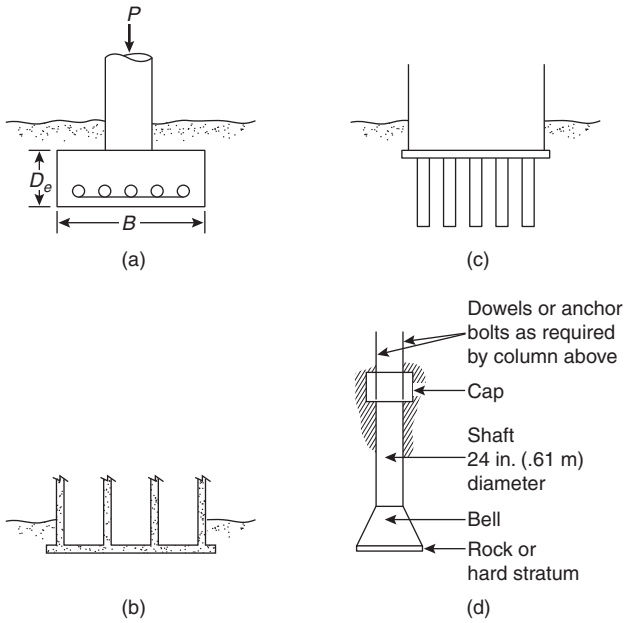

FIGURE 1.2.6 Common Types of Foundation Systems: (a) Spread Footing, (b) Mat, (c) Pile, and (d) Pier or Caisson

Resistance to Lateral Pressure or Impact. Exterior walls, windows, and doors provide the primary protection against wind pressures and small stones and missiles thrown up by wind. Windows must be designed to resist design wind pressures while still maintaining moisture protection at surrounding gaskets. In special hurricane-prone areas, impact protection may be required as well. Near grade and around entrances, missile or impact resistance may also be required for protection against small stones thrown up by lawnmowers or attempted forced entries. Walls must have adequate shear and bending strengths and strong enough connections to resist code-defined wind pressures and earthquake inertial forces.

Accommodation of Building Movements. The structure that supports the building sways and drifts during windstorms or earthquakes. The attached building components must be designed to accommodate these movements without damage. Frequently, by adding jointing and special connection details that allow structural movements without binding against cladding or window elements, these movements can be accommodated. In relatively flexible buildings, glass panels may need to be able to rock within their frames to accommodate building sway without binding. These sway or drift limits are part of the serviceability of performance and must remain within a certain tolerance level to prevent occupants from feeling motion sickness under "usual" conditions.

Accommodation of Long-Term Building Movements. After completion of construction, all buildings experience some

degree of long-term movements as the building adjusts to its environment. Building components can experience some shrinkage or expansion. Foundations can slightly settle. Over the long term, some of this movement may continue in the form of thermal cycling or perhaps continuing foundation movements due to moisture-related expansive soil conditions. These movements often cause slight cracking and distress that can be observed in many buildings. Although not specifically a code-regulated issue, the details of building construction used should attempt to minimize both the amount of such movement that occurs and the damage sustained as a result of such movements.

Moment-Resisting Frames. Moment frames rely on bending forces developed at the connections of the beams to the columns to resist lateral forces. Because moment frames tend to be much more flexible than either shear walls or braced frames, lateral deflections of moment-frame structures tend to be much greater. The ratio between relative story deflection and story height is called the story drift ratio. Moment frames that permit too much story drift during windstorms or earthquakes may permit an excessive amount of damage to nonstructural components, such as siding, partitions, and contents.

Critical design elements of moment-resisting frames include beams and columns and the beam-column connection.

- *Beams and columns.* Frame elements must be designed to resist internal bending and shear forces. Optimum performance is gained when the members selected are stronger in shear than in bending and when the building's columns are stronger in bending than its beams. This provides a controlled damage mode under very large loads and forces and, in multistory frames, increases the total energy dissipation capability of the frame.
- *Beam-column connection.* The stability of the frame is dependent on the rigidity and strength of the beam-column connection. Adequate strength and toughness must be provided in the connection to permit repeated cycling of stresses without a loss of integrity. Connections can be made of bolted or welded components, or a combination of bolted and welded elements. Since the toughness of welded joints is highly dependent on the workmanship, special quality control measures are often required in the most critical welds.

Shear Walls. The shear wall is designed as a vertical beam element. As shown in Figure 1.2.7, critical design considerations for shear walls include in-plane shear, in-plane bending, and bending from forces perpendicular to the wall:

- *In-plane shear.* The wall acts as a web, or shear membrane, to resist in-plane shear forces. Adequate anchorage must be provided along the top and bottom edges of the web to transfer the shearing forces into and out of the web.
- *In-plane bending.* To resist bending stresses due to overturning moments, structural elements, called chords or boundary elements, are concentrated at the vertical edges of the wall. Chords are tension-only elements, which resist the tension component of bending forces. Boundary elements are tension-compression elements, which resist tension forces as well as extremely large compression strains (large enough to cause crushing of unconfined concrete) due to bending and vertical loads. Boundary elements are required by building codes only in high-seismic zones. Both chord and boundary elements must be anchored into a foundation that is capable of transferring the vertical components of overturning forces into the ground.
- *Bending from forces perpendicular to wall.* Adequate bending strength and anchorage must be provided to resist in-

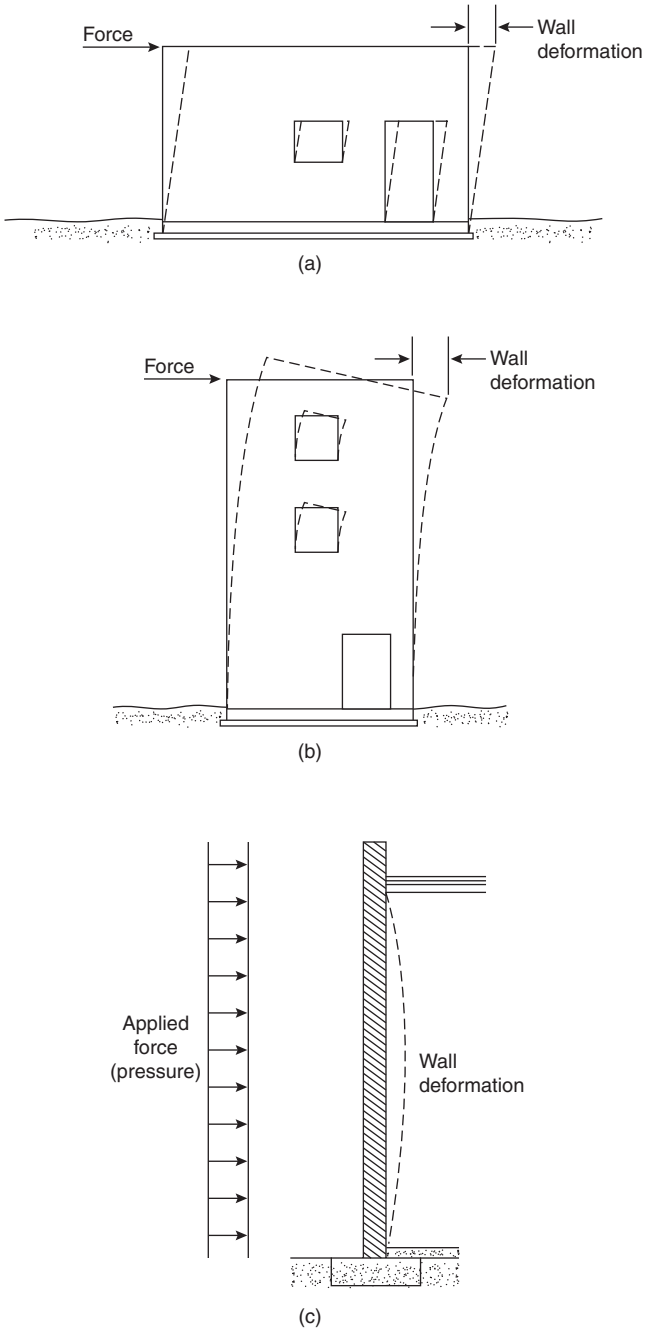

FIGURE 1.2.7 Types of Wall Deformation: (a) In-Plane Shear Deformation, (b) In-Plane Bending Deformation, (c) Bending from Forces Perpendicular to Wall

ertia loads and wind pressures applied perpendicular to the plane of the wall.

Diagonally Braced Frames. Braced systems rely on the axial rigidity of vertical and diagonal elements to resist lateral forces. The configuration of diagonal elements within the bracing can vary, and some configurations have better seismic performance than others. Commonly encountered types of bracing systems, in order of relative performance (best to worst) when subjected to overload or damaging conditions, include the following:

1. *Eccentrically braced frame (EBF).* A special type of bracing system that is designed to provide a high degree of overload resistance by permitting controlled overstresses within a short, ductile beam segment, called a "link." Figure 1.2.8 shows examples of eccentrically braced frames.
2. *Concentrically braced frame (CBF).* A type of bracing system that provides overload resistance by permitting controlled overstresses in the bracing members. Buckling-restrained braced frames (BRBF) are considered a special class of concentrically braced frames, with a high degree of seismic resistance. Figure 1.2.9 shows examples of other concentrically braced frames:
   - *Tension-compression bracing.* Diagonal elements are provided either singly or paired in an "X" pattern to resist forces both in tension and compression.
   - *Chevron bracing.* Arranged in either a "V" or inverted "V" configuration, the diagonal elements resist lateral forces by sharing the load between tension and compression elements. Bracing in this configuration also resists vertical loads applied to the beam, although building codes require that the beam be designed to resist vertical loads as if the bracing did not exist. This configuration can experience problems when overstressed because buckling of the diagonal undergoing compression creates a force imbalance that increases bending forces on the beam.
   - *Tension-only bracing.* Similar to tension-compression bracing, except that the diagonal elements, by being very slender, are assumed to buckle at very low compression forces. This configuration can experience a loss of strength under repeated tension-compression cycles. In regions subject to significant ground shaking, tension-only bracing is limited to structures of less than two stories in height.
   - *K-bracing.* This system provides the poorest overload performance. Overstresses in the diagonal elements can lead to buckling of the diagonal undergoing compression. The resulting force imbalance creates a lateral force on the column, which could possibly lead to a general collapse of the system. Building codes include several restrictions on the use of this type of bracing.

As shown in Figure 1.2.10, critical design elements of bracing systems include diagonal elements, vertical elements, and horizontal elements:

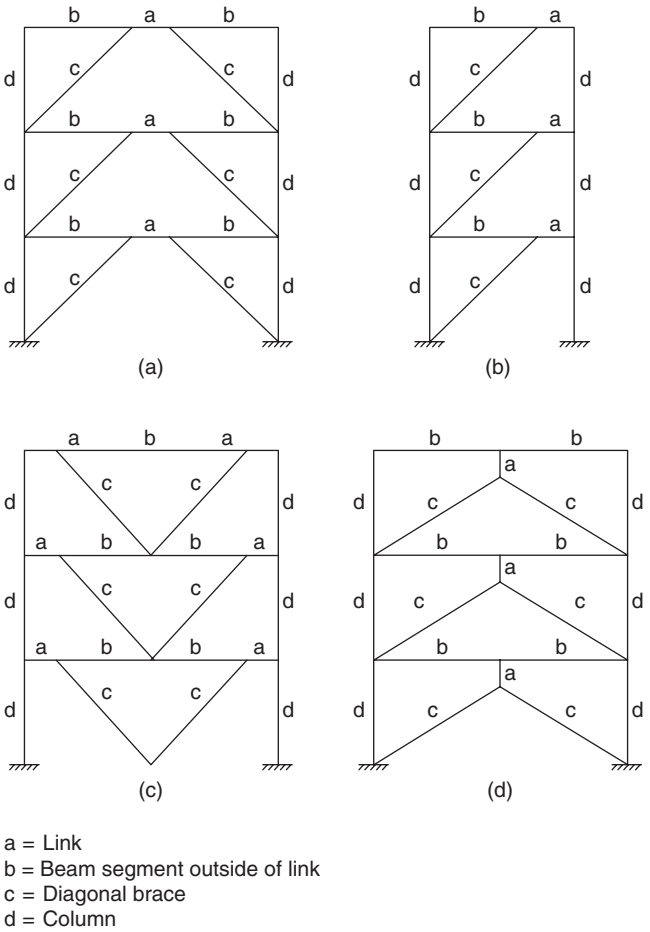

FIGURE 1.2.8 Examples of Eccentrically Braced Frames (Source: Copyright © American Institute of Steel Construction, Inc. Reprinted with permission. All rights reserved.)

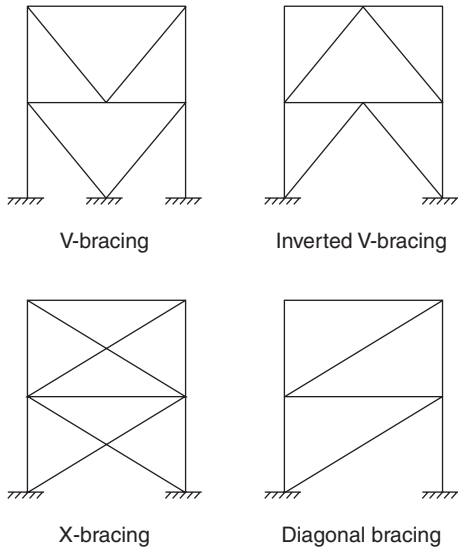

FIGURE 1.2.9 Examples of Concentric Bracing Configurations (Source: Copyright © American Institute of Steel Construction, Inc. Reprinted with permission. All rights reserved.)

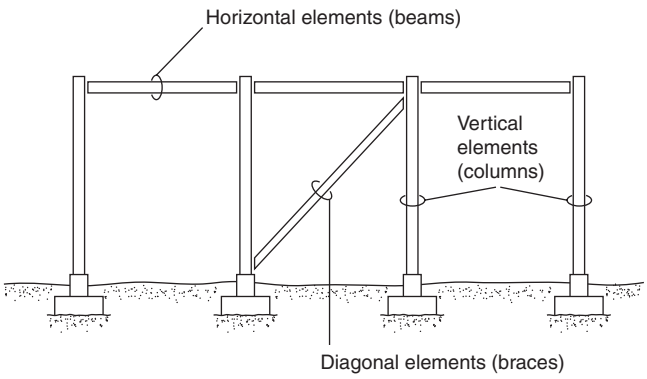

FIGURE 1.2.10 Diagonal Elements, Vertical Elements, and Horizontal Elements

- *Diagonal elements.* Designed to resist lateral (story shear) forces. Because bracing connections often tend to have brittle modes of failure, for some loading conditions the connections must be designed to be stronger than the braces themselves.
- *Vertical elements.* Designed to resist overturning forces.
- *Horizontal elements.* Designed as axial struts to collect and transfer tension and compression forces into the diagonal elements. The strut system can be sloped, such as when pitched roof elements are used as struts.

Diaphragms and Horizontal Bracing Components. Diaphragms are generally designed as beams that span between the vertical-resisting elements (frames, walls, braced frames, etc.). Critical design elements of diaphragm systems include the following:

- *Shear membrane.* The floor or roof acts as a web, or shear membrane, to resist shear forces. The web is assumed to resist shear forces only (no tension or compression).
- *Chords and boundary elements.* Located at the extreme edges of the diaphragm, the chords resist tension forces caused by bending in the diaphragm, in a manner similar to the flanges of an I-beam. When compressive stresses warrant, boundary elements may also be required to resist the compressive forces caused by bending.
- *Collectors.* Also called drag struts, collectors are used to resist axial tension and compression forces within the diaphragm by:
  - Collecting shear forces from the diaphragm and transferring them to the vertical resisting elements (walls, braces, or frames)
  - Redistributing chord forces at diaphragm offsets and gathering loads and distributing them to intersecting walls, braces, or frames
  - Redistributing diaphragm shear forces and local chord forces around openings within the diaphragm
  - Distributing points of concentrated force into the diaphragm, such as from heavy rooftop equipment

Foundation Components. Critical design issues for foundation systems include bearing strength, overturning resistance, sliding resistance, bending and shearing strength, and ground hazards:

- *Bearing strength.* The foundation system must have sufficient strength to transfer the weight of the structure to the surrounding soils without adverse settlements.
- *Overturning resistance.* Piles must have sufficient compressive and tensile capacity to resist overturning loads; spread footings must be massive enough and/or support adequate soil surcharge to counteract uplift.
- *Sliding resistance.* Either passive soil pressure, friction, or a factored combination of both may be used, depending on the soil type and foundation geometry.
- *Bending and shearing strength.* The foundation system must have adequate strength to transmit loads without failure or excessive deflections.
- *Ground hazards.* Some sites are susceptible to special hazards that can occur within the site itself, such as excessive settlement, potential slope failures, water-induced scour or shaking-induced-liquefaction. In some instances, the risk of these hazards can be reduced by conducting site improvements prior to construction, such as by soil densification or by removal of unsuitable materials. In other instances, the site itself may not be suitable for the structure.

FUNDAMENTAL DESIGN CONCEPTS

General Structural Integrity

Building codes and their referenced design load standards require structures to be designed so that, when damage is sustained locally, the damage does not spread to an area disproportionate to the original area of local damage. This is most often accomplished by providing designs that have a robust load path, stable geometry, and structural systems that are designed specifically for overstress.

Load-Path Concept

The load-path concept requires a continuous system of interconnected elements throughout the structure, adequately connected to transfer applied loads and forces from the points of origin or application to the final points of resistance. As an example, columns are used to transfer loads from roof beams to foundations. While providing a continuous load path is an obvious design requirement for vertical loads, a continuous load path is sometimes overlooked or not completely developed when designing for lateral force resistance. The failure to review all members and connections for each combination of load can lead to weak links in the load path.

Important aspects of developing, designing, and detailing the lateral load path include the following:

- Considering all likely conditions of load. In addition to the basic design loads such as gravity forces, forces caused by thermal expansion or contraction, and outside events such

as wind or earthquakes, the possible directions of application of these forces must be considered.
- Providing means of collecting load or force from one element (such as roof sheathing) and transferring it to another (such as a wall).
- Ensuring stiffness compatibility of load-resisting elements acting in parallel (before and after yield). For example, welding cannot be used to "increase" the strength of a connection using bolts, because slight movement or slip within the bolted connection may cause the more rigid weld to bear all of the force and fail.
- Considering eccentric loading or attachment conditions. It is often not physically possible to attach parts together in a concentric manner and some eccentricity must be permitted in order to make the attachment. This eccentricity causes additional bending and deformation forces in the local area around the connection that the structure must be designed to resist. These local forces are often referred to as secondary. However, they can be very large and often cause failures if not adequately considered in the design.
- Considering transfer of design loads through the foundation system into the surrounding soil. Inadequate consideration may result in portions of a structure sliding in the soil or in local foundation settlements due to high bearing pressures.

Structural Geometry

Although it is typically the structural engineer's responsibility to determine the actual details of structural resistance, the architect and other design team members can also greatly affect the ultimate resistance of the structure by controlling the configuration of the structure and the distribution of weight. The configuration of a structure can have significant impact on the way it behaves when subjected to extreme loads.

Although architectural design impacts the overall structural configuration, local geographic, cultural, and climatologic conditions can also dictate many aspects of building geometry. In coastal flood zones, for example, structures may need to be elevated on columns or piers above potential storm surge or flood heights. In inner-city areas, local planners often promote street-level plazas or parking into the design of tall buildings, which redefines the building geometry in lower levels.

A simple, symmetrical, and regular structural geometry tends to result in better performance of structures subjected to extreme loads such as earthquakes or blasts. Buildings with significant irregularities in geometry, mass, or stiffness tend to twist or deform unevenly as the building is overloaded, resulting in local areas of high stress concentration. Although irregular features often create pleasing aesthetic effects, such areas can also become early damage initiation points that can rapidly degrade structural integrity and result in poor performance unless additional attention is given to them during design and construction.

It is the mutual responsibility of the architect and structural engineer to identify and resolve geometry problems early in the design process. The challenge to the design team is to create a building with a structural system that is reasonably regular and yet still retains the intended form and function. Poor geometry can result in poor performance unless special attention is given during the design process (often at increased design and construction cost).

Designing Structures to Resist Overstress

Traditionally, the possibility of overload or overstress has not often been considered in structural design, except in areas of active seismicity or buildings subject to possible blast pressures. Structures designed without such consideration of inadvertent overload could collapse when subjected to moderate overloads or an inadvertent failure of a single member. Structures specifically designed to resist strong earthquakes or large blast pressures, however, are typically detailed with toughness and redundancy. Tough and redundant structures may have the same strength and general appearance as other structures, but contain a reliable method of resisting possible overloads without collapse.

Although buildings are designed to resist most load conditions without damage, unpredicted overload conditions can occur, and for some design load conditions, overstress and damage can result. When these unpredicted conditions happen, structures may experience undesirable failure modes. Undesirable failure modes include those resulting in total collapse of the structure, such as caused by progressive column failures, and those involving sudden failure, such as a buckling or brittle (e.g., shear) failure.

During overload conditions, structural materials that are overstressed may crack, buckle, or yield. Once such behavior, often termed *nonlinear behavior,* occurs, the load-deformation characteristics of the element—that is, its ability to resist loading without adverse deflection—changes substantially. When nonlinearity occurs, the structural elements either behave in a brittle manner, in which rapid loss of load carrying capacity occurs, or in a ductile manner, in which the element can continue to carry load, but may have substantially increased deformation and deflection. The difference between brittle and ductile behavior can be demonstrated by the following example. If a piece of chalk is bent, the chalk quickly breaks, as the bending stress exceeds the tensile strength of the chalk. On the other hand, if a metal paper clip is bent, the metal deforms and refuses to break unless bent back and forth many times. The chalk is brittle; the metal paper clip is ductile.

Ductility is a material property that exists only for nonbrittle materials such as steel. It is a measure of the material's ability to undergo nonlinear deformation without fracture (breaking). Nonlinear behavior can be safely accommodated in structures that use ductile materials (such as steel) either as the primary structural element or as reinforcing for more brittle materials. For example, plain concrete and masonry are brittle materials, but properly reinforced concrete and masonry can behave in a ductile manner and produce structures that exhibit satisfactory seismic performance. Conversely, although steel is an inherently ductile material, proper proportioning of members and design and detailing of connections is necessary to assure ductile behavior of the overall structural system. A structure can be designed to resist overstresses in a ductile

manner. Important features of ductile design include (1) selecting ductile materials and member configurations, (2) assuring that connections are stronger than the elements they connect, (3) providing redundancy or backup systems, and (4) controlling damage modes.

Redundancy in a structural system allows for redistribution of internal loads around local areas of overstress or failure. Redundancy effectively provides a backup system for protection against collapse when localized failures occur. As an example, a cantilever is a nonredundant structural system and collapses when yielding occurs at the base of the cantilever.

Some elements behave in a ductile manner if subjected to one type of loading and in a brittle manner if subjected to other types of loading. For example, reinforced concrete or masonry beams generally behave in a ductile manner when overloaded in bending, but behave in a brittle manner when overloaded in shear. Careful design practice can control the actual failure mechanism by proportioning the beam to be stronger in shear than it is in bending, so that the more ductile mode then controls the behavior.

BASIC DESIGN METHODOLOGY

In building design, there are three basic approaches: allowable stress design, load and resistance factor design (LRFD), and performance-based design.

Allowable Stress Design

Allowable stress design is the simplest and most common method used for building design. Fundamentally, it requires that the applied forces or stresses on any element not exceed the strength of that element divided by a factor of safety. The factor of safety used generally varies from 1.5 to 3.0, depending on the reliability or variability of the data on which the value of strength is determined and also the consequences of failure. Forces in individual elements are calculated using the various design loads and forces prescribed by the building code. Element strengths are calculated in accordance with procedures specified by material design standards published by different organizations supported by the materials industries.

EXAMPLE: A steel beam is made from material with a specified minimum yield strength of 36,000 lb/in.^{2} (248,000 kPA). Building codes require a minimum factor of safety of 1.5 for simple gravity (dead plus live) loads. Thus, the beam must be designed for this condition using a maximum "allowable stress" of 36,000/1.5 = 24,000 lb/in.^{2} (248,000/1.5 ≈ 165,000 kPa).

One drawback associated with the allowable stress design method is that the factors of safety used are generally independent of the certainty inherent in the definition of the applied loading. Structures that support basically nothing other than self-weight are designed using the same factor of safety as structures that support highly variable and unpredictable types of loading, such as vehicular traffic, although it would be more appropriate to provide a greater margin of safety when the loading is uncertain.

Load and Resistance Factor Design (LRFD)

The load and resistance factor design method is an alternative procedure that provides several improvements over the allowable stress design method. These include the following:

- Load and resistance factor design separates the factor of safety into components that are separately applied to the types of loading experienced and the types of elements used. Hence, the factor of safety in any structure or element varies, based on the uncertainty in both the expected loading and the predictability of the element strength.
- The procedures for calculating the strength of structural sections more realistically estimate the likely value than those used in allowable stress design procedures. This provides the opportunity to compare the strengths of any element relative to another, so that the path of failure due to overload becomes more transparent. By calculating the expected strength of each component, the engineer gains the opportunity to proportion the structure in a manner so that overload conditions are less likely to result in catastrophic failures.

Although the load and resistance factor design method offers many improvements over the allowable stress design method, many engineers regard the method as more complex and confusing. Hence, both methods are still commonly used. Although load and resistance factor design is common for concrete elements, allowable stress design has been common for the design of steel, timber, and masonry elements. The design profession is slowly moving toward universal adoption of LRFD procedures.

A Third Approach

Although both the allowable stress and load and resistance factor design methods incorporate a finite probability of structural failure, this may be misunderstood by the public, who may believe that there is no possibility of failure of a code-conforming structure. For example, owners of relatively new buildings may be upset to learn, following relatively moderate earthquakes, that their damaged building had performed within the intent of the building code. The expected response after a hurricane may be similar.

Ordinary occupancy buildings designed in accordance with building codes are intended to provide good and serviceable performance for load conditions commonly encountered, resist relatively rare load conditions with moderate but repairable damage, and provide protection against collapse for very rare extreme events (see Section 1, Chapter 7, "Protecting Against Extreme Events"). For some hazards such as tornadoes, very little protection is provided. Essential facilities such as hospitals and fire stations are designed with expectations of somewhat better performance. Specifically, the minimum permissible design loads for such structures are increased relative to those for ordinary occupancy structures. However, the extent that the actual performance of these essential facilities is improved is not quantifiable. Although very special structures such as nuclear power plants can be and have been designed to resist all kinds of extreme events without damage, the added cost of design and

construction and the required limitations on architectural freedom have limited building codes to providing lower levels of protection.

Sophisticated owners of very valuable or important facilities have sought better quantification of the risks associated with extreme events, to permit them to make better business decisions and tradeoffs between paying added initial costs for better building construction and avoiding the future costs of insurance protection, damage repair, and potential business interruption. This has led to the development of a third design methodology—*performance-based design.*

Performance-Based Design

Rather than following prescriptive requirements contained in the building codes, the design professional using performance-based design procedures directly develops a design capable of achieving specific performance goals and objectives. Performance-based procedures intended to ensure adequate fire/life safety protective features in buildings have been under development for a number of years. Recently, structural engineers have also begun to develop performance-based design procedures, primarily for application to earthquake-resistant design.

The structural engineer using performance-based design applies a procedure to predict and estimate damage or behavior anticipated of a structure's design to design events, compared against preselected objectives. The design is revised until the predictive methodology indicates that acceptable performance can be obtained. Predictive methods can include calculation procedures as well as construction and laboratory testing of prototype designs. Performance-based design benefits owners who want to understand how their buildings may be expected to perform if they are subjected to various design events. It also helps them determine levels of acceptable performance based on the costs of different levels of performance.

Building owners have the three following basic interests in relation to building performance:

- Preservation of safety
- Preservation of capital
- Preservation of function

Some building owners may not be particularly interested in either preservation of the capital invested in a building or in maintaining its function, feeling that the probability of a damaging event is low and that insurance is available and sufficiently inexpensive to provide protection against these rare unexpected events. For other building owners, performance-based structural design is an attractive alternative approach that provides financial justification for providing the same or better performance than that defined in the building code.

Building Importance Defined in Building Codes. The basic reason that municipalities adopt building codes is to protect the public safety; the primary goal of building codes is, therefore, to protect life safety for the most severe events (fire, wind, earthquake, etc.) likely to affect the structure during its life. In effect, codes deem some buildings more important than others. For some types of buildings, structural failure could result in greater loss of life than other types or could result in the loss of vital disaster recovery services. Greater protection is warranted for such buildings. To assist with the assignment of appropriate levels of safety to buildings with different intended occupancies and uses, the American Society of Civil Engineers' *Minimum Design Loads for Buildings and Other Structures*[5] defines several standard occupancy categories. An abbreviated summary of these occupancy categories follows:

- *Occupancy type I.* This category includes structures such as sheds or agricultural buildings that are normally unoccupied. The failure of such buildings is unlikely to result in significant probability of life loss. Therefore, relatively little protection is required for such structures, and it is considered acceptable if they collapse during a rare event.
- *Occupancy type II.* This category includes most types of buildings, including most commercial, residential, and institutional structures. It is literally defined in the building codes as all buildings except those specifically included in other categories. Under extreme loading these structures are expected to be heavily damaged but not collapse.
- *Occupancy type III.* This category includes important buildings that accommodate a large number of people, that provide important public services (such as utilities), or that house occupants with limited mobility such as schools or detention facilities. It also includes facilities that house moderately hazardous substances, such as certain chemicals or petroleum products, and facilities with potential to cause a substantial economic impact or mass disruption of life in the event of failure. Greater protection against collapse is warranted for these structures for rare events, and less damage is acceptable for more moderate events.
- *Occupancy type IV.* This category includes buildings that are deemed to be essential to the public welfare such as hospitals; fire, rescue, and police stations; and essential communication, transportation, and water storage facilities. It is highly desirable that these facilities be capable of functioning following even a rare event.

Benchmark Damage Levels. In recent years, a series of standard definitions of tolerable damage levels, termed *performance levels,* have been developed. Standard definitions are found in *NFPA 5000®, Building Construction and Safety Code®*:

- *Serviceability performance.* The serviceability level of performance is a state in which structural elements and nonstructural components have not sustained detrimental cracking or yielding, or degradation in strength, stiffness, or fire resistance requiring repair that is troubling to occupants or disruptive of building function. Nonstructural components and permanent fixtures and features have also not become displaced or dislodged.
- *Immediate occupancy performance.* The immediate occupancy level of performance is a state in which minor, repairable cracking, yielding, and permanent deformation of the structure and nonstructural elements may have occurred. Although repair may be required, the structure would not be considered unsafe for continued occupancy.

- *Collapse prevention performance.* Under this level of performance, the building may experience substantial damage to structural and nonstructural elements, with some failures occurring. However, collapse is avoided and emergency responders can effect occupant rescue and building evacuation.

Quantification of Risk. The fundamental improvement that the performance-based design method offers is a quantification of the degree of risk of damage associated with load events that are likely to occur, might possibly occur, and could conceivably occur during the existence of a structure. Benefits of this approach are a structure unlikely to experience unwanted damage, and quantification of risk that can be directly used in financial analysis by evaluating the cost/benefit of increased performance versus future insurance payments and risk of loss (Figure 1.2.11). For the basic occupancy types defined in building codes, risk levels for various types of transient loading are defined to be consistent with the performance objectives outlined in Figure 1.2.11.

Criteria to Confirm Compliance. To assess the damage level associated with any risk level of loading, design procedures must present criteria for determining the strength or deformation resistance of each building element at each damage level. ASCE/FEMA 356 "Prestandard for the Seismic Rehabilitation of Buildings"[6] and Appendix G of the SEAOC "Recommended Lateral Force Criteria and Commentary"[7] provide criteria that may be used to determine these values.

SUMMARY

The combination of building codes, design load standards, material design standards, and the engineering process provides a reasonably uniform factor of safety to building design. Design load standards provide a statistically derived method to define the vertical loads and lateral forces to which buildings may be subjected, as well as uniform margins of safety in design. Material design standards define the means to determine the usable strengths of building components. The engineering process provides a rational method to determine the minimum levels of strength and toughness in individual building components and also a measure of warning to permit occupants to evacuate if overload conditions occur. Various methodologies used to design building components in the engineering process include the allowable stress, load-and-resistance factor, and performance-based design methods.

There are many challenges to safe building design. Each building is unique in location, geometry, use, construction, and condition. Because building codes, materials, and methods of construction change with time, and uncorrected deterioration may reduce the strength or safety of buildings with time, many buildings exist that would be considered substandard relative to current building codes. Even in new construction, mistakes or misunderstandings during either the design or construction process can result in building defects. In addition, design load standards referenced in building codes cannot define with certainty the actual ranges of loading or exposure to snow, wind, or other extreme events to which any building may be subjected throughout its existence.

Chapter 3

Codes and Standards for the Built Environment

Arthur E. Cote ■ Casey C. Grant

Throughout history there have been regulations for the built environment that are intended to prevent fire and restrict its spread. Over the years, these regulations have evolved into the codes and standards developed by organizations concerned with safety. In many cases, a particular code dealing with a hazard of paramount importance may be enacted into law.

See also Section 1, Chapter 2, "Fundamentals of Structurally Safe Building Design"; Section 1, Chapter 5, "Fire Prevention and Code Enforcement"; and Section 11, "Fire Prevention Practices."

HISTORY OF REGULATIONS FOR THE BUILT ENVIRONMENT

Rules and Regulations from the Ancient World

King Hammurabi, the famous lawmaking Babylonian ruler who reigned from approximately 1795 to 1750 B.C., is probably best remembered for the *Code of Hammurabi,* a statute primarily based on retaliation.[1]

The *Code of Hammurabi* is arguably the most well-known and best preserved of the regulatory codes serving the ancient world. It was carved on an 8-foot-high black stone monument (Figure 1.3.1) and was clearly intended to be on display in public view for the citizens of the day. In the year 1901 the stone was discovered, not in Babylon, but in a city of the Persian mountains to which some later conqueror is assumed to have carried it in triumph.

This noted code organizes and displays a legal system that appears to be well established and, thus, it provides testament to the earlier societal regulatory doctrines that surely predate it. Extensive in nature and covering many topics, including property, mercantile exchange, and family responsibilities, the following decree from the *Code of Hammurabi* is among those more closely related to what might be considered the inchoate roots of modern building codes:[2]

> 229: If a builder build a house for some one, and does not construct it properly, and the house which he built fall in and kill its owner, then that builder shall be put to death.

Today, society no longer endorses Hammurabi's ancient law of retaliation but rather seeks to prevent accidents and loss of life and property. The current legal system serves as the retaliatory arm when negligence is found to be the cause of harm to an individual. After close to four millennia, rules and regulations have evolved that represent today's codes and standards for the built environment.

The earliest recorded building laws appear to be more concerned with the prevention of collapse. Although fire was still a threat, collapse due to poor construction and the inability to adequately address large-scale destructive events due to naturally occurring hazards such as wind and earthquake seemed to be more prominent in the minds of policy makers of the day.

Arthur E. Cote, P.E., FSPE, is executive vice-president and chief engineer (retired) at NFPA.

Casey C. Grant, P.E., is program director for the NFPA research foundation, and previously secretary of the NFPA Standards Council.

When the cities of the ancient world burned, it was typically due to the incursion of a hostile neighbor, and the likely policy response was military power rather than fire prevention measures incorporated into the built environment. Regardless, the scattered historical records of the ancient world provide brief mention of citywide conflagrations not caused by warfare, most notably the conflagrations said to have occurred in the ancient cities of Knossos, Crete (Greece), in 1450 B.C., Babylon, Mesopotamia, in 538 B.C., Carthage in 146 B.C., and Rome in A.D. 64. However, record keeping and statistical loss data for these early conflagrations are admittedly inconsistent and riddled with exaggerations that at times are striking. As a result many of these incidents exist today more as folklore than verifiable recorded events.

As civilization grew, so did the recognition that fire was a threat that needed to be addressed. Among the earlier legal rules taking a regulatory stand specific to fire, one well-preserved doctrine is traced to the Roman Empire in what is known as *The Law of the Twelve Tables*.[3] Established circa 450 B.C., Table VIII, Part 10 of this set of regulations indicates:

> 10. Any person who destroys by burning any building or heap of corn deposited alongside a house shall be bound, scourged, and put to death by burning at the stake provided that he has committed the said misdeed with malice aforethought; but if he shall have committed it by accident, that is, by negligence, it is ordained that he repair the damage or, if he be too poor to be competent for such punishment, he shall receive a lighter punishment.

As with earlier regulatory codes, retaliation after an incident had occurred remained the primary enforcement vehicle, and preventative design concepts still eluded the primary policy makers. Nevertheless, we see here a focus on fire rather than structural collapse and similar nonfire occurrences, and this focus distinguishes *The Law of the Twelve Tables* of the Roman Empire from other early regulatory codes for the built environment.[4]

Perhaps most notable and best documented among the nonwarfare-initiated conflagrations of premodern civilization is the burning of Rome in A.D. 64. The legacy of this fire is based on the sheer magnitude of the event, as the fire was devastating and Rome was by far the largest city the ancient world had ever seen. The fire began during the night of July 18 in the merchant section of the city, and after burning for six days and seven nights in this city with a population estimated at close to 1 million inhabitants, it left 70 percent of the city destroyed. Only 4 of the city's 14 wards remained intact. In addition to the unparalleled magnitude of the fire, it also gained further lasting historical significance due to the political outfall and subsequent religious persecution of the Christians who became the focus of blame for the fire.[5]

Early Building and Fire Laws

Throughout the Middle Ages, Europe bore witness to numerous citywide conflagrations; however, these were most often the result of raids, attacks, or warfare rather than natural or more conventional accidental occurrence. But the roots of modern fire regulations were slowly evolving. In England, Alfred the Great instituted fire prevention regulations in 871 that mandated the covering of cooking fires at night. Existing fire prevention regulations were reportedly further strengthened by William the Conqueror in 1000. In 1189, the mayor of London promoted the "Assize of Buildings," which regulated all methods of building and among other details recommended use of party walls made of stone to mitigate fire spread. The "Assize of Buildings" is considered one of the earliest of the European building codes, but it is unclear how widely it was used or enforced since large fires still occurred, such as the great fire of 1212 that partially destroyed the city of London.[6]

Later, there evolved many building regulations for preventing fire and restricting its spread. In London, during the fourteenth century, an ordinance was issued requiring that chimneys be built of tile, stone, or plaster; the ordinance prohibited the use of wood for this purpose. All of these measures, however, were relatively primitive and resulted in marginal or nonexistent positive impact. In the meantime, the populations of European cities were increasing at striking rates and the features of many cities were radically changing as they attempted to keep up with the population growth.

Another European citywide fire of historic proportions was the great fire of London in 1666. Burning over a period of five

days, this fire destroyed some 13,000 buildings and left an estimated 100,000 inhabitants homeless. As a result, the English Parliament introduced legislation known as the London Building Act. Yet in the years subsequent to the fire, the noble efforts of the policy makers to rewrite the basic design approach met with only partial success, as there was apparently little or no enforcement mechanism, and they met with questionable success in the years that followed.[7]

Another noteworthy milestone that resulted from the great London fire of 1666 was the spawning of the fire insurance industry. The modern contractual concept of insurance predates the event and may have occurred as early as 1347, based on activities recorded in Genoa, Italy. This contractual insurance arrangement, as well as others, provided the right circumstances to evolve into a viable business model immediately after the fire. Following the disaster, Dr. Nicholas Barton founded the Phoenix Fire Insurance Company and implemented the first use of "fire marks," which were metal or ceramic plaques affixed to the exterior of insured buildings to identify them to the insurance company's private fire brigades that they were to be protected. The Phoenix Fire Insurance Company began underwriting in 1680 and ceased trading in 1712, but the concept prospered and over the next 250 years over 200 different companies used about 80 different design plaques across the United Kingdom. The concept was imported to the United States but developed in reverse, since insurance ultimately evolved from the fire brigades rather than the fire brigades evolving from the insurance companies.[8] Today the insurance industry continues to have a major influence on the collective conscience of society when it comes to fire-safe buildings. Its influence on shaping fire safety policies, including prevention and mitigation, has been significant, since its collective approach to loss is less tolerant than society tends to be on an individual basis. In other words, someone else's losses are no longer someone else's, since we all ultimately pay for those losses through shared increases in our own insurance premiums. Insurance makes us collectively more responsible and, thus, the insurance industry continues to play an important role in shaping today's fire protection safety infrastructure for the built environment.

A conflagration is generally recognized as a large destructive fire, and in the insurance industry it is understood to be a fire that causes substantial destruction. A review of the historical record indicates a seemingly countless list of incidents when cities from the earliest civilizations have been either partially or totally destroyed by fire. Warfare is an obvious factor in some of these incidents, but even when removing those that are the result of embattled people, fire has still been a scourge throughout the millennia. Admittedly, the historical records from ancient times are lacking specificity, but nevertheless a review of various sources on file in the NFPA Library has resulted in mention of the incidents listed in Table 1.3.1.

Although the Industrial Revolution had a dramatic effect on the growth of the populations and overcrowding in urban cities across the globe and the resulting increase in the occurrence of devastating large-scale fires, it also marked a historical turning point for technological innovations that became part of the arsenal for protecting the built environment. The nineteenth century saw a plethora of new devices and technological innovation for fire protection. The proverbial parade of advancements is noteworthy: in 1800 Englishman John Carrey invented a crude automatic sprinkler; in 1821 Joseph Boyd patented the first rubber-lined cotton fire hose; in 1845 William Channing was credited with the invention of the first fire alarm telegraph; in 1852 a patent was issued for the first sprinkler perforated pipe system; also in 1852 the first Central Office (i.e., central station) and fire alarm boxes were installed in Boston; in 1853 the first practical motorized fire pumper was tested in Cincinnati; in 1860 Philip Pratt produced the first practical automatic sprinkler system; in 1863 Alanson Crane patented the first portable fire extinguisher; in 1864 Stewart Harrison produced the first practical sprinkler, significantly improved in 1874 by Henry Parmelee and again in 1880 by Frederick Grinnell. These inventions continued into the twentieth century with important technological innovations, such as the invention in 1940 of soy protein aerofoam by Percy Julian, the introduction of high-pressure water mist fog nozzles in 1942 by the U.S. Navy, and the invention in 1969 of the first battery-powered smoke detector by Randolph Smith and Ken House.[9]

Yet aside from these built-in fire protection devices, tools, and agents, the age-old natural commodity of water still remained the primary tool in the fire protection arsenal. Delivering water to control a fire was viewed as critical in the ancient world, and it remains so today. The earliest fire pump is generally credited to Ctesibius of Alexandria in the second century B.C. During medieval times, the fire pump was reinvented in Europe and is reported to have been used in several German cities, including Augsburg in 1518 and Nuremberg in 1655. Various reports exist throughout the next several hundred years of fire apparatus used in cities such as Boston, London, and Philadelphia, with the eventual development of steam-powered, horse-drawn pumpers replacing more primitive hand pumps, which

TABLE 1.3.1 Various Notable Citywide Nonwarfare Conflagrations Through History

City	*Year*
Knossos, Crete (Greece)	1450 B.C.
Babylon, Mesopotamia	538 B.C.
Carthage	146 B.C.
Rome	64
London	1212
Moscow	1570
London	1666
Constantinople	1729
Lisbon	1755
Bombay	1803

Hakodate, Japan	1934
Chungking	1949
Guatemala City	1960

in turn were replaced by motorized apparatus of similar basic design to what is used today. In the late 1800s, as "tall" buildings (i.e., 15 stories) started to become a part of the cityscape, water towers and aerial ladders made their appearance in European and U.S. cities.[10]

In colonial America, the need for laws that offered protection from the ravages of fire developed simultaneously with the growth of the colonies. The laws outlined the fire protection responsibilities of both homeowners and authorities. Some of these new laws were planned to punish people who put themselves and others at risk of fire.

Among the first legislative acts in colonial America were those of New York City and Boston requiring that dwellings be constructed of brick or stone and roofed with slate or tile, rather than built of wood with thatched roofs and wood chimneys covered with mud and clay. The intention of these building ordinances was to restrict the spread of fire from building to building in order to prevent conflagrations. As an incentive for helping to prevent fires in Boston, a fine of 10 shillings, equivalent to about $100 in 2007, was imposed on any householders who had chimney fires. This fine encouraged citizens to keep their chimneys free from soot and creosote. This ordinance was among the first fire code requirements in America to be established and enforced.

As further examples, in colonial Boston no person was allowed to build a fire within "3 rods" (about 49.5 ft or about 15.5 m) of any building or in ships that were docked in Boston Harbor. It was illegal to carry "burning brands" for lighting fires except in covered containers, and arson was punishable by death. Regardless of such precautions, in Boston and in other emerging communities, fires were everyday occurrences. Therefore, it became necessary to enact more laws with which to govern building construction and to make further provisions for public fire protection. There emerged a growing body of rules and regulations concerning fire prevention, protection, and control. From these small beginnings, various codes have evolved in the United States, ranging from the most meager of ordinances to comprehensive handbooks and volumes of codes and standards on building construction, systems, processes, and general fire safety.[11]

Development of Modern Building and Fire Regulations

The rapid growth of early North American cities inspired much speculative building, and the structures usually were built close to one another. Construction often was started before adequate building codes had been enacted. For example, the year before the great Chicago fire of 1871, Lloyd's of London stopped writing policies in Chicago because of the haphazard manner in which construction was proceeding. Other insurance companies had difficulty selling policies at the high rates they had to charge. Despite these excessively high rates, many insurance companies suffered great losses when fire spread out of control.

With the widespread immigration and rapid growth of North American cities, the nineteenth century witnessed fire after fire sweep through large urban centers. The ability to quickly rebuild and the boundless resources available in the new frontier, along with the laissez-faire attitude of North America settlers, created a societal character of relative indifference to these large-scale fires. A fair question was, when would the plague of destruction reach a point when society would no longer tolerate these events? Some will argue that the turning point occurred with the great Chicago fire of 1871.

The summer and early autumn of 1871 had been particularly dry in the Northern Lakes region of the midwestern United States, and on October 8, 1871, fire visited the city of Chicago. Starting around 9:00 p.m., the incident originated in a cow barn on Chicago's west side and by midnight the fire had spread furiously and jumped the nearby river. When the flames finally were confined two days later, approximately 250 citizens had lost their lives, some 18,000 buildings were destroyed, and approximately 100,000 people were homeless.[12] As a historical footnote, in northern Wisconsin a forest fire unrelated to the Chicago fire occurred on the same evening and virtually erased the town of Peshtigo, Wisconsin, and surrounding villages, resulting in a death toll estimated at over 1500 and ranking among the worst life-loss fire events in North American history. Since 1922, based on a presidential proclamation, Fire Prevention Week is celebrated during the first week of October each year in remembrance of the Chicago and Peshtigo disasters.[13]

Following the Chicago fire, the so-called "great rebuilding" took place with rapid replacement of the structures in the burned districts. Unfortunately, the freewheeling construction and nonexistent enforcement replicated many of the inherent design mistakes that allowed the fire of 1871 to spread with such rapidity, and just three years later in 1874, another fire occurred that destroyed 800 buildings. Finally, more definitive action occurred to strengthen the local building and fire regulations.

Following the great Chicago fire of 1871, various professionals seeking to learn from the disaster visited the city. Boston Fire Chief John S. Damrell learned much from the Chicago fire, but his warnings to his own city were ignored by the city fathers who held the somewhat condescending view that their style of masonry and granite construction was superior to the heavily wooden construction of the Midwest and elsewhere. Damrell thought otherwise and was significantly concerned with the wood mansard roofs atop the granite and masonry structures as well as the poor water supplies in the heavily congested downtown area. His fears would manifest themselves on Saturday, November 9, 1872, sometime after 7:00 p.m., when fire struck a five-story mercantile building in the high-value business district. A delayed alarm, along with an equine epidemic that crippled all the fire horses throughout the city, resulted in the fire gaining significant headway and soon it was jumping from rooftop to rooftop. By the time it was brought under control the following day, 14 people had died and 776 buildings were destroyed in the heart of the city.[14]

It is worth pausing to reflect on the significant influence of Chief Damrell in advancing the cause of fire safety after the great Boston fire. Damrell was chief of the Boston Fire Department from 1866 to 1877 (which includes the great Boston fire of 1872). He then became chief of the City Department of Inspection in Boston from 1877 to 1903. He was one of the founders of the National Association of Fire Engineers (NAFE) in 1873, which today is the International Association of Fire

Chiefs (IAFC), and was its first president. He also was one of the founders of the National Association of Commissioners and Inspectors of Public Buildings (NACIPB) in 1891 and likewise served as its first president. Among his accolades relating to the built environment, he was an outspoken proponent of the need for national building and fire codes, and he directly contributed to a draft developed by the NAFE in the mid-1870s. This document was among the earlier comprehensive draft building codes of that era, which subsequently had an influence on the development in 1896 of the "National Board's Model Building Law," compiled by the National Board of Fire Underwriters (NBFU) for an unsuccessful initiative to have a building code adopted in New York State.[15] This eventually led to the publication in 1905 (after his death) of the *Building Code Recommended by the National Board of Fire Underwriters,* published by the NBFU, which was operating at that time in conjunction with the National Fire Protection Association (NFPA).[16]

The National Board of Fire Underwriters, which was later renamed the American Insurance Association (AIA) and now is the American Insurance Services Group (AISG), organized in 1866, realized that the adjustment and standardization of rates were merely temporary solutions to a serious technical problem. This group began to emphasize safe building construction, control of fire hazards, and improvements in both water supplies and fire departments. As a result, the new tall buildings constructed of concrete and steel conformed to specifications that helped limit the risk of fire. These buildings were called Class A buildings. The 1905 *NBFU Building Code,* which would later become the *National Building Code* (NBC), was a first and very useful attempt to show the way to uniformity. As reported at the 19th Annual Meeting of the NFPA (in 1914) that included a symposium on state and local building codes, North Carolina was the first state to adopt a state building code (about 1905), Wisconsin had also adopted a code, and Ohio, Illinois, and Pennsylvania were in the process of doing so.[17]

In San Francisco in early 1906, although there were some new Class A concrete and steel buildings in the downtown section, most of the city consisted of fire-prone wood shacks. Concerned with such conditions, the National Board of Fire Underwriters wrote that "San Francisco has violated all underwriting traditions and precedents by not burning up."[18]

On April 18 of that same year, the city of San Francisco experienced a conflagration—started by an earthquake—that killed 452 people and destroyed some 28,000 buildings. Total financial loss was $350 million, which is over $6.7 billion in estimated 2000 dollars.[19] Although the contents of many of the new Class A buildings were destroyed in the San Francisco fire, most of the walls, frames, and floors remained intact and could be renovated.

Cities across North America have experienced significant destruction throughout the years by large destructive fires. Even after eliminating consideration of fires caused by warfare, there is a significant number of these incidents. A review of various sources on file in the NFPA Library has resulted in mention of the incidents listed in Table 1.3.2.

The burning of the city of San Francisco in 1906 was daunting by its sheer magnitude of loss, as illustrated by Figure 1.3.2. Yet of the many individual stories of survival, one particularly worthy of further mention from a historical context is the successful defense of the San Francisco Mint, also known by the nickname of the "Granite Lady." Built in 1874, by 1880 it was producing 60 percent of U.S. gold and silver coins, and until the Fort Knox depository opened in 1937 it would hold roughly a third of the nation's gold reserves in its vaults. With a group of mint employees and soldiers, mint Superintendent Frank Leach used a specially designed internal water-well and hose system to defend the building while everything around it was totally consumed by fire. The direct loss of the facility would have been catastrophic, but some have estimated that the indirect loss would have been worse and might have included the collapse of the U.S. economy. After the fire, the mint was the focal point of the financial regrowth, and today the landmark building is the San Francisco History Museum.[20]

Following analysis of the fire damage caused by the San Francisco disaster and other major fires, the National Board of Fire Underwriters became convinced of the need for more comprehensive standards and codes relating to the design, construction, and maintenance of buildings. With this increasing recognition of the importance of fire protection came more knowledge about the subject. Engineers started to accumulate information about fire hazards in building construction and in manufacturing processes, and much of this information became the basis for the early codes and standards.

TABLE 1.3.2 Various Notable Citywide Nonwarfare Conflagrations in North America

City	*Year*	*Estimated Buildings Destroyed*
Charleston	1740	300
New York City	1835	674
Charleston	1838	1,158
Philadelphia	1839	52
Pittsburgh	1845	1,115
Quebec	May 1845	1,500
Quebec	June 1845	1,300
San Francisco	1851	500
Sacramento	1852	2,600
Troy, NY	1862	507
Philadelphia	1865	50
Portland, ME	1866	1,500
Chicago	1871	15,000
Boston	1872	776
Galveston, TX	1885	568
Seattle	1889	640
Minneapolis	1893	200
Atlantic City	1902	12
Baltimore	1904	1,600
San Francisco	1906	28,188
Chelsea, MA	1908	3,500
New Bern, NC	1922	600
Chelsea, MA	1973	1,400

Note: For sake of comparison, the great fire of London in 1666 consumed 13,000 buildings.

FIGURE 1.3.2 The Great Earthquake and Ensuing Conflagration That Devastated San Francisco in 1906

At the dawn of the twentieth century the cities of North America were experiencing rapid growth, and the scourge of uncontrolled fires destroying portions or even entire cities was the primary focus of the building professionals of the day. But as the built environment began a fundamental shift in the early 1900s to superior building techniques that limited the building-to-building affliction of fire, attention also began to constrict inward with an additional focus on fires occurring within a single building and, in particular, fires that caused a large loss of life. A string of large life-loss fires began to catch the attention of the general public and reached an apogee with the Iroquois Theater Fire in Chicago, Illinois, that occurred on December 30, 1903, killing 602 and injuring more than 250 people.[21]

The public was becoming less tolerant of these large life-loss fires during the early years of the 1900s. The turning point came in 1911, when on March 25 a fire struck the top three floors of the 10-story Asch Building in New York City. These floors were occupied by the Triangle Shirtwaist Company, which employed garment workers (mostly young women and girls) in so-called "sweatshops." By the time this fast-moving fire was out, 146 workers had either burned to death on the upper floors or plunged to their deaths in front of tens of thousands of onlookers.

The impact of the Triangle Shirtwaist fire on the public conscience was profound. This was due in large part to the growing labor movement that was occurring at the same time, and the fire became a rallying cry for the rights of workers as exemplified by the funeral parade that followed, with an estimated crowd of 400,000 people. The event was likewise a milestone from the standpoint of codes for the built environment. One direct result of this fire of paramount historical importance was the establishment of the NFPA *Building Exits Code* two years later at the 1913 NFPA Annual Meeting. Through the years this essential model code came to be retitled as NFPA *101*®, *Life Safety Code*®, and today provides the backbone of the building exit requirements in building codes used throughout North America and in other parts of the world.[22]

CONCEPTS OF SAFETY VERSUS RISK

There are two broad categories of voluntary codes and standards: (1) safety codes and standards and (2) product standards. These documents are not solely a matter of science, especially safety codes and standards.[23] Codes and standards embody value judgments as well as facts and sometimes must use empirical evidence on judgment to compensate for gaps or limits in the relevant science (also see the *SFPE Handbook of Fire Protection Engineering*[24]). Codes and standards oriented toward safety tend to be more complicated and extensive than product standards. Furthermore, safety codes and standards are often adopted with the power of law and, thus, require more extensive technical advisory support and enforcement.

Safety is the inverse or opposite of risk, so greater safety means the reduction or elimination of some risk to people or property or some other vulnerable entity of concern. Risk can never be entirely eliminated, and so safety is never absolute. Even short of absolute safety, any relative increase in safety will not have unlimited value. Individual, organizational, or societal decision makers must decide whether a particular increase in safety (i.e., reduction in risk) is worth more to them than what they must pay in order to achieve that safety increase.

Because financial resources are the most obvious sacrifice required to decrease risk, the trade-off involved is often called "willingness to pay." The lower the risk becomes, the more it typically costs to achieve each additional constant or incremental increase in safety. In addition, part of the cost of risk elimination can be the reduction of some freedoms. Many aspects of safety systems or materials standards have this effect, as they come to bear on the establishment of an "acceptable level" of

risk.[25] In addition, the standard of care provided by the code may either eliminate certain materials or processes or set demanding performance criteria for such elements.

Assessments of levels of risk are also needed with respect to cost of use of the codes and standards themselves, including complex calculations or other costs of information. If tolerance limits are exceeded, codes and standards will be modified in practice or ignored. Also, the more onerous and costly compliance becomes, the more carefully critics will examine the "degree of contribution to a safe environment" that the code or standard will bring about. In other words, attempts at applying cost–benefit models may be used as a part of the justification for an increased level of performance or, conversely, to show why the suggested performance is impractical from an economic standpoint.

The many effects of codes and standards on what people value bring various complex factors into play—social, economic, political, legal, business-competitive, and others—that affect how much people value safety and how much they value what may be sacrificed for safety. No solely economic, engineering, or public health approach can do justice to all these factors, many of them unavoidably or even intrinsically subjective, in establishing a cost–benefit analysis.

One of the strengths of the voluntary consensus codes and standards-development system in the United States is that the deliberative committee structure, which comprises a balanced representation of all affected interests, including users, consumers, manufacturers, suppliers, distributors, labor, testing laboratories, enforcers, and federal, state, and local government officials, can consider all of the diverse factors at hand and develop a consensus on an acceptable level of standardization. It has been observed that "this may be one of the greatest strengths of the present private standards-writing system, insofar as it truly represents variety, and one of the greatest insufficiencies of a governmental system."[26] So-called government consensus simply seeks agreement from one segment of like-minded thinkers—hardly a model for consensus.

ROLE OF CODES IN THE BUILT ENVIRONMENT

Understanding the Built Environment

A *code* is a law or regulation that sets forth minimum requirements and, in particular, a *building code* is a law or regulation that sets forth minimum requirements for the design and construction of buildings and structures. These minimum requirements, established to protect the health, well-being, and safety of society, attempt to represent society's compromise between optimum safety and economic feasibility.[27]

Although builders and building owners often establish their own requirements, the minimum code requirements of a jurisdiction must be met. Features covered include, for example, structural design, fire protection, means of egress, light, sanitation, and interior finish. Inasmuch as a model building code is actually a law once adopted, various state and local jurisdictions write their own codes. Because of the complexities of modern building code development, several organizations develop model building codes for use by jurisdictions, which can then adopt the model codes into law either in total or with amendments deemed to be necessary for that jurisdiction.

In a stylistic sense, there are two broad, general approaches used to write codes for the built environment: specification or prescriptive codes and performance-based codes.[28]

Prescriptive-Based Codes

Prescriptive or specification-based codes spell out in detail what materials can be used, the building geometry (heights and areas), and how the various building components should be assembled. The traditional codes that have evolved through history tend to be prescriptive or specification oriented.

The requirements contained in the traditional building codes are generally based on the known properties of materials, the hazards and risks presented by various occupancies, and the lessons learned from previous experiences, such as fire and natural disasters. As mentioned earlier, the promulgation of modern building codes in North America began with the disastrous conflagrations that occurred in the late nineteenth and early twentieth centuries. Early building codes have grown into documents prescribing or specifying minimum requirements for structural stability, fire resistance, means of egress, sanitation, lighting, ventilation, and built-in safety equipment. Typically, more than half of a modern building code usually refers in some way to fire protection.

The establishment of height and area criteria, which is a common feature in today's building codes, provides a good example of the impact of prescriptive or specification-oriented building codes on fire protection and prevention. The criteria establish the maximum height and area of a particular building on the basis of its intended use. These requirements have typically varied considerably from one type of occupancy to the next. Requirements such as those based on height and area criteria establish inherent fire limits or fire districts for buildings or groups of buildings in certain areas of a municipality.

The prescriptive evolution of height and area requirements has a historical orientation. In 1913, Professor Ira Woolson of the National Board of Fire Underwriters presented a paper before the American Society of Mechanical Engineers, and this document provided one of the first recorded attempts to clearly articulate a set of allowable heights and areas for factory buildings. This paper was published in the January 1914 issue of the NFPA *Quarterly*.[29]

From a prescriptive or specification perspective, the types of building construction are important factors in establishing height and area limitations, and only specific types of construction are allowed within the fire limits. Such a restriction is intended to reduce the conflagration potential of the more densely populated areas. Other requirements found in prescriptive or specification-oriented building codes that directly relate to fire protection include (1) enclosure of vertical openings such as stair shafts, elevator shafts, and pipe chases; (2) provision of exits for evacuation of occupants; (3) requirements for flame spread of interior finish; and (4) provisions for automatic fire suppression systems. Exit requirements found in most building codes are based on requirements found in NFPA *101*®, *Life Safety Code*®.

Prescriptive or specification-oriented building and fire codes have historically served us well, but they also have limitations. Because of their well-defined yet rigid nature, they tend to lack flexibility for unusual or alternative designs, and they don't necessarily take advantage of the most cost-effective design solution or a clearly desirable specific level of safety. Further, they generally do not make direct use of new and useful design tools, such as state-of-the-art computerized fire models.[30]

Performance-Based Codes

Performance-oriented building and fire codes detail the goals and objectives to be met and establish criteria for determining if the objective has been reached. Performance-oriented building and fire codes are a relatively new and evolving concept, which is only in recent years enjoying widespread acceptance.

Unlike prescriptive and specification-based codes, which may or may not explicitly state their goals and objectives, a performance-based code is fundamentally grounded on the goals and objectives it contains. Its entire focus is to clarify these goals and objectives and provide an implementation method for achieving them. In contrast, prescriptive and specification-based codes are like a recipe of items that are to be followed absent of any meaningful interpretability beyond what the code states.

Building and fire codes that are performance oriented allow more flexibility for state-of-the-art designs and help identify the most cost-effective design solutions without compromising levels of safety. Performance-based codes may still embody a fair number of specification-type requirements, but provisions exist for widespread substitution of alternate methods and materials ("construction modifications"), if they can be proven adequate in the regulatory framework that accompanies the performance-based code. Thus, the designer and builder gain added freedoms to select construction methods and materials that may be viewed as nontraditional as long as it can be shown that the performance criteria can be met. Performance-based approaches have been and are being utilized today through the "equivalency" provision found in most codes and standards for a limited number of applications. In other cases, building configurations or designs may be so unusual that the only way to design them is to apply performance-based design principles to the entire structure. Examples include developing fire safety for unique architectural designs not anticipated by current codes and standards, developing equivalent means of protection to existing prescriptive requirements, and preparing fire reconstructions.[31]

Performance-based approaches today generally require a major interactive undertaking by both the designer and the authority having jurisdiction (AHJ). As performance-based approaches and their supporting pieces further mature, they can be expected to enjoy greater acceptance overall.

INTERNATIONAL CONSIDERATIONS

Basics of International Standards Development

In the common lexicon of codes and standards development, and especially in the various international arenas, the term *standards* is most generally used to characterize all the various types of standardizing documents (i.e., codes, standards, guides, policies, norms, etc.). Further clarification of the term *standard,* however, is helpful for this discussion.

This is especially true since the Agreement on Technical Barriers to Trade (TBT) under the World Trade Organization (WTO), which is further discussed later, defines the term "Technical Regulation" and "Standard." These definitions are noteworthy because of the influence of the WTO. These terms are (1) Technical Regulation: documents which lay down product characteristics or their related processes and production methods, including the applicable administrative provisions, with which compliance is mandatory; and (2) Standard: documents approved by a recognized body, that provide, for common and repeated use, rules, guidelines or characteristics for products or related processes and production methods, with which compliance is not mandatory.[32]

As a further clarification of the lexicon of international standards writing, the entities that administer various "standardizing activities" are generally known throughout the world as "standards-developing organizations" and are commonly referred to by the acronym SDO, which has been expanded in the last few years to include those SDOs that have activities or a basis in more than one country. These are now being recognized as international SDOs, or ISDOs.[33]

It is estimated that there are approximately three-quarters of a million standards in the world, based on information last compiled in 1997.[34] The number of reported documents is between one-half and three-quarters of a million documents, and the higher estimate reflects anticipated underreporting of the data and countries not included in the analysis. For purposes of comparison, Figure 1.3.3 provides general estimates of certain larger collections of national standards for selected countries around the world.

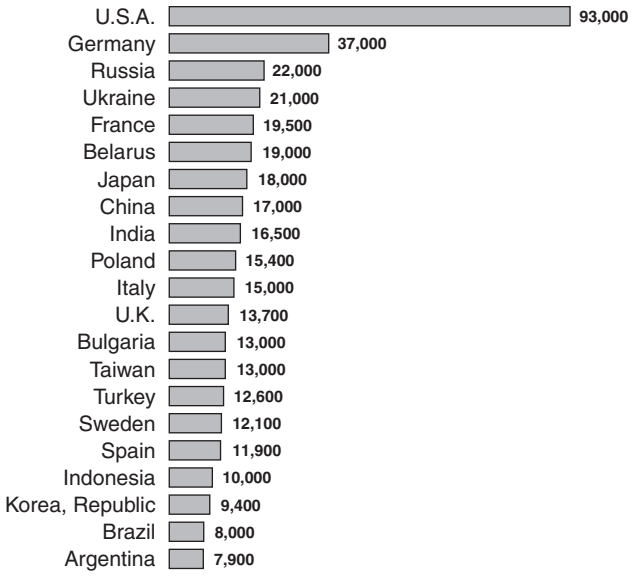

FIGURE 1.3.3 Estimates of Various Collections of National Standards Throughout the World (as of 1997)

"One-Country/One-Vote" Model. Arguably the most widely recognized ISDOs today are those of the "one-country/one-vote" design based in Geneva, Switzerland. Perhaps most notable among these are the ISO (International Organization on Standardization), IEC (International Electrotechnical Commission), and ITU (International Telecommunication Union). These organizations enjoy a casual bureaucratic recognition by various world political organizations that is not readily available to other ISDOs. They are referred to herein as "one-country/one-vote" organizations because the prime mechanism for establishing a final position on any particular subject is by a single vote from each participating country.

These organizations claim to achieve both "technical" consensus and "political" consensus. They do so by obtaining agreement of those participating on their various technical committees, first by establishing technical consensus, and then having the technical agreements ratified by a majority of member countries, which effectively establishes political consensus.

Perhaps the most noteworthy contrast to the "one-country/one-vote" processes are those based on principles involving "full consensus." This process is characteristic of the methods used by the ISDOs of North America. Each individual person, regardless of his or her particular nationality, has the ability to participate directly in the issues under consideration. "Full-consensus" organizations are more democratic in their design in comparison to those organizations based on "one-country/one-vote" and do not require a ratification of their technical consensus on a country-by-country basis.

"Full-Consensus" Model. In the realm of codes and standards development, the ISDOs located in North America have certain characteristics that make them relatively unique.[35] The significant private-sector standards-development system in the United States is largely self-regulated, with certain oversight and coordination efforts provided by ANSI (American National Standards Institute), a federation of U.S. codes and standards developers, and corporate and government users of those standards. Unlike most areas of the world, nongovernment organizations (NGOs) are responsible for the establishment, development, and ongoing maintenance and updating of these private-sector documents.

ANSI provides accreditation for the development of documents that meet its fundamental principles for full consensus. Organizations that meet these requirements typically have elaborate processes involving volunteer committees and utilizing extensive public input and decision-making authority. Although federal, state, and local governments usually participate, they do so as would any other participant. The resulting documents are referred to as "model documents," and it is then up to any particular authority to subsequently implement the issued document as it sees fit (i.e., into law, as a specification, etc.).

Of all the attributes of the North American ISDOs, of special note is the fact that they are oriented around a particular subject matter and based on individual participant involvement. A trademark of North American processes is that they are blind to the geographic roots of their input and, thus, they allow anyone, anywhere, to participate on an equal basis.

In Search of Alternative ISDO Approaches. The developers of codes and standards based in North America are characterized as either an SDO or an ISDO. These organizations typically exist with a dual personality, providing for the domestic needs of their constituents, while at the same time not being exclusively dedicated to any particular collection of those constituents (i.e., serving the needs of constituents in multiple countries).

It is admittedly a virtue to have participants involved in any process that provides wide representation rather than simply a narrow or limited focus. But is there an outward boundary to such representation, and at what point does the representation become misleading? When does it become "involvement without representation"?

At the root of these questions is the effectiveness of processes based on the collective representation of very large entities such as entire nations (i.e., the "one-country/one-vote" design). This model lends itself well to consideration of universal issues of sweeping impact, in which the singular voice of each country is able to speak clearly and contribute decisively to a common good.

But is this same model the most appropriate approach, or more importantly, to be considered the *only* approach, to myriad technical details on which civilization is built? Although it can be argued that the "one-country/one-vote" model may perhaps lend itself well to certain topics and certain types of standards-development activities, it should not be expected to be the *only* approach for all standards activities. Clearly, alternative approaches exist, and one of these approaches is the "full-consensus" approach.

The "one-country/one-vote" model does not have the flexibility to equitably address detailed technical issues in the same manner as the "full-consensus" approach. It is convenient, of course, when a particular technical topic is used in the same manner in all of the countries of the world, but the many blends of society make such a convenience a rarity.

For example, consider the common scenario in which a technical standard addresses a focused topic. In particular, consider a case study that has a relatively extreme focus, such as a hypothetical standard addressing harness gear for reindeer. Does it make sense for all the nations of the world to vote equally on this standard? Why should the nations at the equator have an equal vote with the Nordic nations that are clearly more familiar with—and affected by—the topic? The casual assumption that all topics exist equally in all nations, and that the "one-country/one-vote" model is the *only* approach needed, is not well founded.

Regional Nature of ISDOs. When discussing SDOs and ISDOs, a topic of related interest is regional organizations. These exist today both in a formal sense and in a less than formal or de facto sense.[36]

Although many jurisdictions have country-specific SDOs, there is a tendency for them to cluster regionally to assert their collective presence. The boundaries of such regions are not always geographically clear. More commonly, they are generally based on the culture and influence of the primary participants or at least those participants with the primary control.

Various examples exist of formalized regional standards bodies. Fitting this description are organizations such as CEN

(European Committee for Standardization) for Europe, COPANT (Pan American Standards Commission) for the Americas, and PASC (Pacific Area Standards Congress) for the Pacific Rim nations. Although organizations such as these are easily distinguished, it is the nonformalized regional developers that are of interest in this discussion.

In a unified sense, all the various codes and standards developers of the United States comprise a de facto regional standards body, which is particularly the case based on the coordinating role played by American National Standards Institute (ANSI). Thus, we can observe that the standards-developing organizations of the United States exist independently as SDOs, in a collective sense as a regional organization, and in a practical sense as ISDOs.

As a contrast to the North American situation, the organizations of the "one-country/one-vote" design based in Geneva, Switzerland, and in particular ISO and IEC, enjoy an informal recognition by various world political organizations that is not readily available to other ISDOs. Despite their international stature, however, are implications that they are a European-based regional organization based on their operating characteristics. For example, in late 2000 it was reported that CEN and CEN-affiliated countries (33 in all) have 50 percent or more voting members on 80 percent of all ISO committees.[37]

Today, as an observation, ISO and IEC are typically considered as ISDOs, while gaining recognition as European regional SDOs. Meanwhile, the standards organizations based in the United States are typically considered as North American regional SDOs, while gaining recognition as ISDOs.

World Trade Organization (WTO) and the Technical Barriers to Trade (TBT) Agreement. The World Trade Organization (WTO) is today generally considered the foremost-recognized global organization dealing with the rules of trade between nations.[38] Its main function is to ensure that trade flows smoothly, predictably, and freely. The goal is to help producers of goods and services, exporters, and importers conduct their business.

The WTO is headquartered in Geneva, Switzerland, with a staff of approximately 500, and is represented by 140 member countries and customs territories (as of November 30, 2000) that account for over 90 percent of world trade. Over 30 other countries are negotiating membership. At its heart are the WTO agreements, negotiated and signed by the bulk of the world's trading nations and ratified in their parliaments.

Technical Barriers to Trade. The WTO's top-level decision-making body is the Ministerial Conference, and reporting to the Ministerial Conference and considered the prime operational entity is the General Council. Three other councils and various committees, working groups, and working parties report to the General Council, but of particular note is the Council for Trade in Goods. The Council for Trade in Goods likewise has various committees reporting to it, one of which is the Committee on Technical Barriers to Trade.

This committee is responsible for the Agreement on Technical Barriers to Trade (TBT), which tries to ensure that regulations, standards, testing, and certification procedures do not create any unnecessary obstacles to free trade. Technical regulations and industrial standards may vary from country to country, and having too many different standards makes life difficult for producers and exporters. If the standards were set arbitrarily, they could be used as an excuse for protectionism.

However, the TBT Agreement recognizes that countries have the right to establish protection at levels that they consider appropriate, and they should not be prevented from taking measures necessary to ensure that those levels of protection are met based on the need to fulfill certain legitimate objectives. These legitimate objectives include protection of human health and safety, national security, prevention of deceptive practices, protection of animal or plant life or health, and the environment.

International Standards. The TBT Agreement encourages the countries to use international standards when these are appropriate, although it does not require them to change their levels of protection as a result of standardization. As guidance for member countries, Annex 3 to the TBT Agreement provides the *Code of Good Practice for the Preparation, Adoption, and Application of Standards,* which attempts to ensure that standards do not present an obstacle to international trade.

An obvious question that comes into play when attempting to implement the TBT Agreement is "What is an international standard?" This matter was first addressed in the Report (2000) of the Committee on Technical Barriers to Trade.[39] Included in this particular report is Annex 4, entitled "Decision of the Committee on Principles for the Development of International Standards, Guides and Recommendations with Relation to Articles 2,5 and Annex 3 of the Agreement." This annex outlines the principles and procedures that should be observed for the preparation of international standards and attempts to ensure the following essential characteristics:

- Transparency
- Openness
- Impartiality and consensus
- Effectiveness and relevance
- Coherence
- Ability to address the concerns of developing countries

The elements outlined here can be found as inherent traits in the various organizations that exist today to develop codes and standards in the international arena. For example, these elements fit the more commonly recognized international developers like ISO and IEC, but clearly others also meet or exceed these requirements, such as many of the North American codes and standards developers (e.g., ASME, ASTM, IEEE, NFPA, and others). For certain aspects such as openness, impartiality, and consensus, the "full-consensus" approach and the "one-country/one-vote" approach are arguably equivalent in the way they meet these characteristics. No directly interested party is disenfranchised.

ROLE OF STANDARDS IN THE BUILT ENVIRONMENT IN THE UNITED STATES

While the term *standards* is often used to describe all standardizing documents, including codes for the built environment (es-

pecially in North America), a distinction exists between codes versus standards. As previously noted, a code is a law or regulation that sets forth minimum requirements where something must be done. A standard typically spells out the methods for achieving the desired result; that is, "how" something must be done. However, the distinction is not precise and it is not always easy to differentiate between a code and a standard.

Many requirements found in building codes are excerpts from, or based on, the standards published by nationally recognized organizations. The most extensive use of the standards is their adoption into building codes by reference, thus keeping the building codes to a workable size and eliminating much duplication of effort. Such standards are also used by specification writers in the design stage of a building to provide guidelines for the bidders and contractors.

Numerous NFPA standards are referenced by model building codes and, thus, obtain legal status where these model codes are adopted. Notable examples of such referenced NFPA standards are those that deal with extinguishing systems, flammable liquids, hazardous processes, combustible dusts, liquefied petroleum gas, electrical systems, and fire tests.

The model building codes contain entire chapters or appendices that list standards published by many organizations, including standards-making organizations, professional engineering societies, building materials trade associations, federal agencies, and testing agencies. The sections are prefaced with a statement indicating that the standards are to be used where required by the provisions of the code or where referenced by the code.

Fundamentals of Voluntary Consensus

The voluntary standards development system in the United States is efficient, cost-effective, and highly productive and results in the promulgation of thousands of quality standards each year. A diverse, decentralized network of private-sector entities develops the U.S. voluntary standards. Many different organizations are involved, and this feature is one of the great strengths of the system.

Based on information compiled in 1996 and not updated since that time, the U.S. standardization community currently maintains approximately 93,000 standards in active status.[40] The number of U.S. standards at any given moment in time, however, is difficult to identify. Today, it is assumed that the number 93,000 is still a relatively valid estimate, since various newly created standards tend to offset a trend of the largest U.S. producer of standards, the U.S. Department of Defense, to retire more standards each year than it generates.

Standards exist for virtually all industries and product sectors. The oldest standards-developing organization in the United States is the U.S. Pharmacopeia, which published standards for 219 drugs in 1820. Today, the U.S. federal government supports the overall approach used in the United States through Public Law 104-113, which indicates that the federal government will support and (as needed) participate in the development of private, voluntary consensus documents, or if not, then to justify otherwise. This is further discussed later in the section entitled "National Technology Transfer and Advancement Act."

For a variety of reasons, data on the number of standards must be treated with caution. These reasons include (1) uncertainty on whether to consider as a standard a product description, specification, definition of a term, or description of a procedure; (2) the distinction between a single standard with many sections and a series of separate but related standards may be arbitrary; (3) the influence and impact of various standards on the economy can vary dramatically; (4) many documents become technologically obsolete but remain in a technically active status; (5) information on the number of state and local government standards is extremely limited and fragmented; and (6) statistical information typically does not include de facto standards (i.e., unsponsored and unwritten yet widely accepted standards, such as the configuration of typewriter and computer keyboards).

The 93,000 standards in the United States generally comprise 49,000 (53%) private-sector standards and approximately 44,000 (47%) federal government standards. Furthermore, private-sector standards (i.e., developed by NGOs) can be further subdivided based on the type of sponsoring organization: standards-developing organizations, scientific and professional societies, and industry associations. Table 1.3.3 provides a summary of this information.[41]

In comparison to most systems, the institutional structure of the U.S. voluntary consensus standards system is highly decentralized. Approximately 700 standards developers exist in the United States, with approximately 620 engaged in ongoing standards-setting activities that are mostly organized around an academic discipline, profession, or a given industry. The

TABLE 1.3.3 U.S. Standards and Their Developers

	Number of Standards	*Percentage*
Private Sector		
Standards-developing organizations	17,000	18
Trade associations	16,000	17
Scientific and professional societies	14,000	15
Developers of informal standards	3,000	3
Subtotal of private sector	49,000	53
Federal Government		
Department of Defense (DOD)	34,000	37

remainder of the aforementioned 620 organizations typically have a small number of standards that were developed in the past, which may or may not be occasionally updated.

It is interesting to note that, of the 620 private-sector standards developers in the United States, the 20 largest developers account for a little more than 70 percent of all private-sector development. Table 1.3.4 indicates the number of standards organizations by sector for the U.S. standards-development community.[42]

American National Standards Institute (ANSI)

The significant private-sector standards-development system in the United States is largely self-administered, with oversight and coordination provided by ANSI, a federation of U.S. codes and standards developers, company organizations, and government users of those standards.

Originally known as the American Engineering Standards Committee, its first meeting was held on January 17, 1917, by the following founding organizations: American Institute of Electrical Engineers, American Institute of Mining Engineers, American Society of Civil Engineers, American Society of Mechanical Engineers, and the American Society of Testing and Materials. The government Departments of War, Navy, and Commerce were soon involved, along with NFPA and other organizations. One of the first documents that was accepted and registered under the established rules as an "American Standard" was the 1920 edition of NFPA 70, *National Electrical Code®*.

TABLE 1.3.4 Number of U.S. Standards-Developing Organizations

Source: Toth, R. B., "Standards Activities of Organizations in the United States," NIST Special Publication 806, National Institute of Standards and Technology, Gaithersburg, MD, 1996.

In 1928 the name of the American Engineering Standards Committee was changed to the American Standards Association. This organizational title was used until 1968 when the organization became known briefly as the United States of America Standards Institute (USASI) before adopting the current title of American National Standards Institute.

Organizational membership in ANSI fluctuates, but as of 2006 it is comprised of approximately 265 U.S. professional organizations, technical societies, and trade associations, along with 1100 U.S. companies. ANSI is able to fulfill its coordinating role for the voluntary standards system in the United States because of the support it receives from those actively involved in standards work. NFPA is an ANSI-accredited codes and standards organization, with "audited-designator status," resulting in ANSI accreditation for virtually all NFPA codes and standards. Approximately 11,180 standards approved by ANSI were designated as "American National Standards."

ANSI coordinates and harmonizes private-sector standards activity in the United States. In order for a document to be designated an American National Standard, the principles of openness and due process must have been followed in its development, and consensus among those directly and materially affected by the standard must have been achieved. ANSI also represents the interests of the United States in the international standardization activities of the International Electrotechnical Commission (IEC) and the International Organization for Standardization (ISO).

The ANSI arrangement is unique in the ISO/IEC arena, since most countries are represented by a single organization that is either fully or partially funded by that country's national government. The United States, however, is represented by a single private organization (ANSI) that further represents the interests of numerous organizations, including private standards-development organizations (e.g., ASTM, IEEE, NFPA, etc.). This results in a complex legal and business environment involving international copyright.

Further complicating this situation is that U.S. standards developers (SDOs) do not limit their activities to only U.S. constituents and typically have members involved from other countries. It is not unusual for the U.S. representation or secretariats in IEC and ISO standards-developing activities to be true international standards developers (ISDOs) in their own right.

Under ANSI procedures, all American National Standards must be reviewed and reaffirmed, modified, or withdrawn no less frequently than every five years—a requirement that ensures that voluntary standards in the United States keep pace with developing technology and innovations. Thus, the voluntary system produces quality standards that do not become outdated.

United States Standards Strategy. A "National Standards Strategy for the United States" was first approved by the ANSI board of directors on August 31, 2000, and it was superseded by a second edition, now renamed as the "United States Standards Strategy" (USSS), which was approved by the ANSI board of directors on December 8, 2005.[43]

Work on this latest edition of the USSS began in 2004 as the result of a collaborative process when ANSI convened a committee to review and revise the previously published National Standards Strategy for the United States (2000). The updated and renamed U.S. Standards Strategy reflects the input of hundreds of representatives of industry; small, medium and large enterprises; standards developers and consortia; consumer groups; and federal and state governments that contributed to the revision process.

The USSS establishes a framework that will be used by U.S. stakeholders to improve trade issues in the global marketplace, enhance consumer health and safety, meet the needs of diverse industries, and advance U.S. viewpoints in the regional and international standardization arenas. The U.S. standardization system functions under the belief that standards should meet societal and market needs and should not be developed to act as technical barriers to trade. The USSS promotes standards that are technically suitable, applied globally, and developed in accordance with the principles of openness, transparency, consensus, and due process within the World Trade Organization's Technical Barriers to Trade Agreement.

The document is built on 12 initiatives that address the role of government; health, safety, and environmental responsibilities; consumer interests; prevention of standards as trade barriers; responsiveness to cross-cutting technologies; efficiency in standards development; the priority of standards education; and other crucial considerations. Key updates to the strategy relate to intellectual property rights, funding models for the standards system, national priorities, and global trade issues.

National Technology Transfer and Advancement Act

Of particular interest to anyone involved with the development of codes and standards in the United States is the National Technology Transfer and Advancement Act of 1995 (NTTAA). The NTAA, also referred to as Public Law 104-113, was signed into law on March 7, 1996, and requires that all federal agencies use standards developed by voluntary consensus standards bodies instead of government-unique standards whenever possible. Perhaps even more importantly, the act includes provisions that encourage federal agencies to partner with the private sector in the development of standards that not only help improve the efficiency and effectiveness of government but also strengthen the U.S. position in the global marketplace.

A similar government document that preceded the NTTAA and also still referenced is the OMB (Office of Management and Budget) Circular A119, *Federal Participation in the Development and Use of Voluntary Consensus Standards and in Conformity Assessment Activities.* The enactment of the NTTAA and the OMB Circular A119 that guides federal agencies in their implementation of NTTAA has prompted federal, state, and local agencies to increasingly turn to voluntary consensus standards as alternatives to requirements and specifications developed by government agencies

The adoption of voluntary consensus standards developed in the private sector by agencies at all levels of government makes good sense. As stated in OMB Circular A119, "the use of [voluntary consensus] standards, whenever practicable and appropriate, is intended to achieve the following goals:

- Eliminate the cost to the Government of developing its own standards and decrease the cost of goods procured and the burden of complying with agency regulation;
- Provide incentives and opportunities to establish standards that serve national needs;
- Encourage long-term growth for U.S. enterprises and promote efficiency and economic competition through harmonization of standards; and
- Further the policy of reliance upon the private sector to supply Government needs for goods and services."[44]

The NTTAA compelled federal agencies to decisively turn to consensus-based, voluntary standards as alternatives to specifications that had previously been developed only for government use. The streamlined approach to standards development and implementation central to the NTTAA has saved millions of U.S. dollars by using consensus standards for procurement purposes and mitigating overlap and conflict in regulations. Since the passage of NTTAA in 1996, tremendous progress has been made in the cooperative standardization efforts of industry and government. Significant accomplishments have been realized in critical areas such as health and safety, security and defense, protection of the environment, and technological advancements.

Standards-Developing Organizations (SDOs) in the United States

Authority and technical expertise in the U.S. standards-developing system are highly decentralized and linked to specific industry sectors. This system has evolved based on the development of a wide range of consensus standards processes in many different standards-developing organizations (SDOs). The basic common principles of consensus codes and standards development are, thus, applied in different ways, with procedures and objectives specific to the needs of a particular industry or professional community. The following three types of organizations generally develop standards handled and administered by the private sector.[45]

Standards-Developing Organizations. These organizations typically have the development of codes and standards as one of their central activities or missions. Membership-oriented codes and standards-developing organizations are the most prominent of these organizations, and they tend to have the most diverse membership among all SDOs, since they are not limited to a particular industry or profession. These membership organizations have a notable number of international members, which is a feature of many U.S. SDOs in general, and makes the U.S. codes and standards-developing system somewhat distinct from the rest of the world. Because of their diverse membership, codes and standards-developing membership organizations tend to have the strictest due-process requirements. Aside from membership organizations, standards development is also a key activity of certain testing and certification organizations, such as Underwriters Laboratories Inc. or the American Gas Association.

Two examples of standards-developing organizations are ASTM and NFPA, both of which are membership based. ASTM has a membership of approximately 30,000. The 132 ASTM technical committees are responsible for more than 12,000 standards, and approximately one-third of ASTM's sales of standards are to international users. NFPA, for sake of comparison, has about 80,000 members. The approximate 250 consensus technical committees of NFPA are responsible for about 300 safety-oriented documents, which are dramatically fewer than ASTM. This difference in committee structure provides some indication of the distinction between product standards handled by ASTM and safety codes and standards handled by NFPA.

Furthermore, despite NFPA having substantially fewer documents than ASTM and some other standards developers, the total number of pages generated by NFPA (because they are mostly safety-oriented documents rather than product oriented) is often comparable and, in some cases, clearly more. As noted earlier, safety standards tend to be more complex, which leads to greater length.

The number of published standards is not necessarily an absolute indicator of overall activity level or significance, and a vivid example of this concept is the *Boiler and Pressure Vessel Code* administered by ASME. Although it is considered a single standard, it is approximately 12,000 pages in content and far exceeds the size of almost all other standards that are more commonly only several pages in length. In a similar fashion, any of the model building codes and similar safety-related documents for the built environment far exceed most other standards in terms of page count. In fact, neither numbers nor page counts are as valid indicators of impact as would be numbers of users by document and numbers of lives and dollars affected, but both of these measures are very hard to develop.

Scientific and Professional Societies. These societies are a refined form of membership organizations that support the practice and advancement of a particular profession. The most recognized of these societies involve the engineering disciplines. A unique characteristic of these societies is that the participants, as part of their standards-development processes, typically function as individual professionals and not as specific representatives of their sponsoring organization or industry.

Prominent examples of scientific and professional societies include the American Society of Mechanical Engineers (ASME) and the Institute of Electrical and Electronics Engineers (IEEE). ASME has an international membership of more than 120,000. The ASME standards process has more than 700 committees responsible for 600 codes and standards. ASME has responsibility for the previously mentioned *Boiler and Pressure Vessel Code* and is one of the most prominent single documents in the U.S. standards-development arena and in the world. IEEE has a worldwide membership of more than 365,000 engineering professionals. The approximately 900 standards published by IEEE focus specifically on areas of electrotechnology.

Another example involving a relatively new developer is the Society of Fire Protection Engineers (SFPE). The SFPE was established in 1950 and incorporated as in independent organization in 1971, but only in the last few years has it pursued the development of standards and guides on various technical topics. The SFPE is the professional society representing those practicing in the field of fire protection engineering. With approximately 4500 members and 57 regional chapters, the society's purpose is to advance the science and practice of fire protection engineering and its allied fields, to maintain a high ethical standard among its members, and to foster fire protection engineering education. Several volunteer committees and task groups work under the society's auspices on technical projects to further advance the state of the art.

Industry Associations. Industry or trade associations are organizations of manufacturers, service providers, customers, suppliers, and others that are active in a given industry. The development of technical standards is specifically intended to further the interests of their particular industry sector.

The Association for the Advancement of Medical Instrumentation (AAMI) is an example of a trade organization that develops standards. Approximately 2000 health care professionals support its activities and include representatives from industry, health care facilities, academia, research centers, and government agencies, such as the Food and Drug Administration (FDA). Industry association SDOs are likely to be more openly responsive to commercial market concerns than other types of SDOs. Other examples of industry associations include the American Petroleum Institute (API) and the National Electrical Manufacturers Association (NEMA).

ENFORCEMENT OF CODES AND STANDARDS

The types of government and the characteristics of governing authorities around the world vary considerably, yet despite the differences, there are some aspects that are common with relation to legislative adoption of codes and standards. For the sake of illustration, the following discussion focuses on this topic, based on a form of government similar to that used in the United States.

Today the life and property of every citizen are safeguarded to at least some extent by safety legislation enacted by the Congress of the United States, state legislatures, city councils, town meetings, and many other jurisdictions and levels of government. The implementation and enforcement of this legislation are in the hands of administrative agencies of government, such as federal departments and agencies, state fire marshal offices and other appropriate state agencies, local fire departments, building departments, electrical inspectors, and so on.

In the earlier days of the United States, the protection of citizens from fire was solely the concern of the local community. Present-day fire fighting is carried on by local fire departments. Although most communities have had some type of building code since the beginning of the twentieth century, they have not had fire prevention or life safety codes until more recently.

With the need for more detailed, comprehensive standards and codes relating to the construction, design, and maintenance of buildings came the knowledge that regulations based on such codes certainly could prevent most incidents of damage to the building, its contents, and the activities therein, as well as reduce losses in the incidents that did occur.

Regulations relating to safety are determined and enforced by different levels of government. Although some functions overlap, federal and state laws generally govern those areas that cannot be regulated at the local level.

Nationally Based Safety Regulations

There is a substantial amount of federal regulation pertaining to safety. Under the U.S. Constitution, Congress has the power to regulate interstate commerce. This power has been interpreted to permit Congress to pass laws authorizing various federal departments and agencies to adopt and enforce regulations to protect the public from hazards.

Any federal department or agency in the United States can promulgate safety regulations only if authority to do so is granted by a specific act of Congress. These regulations have the force of law, and violations can result in legal action. In general, such federal laws can be enacted to provide (1) that all state laws on the same subject are superseded by the federal law, (2) that state laws not conflicting with the federal law remain valid, or (3) that any state law will prevail if it is more stringent than the federal law. Among the federal agencies that have the authority to promulgate fire safety regulations are the Consumer Product Safety Commission (CPSC), the Department of Health and Human Services (HHS), the Occupational Safety and Health Administration (OSHA), and the Department of Homeland Security (DHS). Fire safety regulations are compiled for effective use in documents like NFPA 1, *Uniform Fire Code*™, which provides us with an important tool for mitigating unwanted fire. Figure 1.3.4 illustrates the level of adoption of NFPA 1.

It must be recognized that model codes are only representations of possible regulations, and they do not actually become law until enacted by state and municipal legislatures.[46] In addition, local or special geographical circumstances may dictate additional criteria that are deemed to be unnecessary for inclusion in the model document. The general areas of model code adoption and use in the United States can be seen in the examples provided in Figures 1.3.4 and 1.3.5. Although these illustrations are representative of code adoption activities in the United States, a similar approach of using model codes exists in numerous other countries. The world's most widely adopted code, NFPA 70, is adopted in virtually every state in the United States, Mexico, and several other countries in Central and South America and elsewhere around the world.

Regulations of State and Local Government

Within the scope of the police power of state government in the United States is the regulation of building construction for the health and safety of the public—a power usually delegated to local government jurisdictions of the state.

Building code requirements usually apply to new construction or to major alterations to existing buildings. Retroactive application of code requirements is very rare. Building code applicability usually ends with the issuance of an occupancy permit or certificate of occupancy. The basic premise that legislation should regulate for the safety of current occupants and for current risk is not generally the province of building codes once a structure is occupied. Then, after-occupancy codes or safety maintenance codes apply. Also, at this point the authority of the building official usually ends and the fire official begins. A notable exception is NFPA *101, Life Safety Code*®. NFPA *101* does impose retroactive criteria on existing buildings even when no work or renovation is planned. This approach recognizes that changes in the state of the art do occur over the life of the building. Previously unknown or misunderstood hazards or threats may demand changes to some level of the life safety features in the building. Thus, the retroactive imposition of certain requirements is mandated by NFPA *101*.

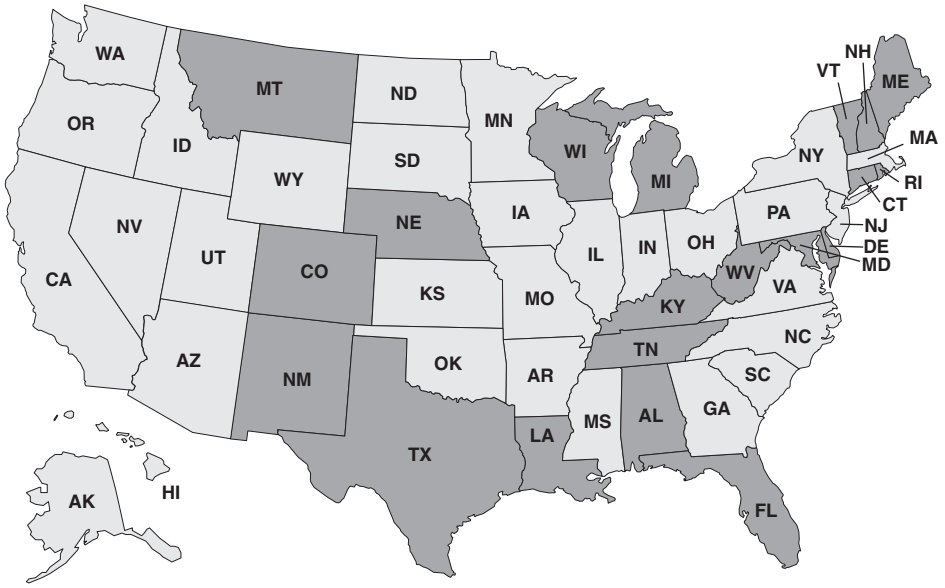

FIGURE 1.3.4 Adoption of NFPA 1, *Uniform Fire Code*™ (as of 2006)

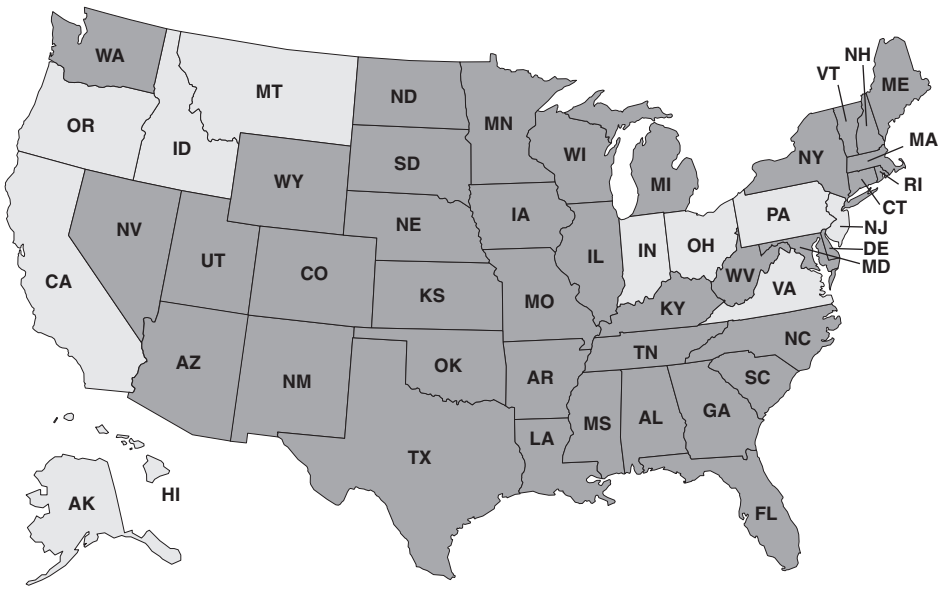

FIGURE 1.3.5 Adoption of NFPA *101*®, *Life Safety Code*® (as of 2006)

This division of authority, however, does not preclude interaction between the two officials during both a building's development and its subsequent use. In practice, many jurisdictions assign responsibilities to officials in various departments for codes whose natural "homes" are or are not in their departments. This division of authority varies considerably among communities.

In most states in the United States, the principal fire official is the state fire marshal. For the most part, the state fire marshal is the statutory official charged by law with responsibility for the administration and enforcement of state laws relating to safety of life and property from fire. Usually the state fire marshal also has the power to investigate fires and to conduct arson investigations.

The manner in which each state handles the promulgation of building and fire regulations varies widely. In some states, each local government may have its own code, whereas in others the local authority has the option of adopting the state codes. In still others, the state codes establish the minimum requirements below which the local regulations cannot go. Finally, in some states the local government has no choice and must adopt the state code. Another variation of this is the Mini-Max (for minimum-maximum) code that asserts that a community may not require less than, or more than, the state-specified regulation.

These situations have resulted in a plethora of different local codes. Some of the local governments adopt one or more of the model codes. In many instances, these adoptions include some form of local amendments that remove or add various requirements. Others draft their own local codes. This lack of uniformity has been criticized by materials producers, building designers, builders, and others and some years ago prompted the appointment of federal commissions to study the situation and make recommendations to the administration.[47–49]

The legal procedure for adopting codes and standards into law can also vary from one enforcing jurisdiction to another. Usually, the simplest and best way is to adopt by reference. This method, applicable to public authorities as well as to private entities, requires that the text of the law or rule cite the code or standard by its title and give adequate publishing information to permit its exact identification. The code or standard itself is not reprinted in the law. All deletions, additions, or changes made by the adopting authority are noted separately in the text of the law. Adoption of a current edition of a code or standard obviates outdated editions maintained as law until a new law referencing a new edition is adopted.

CODES FOR THE BUILT ENVIRONMENT

Although building codes provide much focus, a variety of other related codes also readily serve the built environment. Specifically, these codes address distinct interrelated topics that are essential components in structures of all kinds.

Topics that are typically addressed include electrical, plumbing, mechanical, fuel gas, energy, and fire prevention. Yet this is not an all-inclusive list, and any particular subject that lends itself to specific and detailed criteria is eligible and, thus, "electrical codes," "plumbing codes," "mechanical codes," and so on have also evolved. Often the reference to "building codes" is intended to include, in a general sense, a reference to all of these related codes for the built environment.

Of these different related topics, fire prevention codes are somewhat unique (e.g., construction versus ongoing operation and maintenance). It often is difficult to differentiate between items that should go into a fire prevention code and those best included in a building or other related code, or in some cases, identical requirements that need to appear in two or more codes. Generally, those requirements that deal specifically with construction of a building are part of a building or similar code administered by the building department. A fire prevention

code, on the other hand, includes information on fire hazards in a building and is usually regulated by the fire official.

Requirements for exits and fire-extinguishing equipment are generally found in building codes, whereas the maintenance of such items is covered in fire prevention codes. More simply stated, building and other related codes address the original design or major renovation of a building, whereas a fire prevention code usually addresses the building during its useful life after the initial construction or renovation is complete.

U.S. Codes for the Built Environment

With the exception of the independent operations of some of the largest cities, the business of code development for the built community in the United States is primarily in the hands of the model code organizations. The primary objectives of these organizations are to provide standardization of construction regulations and/or support of the enforcement of these regulations. In the United States, the following provides further discussion on the two prominent organizations that currently have code sets for the built environment.

NFPA. In December 1999, NFPA embarked on a project to establish a complete set of consensus codes and standards for the built environment. NFPA already had at its disposal a number of major codes such as NFPA 1, *Uniform Fire Code*™, NFPA 54, *National Fuel Gas Code,* NFPA 70®, *National Electrical Code*®, and NFPA *101*®, *Life Safety Code*®, among others that could serve as a strong foundation for the basis of this collection, as well as the balance of the 300 NFPA codes and standards that directly support these leading documents.

NFPA has historically been involved with the development of a model building code as early as 1905 through the collaborative efforts of the National Board of Fire Underwriters, but a current up-to-date version was needed to cover structural design issues and other items normally found in a building code. Although major NFPA codes like NFPA *101* covered the most salient building code issues as they relate to fire protection, other items such as general structural design, foundation and building envelope issues, energy conservation, and accessibility were not as well addressed as they could and should have been in the existing NFPA codes and standards. The result was the development of *NFPA 5000*®, *Building Construction and Safety Code*®, with the 2002 edition being the first edition. Other important codes, such as a plumbing code, mechanical code, and energy code, were contributed to the set by partnering organizations.

In the setting of this coalition, model codes and standards are developed through a full, open, ANSI-accredited, consensus-based process allowing full participation and decision making by all interested groups. This process has long been the hallmark of the U.S. system of codes and standards development under the auspices of ANSI and its predecessor organizations. This unique system relies on the energies and expertise of private citizens brought together by nongovernment organizations like NFPA and its partners to forge consensus over important issues of technology and public safety. The building and construction fields have greatly benefited from this type of codes- and standards-development process. Consensus codes and standards exist today that address almost every aspect of the built environment, from life safety to electrical safety, from fuel gas to energy efficiency.

The codes and standards processes of NFPA and its partners are accredited by the American National Standards Institute (ANSI), and the features that earned that accreditation make them considerably more accessible to the general public than the processes used by other code organizations. This coalition is the only one that is based on truly national and international organizations and is not an amalgamation of regional (partial U.S.) organizations, each of which has an independent and arguably narrow geographic focus.

ICC (International Code Council). In 1995 the International Code Council (ICC) was established. The purpose of the ICC was to combine the codes of the three traditional regional model-building code organizations into a single national model. In a sense, the ICC is coming of age as a national organization and is striving to overcome the challenges of combining three distinctly different regional organizations, each of which has uniquely inherent geographic characteristics.

The three regional organizations that joined forces to create ICC are the Building Officials and Code Administrators (BOCA), the International Conference of Building Officials (ICBO), and the Southern Building Code Congress International (SBCCI). BOCA was originally known as the Building Officials Conference of America and published its first regional building code in 1950. It has traditionally had a regional focus on the Northeast and Great Lakes portions of the United States. ICBO first published its regional building code in 1927. The ICBO codes have traditionally been used in the western United States but have also been utilized in municipalities as far east as Indiana. Organized in 1940, SBCCI first published its building code in 1945, which has traditionally been used throughout the southern United States.

The current documents of the ICC, as well as its three founding regional organizations (BOCA, ICBO, and SBCCI), are developed in a process that has traditionally been by and for building officials, which restricts involvement and final voting to the building official community. This is in contrast to the codes and standards developed and maintained in an open, full-consensus process that allows widespread involvement, such as those accredited by the American National Standards Institute and used by NFPA. In particular, the documents of NFPA and its partners are developed and maintained in an open, full-consensus process that allows widespread involvement, inclusive of decision-making authority, and, thus, provides documents that are more technically balanced and economically fair.

Other Organizations Related to Codes for the Built Environment

Wide ranges of organizations provide support, input, or involvement for the codes and standards infrastructure in North America. The following paragraphs provide additional information on certain applicable groups.

AISG (American Insurance Services Group). As previously noted, the National Board of Fire Underwriters (NBFU), renamed the American Insurance Association (AIA), and now known as the American Insurance Services Group (AISG), first published the *National Building Code* in 1905. This early building code initiative occurred as part of the close collaborative relationship through the years between the NBFU and NFPA technical committees, which began soon after NFPA was created in 1896 and continued until the early 1960s, when NBFU evolved into the AIA. The building code was used as a model for adoption by cities, as well as a basis to evaluate the building regulations of towns and cities for town grading purposes. The code was periodically reviewed by the NBFU staff, revised as necessary, and republished. The last code revision was the 1976 edition. Since then, the AISG has discontinued updating and publishing the *National Building Code,* and Building Officials and Code Administrators (BOCA) acquired the right to use the name *National Building Code* on its regional building code, although this code was discontinued with the formation of ICC. The AISG also developed a fire prevention code, most recently published in 1976, but has also discontinued the updating and publishing of this document.

ANSI (American National Standards Institute). The significant private-sector standards-development system in the United States is largely self-regulated, with oversight and coordination provided by ANSI, a federation of U.S. codes and standards developers, company organizations, and government users of those standards.

ANSI coordinates and harmonizes private-sector standards activity in the United States. In order for a document to be designated an American National Standard, the principles of openness and due process must have been followed in its development, and consensus among those directly and materially affected by the document must have been achieved. ANSI also represents U.S. interests in the international standardization activities of the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC) and serves as the primary gateway for voicing the U.S. position in these arenas.

ASHRAE (American Society of Heating, Refrigeration and Air-Conditioning Engineers). ASHRAE was formed by the merger of two societies, American Society of Heating and Ventilating Engineers (ASHVE)—which was originally established in 1895 and known after 1954 as the American Society of Heating and Air-Conditioning Engineers (ASHAE)—and the American Society of Refrigerating Engineers (ASRE), which was founded in 1905. The two societies merged in 1959 to form the American Society of Heating, Refrigeration and Air-Conditioning Engineers (ASHRAE).

The mission of ASHRAE is to advance the arts and sciences of heating, ventilation, air conditioning, refrigeration, and related human factors to serve the evolving needs of the public and ASHRAE members. The standards and guidelines generated by ASHRAE are administered by almost 90 active standards and guideline project committees, addressing such broad areas as indoor air quality, thermal comfort, energy conservation in buildings, reduction of refrigerant emissions, and the designation and safety classification of refrigerants.

Association of Major City Building Officials (AMCBO). The Association of Major City Building Officials (AMCBO) was formed in 1972 by the Building Commissioners of 20 of the nation's largest cities to serve as a national forum in which major cities could come together to identify common problems and seek common solutions. This group focuses on issues of building codes, administrative techniques, and public safety in buildings. The association has approximately three dozen members and is focused on providing a national forum of city and county building officials united to discuss topics of mutual interest.

AMCBO is affiliated with the National Conference of States on Building Codes and Standards (NCSBCS). The activities of AMCBO include encouraging the development of comprehensive training and educational programs for building code enforcement personnel, providing scientific and technical resources for the improvement of building codes, and enhancing building technology and products to reduce the cost of construction and maintain safety levels.

CFPA-I (Confederation of Fire Protection Associations–International). CFPA-I is a body of leading fire protection organizations from around the world that have joined forces to collectively direct their resources at reducing the global fire problem and increasing life safety. By sharing experience, research, technical know-how, and fire statistics, the group aims to maximize the effectiveness of fire prevention and protection and foster improved international fire safety codes and standards. The CFPA-I typically meets in full session every three years at which time some of the more challenging global fire problems are debated. These sessions provide an opportunity to share advanced research and developments that have taken place in specific problem areas. Significant advances have been made in recent years in fire safety and CFPA-I has provided an exceptional forum to disseminate this knowledge. At this time, two suborganizations that exist within CFPA-I are the Confederation of Fire Protection Associations-Europe (CFPA-E), which is comprised of European fire protection associations, and the CFPA-Asia (CFPA-A), which includes the fire protection associations in the Asian region.

Council on Tall Buildings and Urban Habitat (CTBUH). The Council on Tall Buildings and Urban Habitat was initially formed in 1969 and at that time was known as the Joint Committee on Tall Buildings. The original membership and support were from the International Association of Bridge and Structural Engineers and the American Society of Civil Engineers. In 1973, as a result of the increased emphasis on planning and environmental criteria, other prominent organizations became sponsoring societies of the council, and in 1976 it was renamed to its current title as the Council on Tall Buildings and Urban Habitat. In 1974 the council was admitted as a consulting nongovernmental organization to the United Nations' UNESCO under Category C, and in 1979 it was admitted as a Category B organization.

The CTBUH is sponsored by architectural, engineering, planning, and construction professionals, and as an international

nonprofit organization was established to facilitate professional exchanges among those involved in all aspects of the planning, design, construction, and operation of tall buildings and the urban habitat. The council's primary goal is to promote better urban environments by maximizing the international interaction of professionals and by making the latest knowledge available to its members and to the public at large in useful form.

Inter-Jurisdictional Regulatory Collaboration Committee (IRCC). The purpose of the Inter-Jurisdictional Regulatory Collaboration Committee, which has evolved into a more identifiable existence during the 1990s, is to work internationally, producing documents on the development, implementation, and support of construction-related, performance-based regulatory systems. The current membership of approximately a dozen key government and private organizations from around the world supports the IRCC focus to identify public policies, regulatory infrastructure, and education and technology issues for implementing and managing these systems, where necessary in conjunction with international bodies having compatible interests.

IAPMO (International Association of Plumbing and Mechanical Officials). The International Association of Plumbing and Mechanical Officials began in 1926 as the Plumbing Inspectors Association of Los Angeles, to bring about an improvement in the application of commonsense codification and application of ordinances based on scientific knowledge.

In 1928, additional cities joined and it became known as the Plumbing Inspectors Association of Southern California, and the following year it became the California Plumbing Inspectors Association because of statewide interest. In 1935 the name was changed to Pacific Coast Plumbing Inspectors Association because of interest from other states, which at that time included the 11 western states. In 1945, the name was changed to Western Plumbing Officials Association, and in 1967, due to interest in the association and its goals beyond the borders of the United States, the name was again changed to its current tile of the International Association of Plumbing and Mechanical Officials (IAPMO).

Today, IAPMO is responsible for administering the development of the Uniform Plumbing Code and the Uniform Mechanical Code. Recent editions of these documents are ANSI-accredited, consensus-based codes. They are the most widely adopted plumbing and mechanical codes in the United States and are also used in various jurisdictions around the world.

National Conference of States on Building Codes and Standards (NCSBCS). NCSBCS is a nonprofit corporation founded in 1967 as a result of congressional interest in the reform of building codes. It attempts to foster increased interstate cooperation in the area of building codes and standards and coordinates intergovernmental code administration reforms. NCSBCS is an executive branch organization of the National Governors Association and includes as members governor-appointed representatives of each state and territorial government. It has a working relationship with the National Conference of State Legislatures and the Council of State Community Affairs Agencies.

National Institute of Building Sciences (NIBS). NIBS was authorized by Congress in 1974, under Public Law 93-383, as a nongovernmental, nonprofit organization governed by a 21-member board of directors. Fifteen of the board members are elected and six are appointed by the president of the United States, with the advice and consent of the U.S. Senate. The institute is a core organization that serves primarily as an investigative body, offering its findings and recommendations to government and to responsible private-sector organizations for voluntary implementation. It carries out its mandated mission essentially by identifying and investigating national problems confronting the building community and proposing courses of action to bring about solutions to the problems. NIBS's activities are broad based and center around regulatory concerns, technology for the built environment, and distribution of technical and other useful information.

Working under its very broad mandate, NIBS has established a Consultative Council, with membership available to representatives of all appropriate private trade, professional, and labor organizations; private and public standards, codes, and testing bodies; public regulatory agencies; and consumer groups. The council's purpose is to ensure a direct line of communication between such groups and the institute and to serve as a vehicle for representative hearings on matters before the institute.

World Organization of Building Officials (WOBO). WOBO was founded in 1984, with the primary objective of advancing education through worldwide dissemination of knowledge in building science, technology, and construction. WOBO was established because of increased participation of nations in the global marketplace, the rapid development of new international building technologies and products, and development of international standards that now make it impossible for building officials to confine their concern to activities within their own national boundaries. It currently has consultative status with the United Nations under the nongovernment organization classification.

SUMMARY

Codes and standards serve many purposes, but foremost is their contribution to the overall betterment of civilization. Their role is particularly important as we work toward the challenges of a safer and more cost-effective built environment. In today's complex world, codes and standards provide a point of measurement to simplify our lives. In this sense, codes and standards provide the practical foundation for a better tomorrow.

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on building and fire codes and standards discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 1, *Uniform Fire Code*™
NFPA 30, *Flammable and Combustible Liquids Code*
NFPA 54, *National Fuel Gas Code*
NFPA 70, *National Electrical Code*®
NFPA 70A, *National Electrical Code Requirements for One- and Two-Family Dwellings*
NFPA 80, *Standard for Fire Doors and Other Opening Protectives*
NFPA 80A, *Recommended Practice for Protection of Buildings from Exterior Fire Exposures*
NFPA 88A, *Standard for Parking Structures*
NFPA 88B, *Standard for Repair Garages*
NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems*
NFPA 90B, *Standard for the Installation of Warm Air Heating and Air-Conditioning Systems*

NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences*
NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces*
NFPA 99, *Standard for Health Care Facilities*
NFPA *101*®, *Life Safety Code*®
NFPA 105, *Standard for the Installation of Smoke Door Assemblies and Other Opening Protectives*
NFPA 204, *Standard for Smoke and Heat Venting*
NFPA 220, *Standard on Types of Building Construction*
NFPA 241, *Standard for Safeguarding Construction, Alteration, and Demolition Operations*
NFPA 703, *Standard for Fire Retardant–Treated Wood and Fire-Retardant Coatings for Building Materials*

Integrated Consensus Code Set for the Built Environment (NFPA and partners)

NFPA 1, *Uniform Fire Code*™
NFPA 30, *Flammable and Combustible Liquids Code*
NFPA 30A, *Code for Motor Fuel Dispensing Facilities and Repair Garages*
NFPA 54, *National Fuel Gas Code*
NFPA 58, *Liquefied Petroleum Gas Code*
NFPA 70, *National Electrical Code*®
NFPA *101*®, *Life Safety Code*®
NFPA 5000®, *Building Construction and Safety Code*®
Uniform Plumbing Code—IAPMO (NCA/NAPHCC)
Uniform Mechanical Code—IAPMO
ASHRAE 90.1, *Energy Standard for Buildings Except Low-Rise Residential Buildings*
ASHRAE 90.2, *Energy Code for New Low-Rise Residential Buildings*

Chapter 4

Legal Issues for the Designer and Enforcer

Arthur E. Schwartz

Chapter Contents

General Land Use and Building Regulation
Key Legal Concepts for the Engineer and Enforcer
The Engineer and Negligence
The Engineer and the Americans with Disabilities Act
Engineer and Enforcer Inspections
Liability of Code Enforcement Officials

Key Terms

Americans with Disabilities Act, building code, fire code, inspection, intentional tort, negligence, quality assurance, quality assurance plan, quality assurance program, strict liability, tort

The collection of codes and standards that regulate the built environment represent a compilation of methods, systems, and uses that society deems as providing an acceptable level of safety and performance. These documents can be legislatively implemented or adopted and are normally considered to be part of statutory law. This type of law prescribes, among other things, the basic requirements of matters of design and construction for that particular government jurisdiction.

Codes and standards such as those developed by NFPA, the International Code Council, the International Association of Plumbing and Mechanical Officials, and numerous other private sector organizations are voluntary documents that are developed under some set of procedures established by the organization. The voluntary nature of such documents means they are not legally binding until adopted by a government entity at the federal, state, or local level. Once adopted, they can be legally imposed, enforced, and established as the standard of care—a statutory law for that particular jurisdiction. In simple terms, they do become *the* law for design and construction issues in that community or state.

The collection typically represents minimum levels of performance or *de minimus* care rather than optimum or maximum levels of performance. One of the ways in which a code or standard stops short of requiring maximum performance is through limits to conditions under which the required standard of care can be expected to produce specified outcomes, such as the following:

- Applies to occupants not intimate with ignition
- Assumes a single ignition point
- Assumes the maximum considered earthquake (MCE)

These statements define challenges that may otherwise be too great to assure the desired level of performance. This is perhaps for economic reasons (cost is too much), for technological reasons (no existing system or feature addresses the problem), or for reasons of physics (no imaginable system or feature could address the problem). In most cases, it is a combination of two or all three of these reasons. With that said, the designers and owners have an obligation to maintain a standard of care for their project. That standard is to protect the general population from harm in most cases, and the most commonly applied measure of that protection will be in the prevailing code.

In building design and construction, an orchestra of owners (money), architects and engineers (design talent), and code officials or authorities having jurisdiction (AHJ) (enforcement talent) work to develop a clear plan and picture for a usable and safe building or structure. The contract documents, normally comprising the plans and specifications, must not only be prepared to meet the requirements of the prevailing codes and standards; they must also be clearly understood by the general contractor and their subcontractors, component or supplier vendors, fabrication shops, and third party inspection agencies.

Adopted codes and standards become the starting point for the designer and the code official to ensure that minimum standards of care for that community are met. In this context, codes are not providing just good ideas or suggestions, they provide a baseline of performance and legally binding obligations on the parties to a building project. Designers may choose to do more, but they may not

Arthur E. Schwartz, CAE, is deputy executive director and general counsel of the National Society of Professional Engineers (NSPE).

choose to do less without penalty. Likewise, those who review the plans and specifications, or who conduct on-site inspections must be acutely aware of the provisions of the code, and they must verify that what has been specified has been provided.

Code-based regulations that may be available but not yet adopted, forensic studies that may have identified a previous problem or issue but have yet to be codified in some consensus-based document, or current research that may indicate potential solutions to emerging problems or existing issues, may cloud the *standard of care* criteria for that jurisdiction should a failure occur that results in death or injury to building occupants or even to first responders. Such documents may serve a role when a negligence claim is filed. Short of negligence resulting in personal injury in the duty of care, however, are other circumstances where a designer may have failed to meet certain contract obligations that required compliance with the prevailing code documents. Improper specification and selection of wall coverings, incorrect selection of sprinkler system types and designs, failing to address concerns based on the Americans with Disabilities Act (ADA), or failing to provide a useable building to the client fall short of causing injury to occupants, but are a type of harm according to the law.

GENERAL LAND USE AND BUILDING REGULATION

The Tenth Amendment to the U.S. Constitution states, "The powers not delegated to the United States by the Constitution, nor prohibited by it to the States, are reserved for the States respectively, or to the people." It is deemed to be the defining statement that defers matters such as public safety in certain circumstances away from the federal government and gives it to each state. Such matters include building restrictions, which have been accomplished through such public means as municipal ordinances, zoning laws, covenants, height restrictions, and smart growth laws.

Prior to establishing building regulations, issues of land use were among the early topics to be considered. Prior to the 1850s the owner of a *fee simple absolute* had the maximum extent of rights possible in and under the law. Under U.S. jurisprudence, few forms of private and public land use controls existed prior to 1850. In the mid-nineteenth century, the courts accepted the creation of subdivisions by developers, which contained restrictions on all lots. For example, a developer may have provided that only single-family dwellings could be constructed on the lots. Minimum lot sizes, property line setbacks, and access to such areas are typical follow-on rules for such subdivided spaces. Such general land use and building restrictions set the stage for the development and implementation of building and fire codes.

Zoning Ordinances

In the twentieth century, zoning ordinances became widespread. Under such ordinances, municipalities are permitted to divide an area into various uses. These may include residential uses (single-family, manufactured housing, town-home, multifamily), industrial, commercial, or agricultural uses among others.

Private restrictions such as easements and restrictive covenants are also often enforced. Whereas these restrictions may encompass the use of the building (multifamily residential occupancy versus a residential board and care occupancy) or the allowable number of occupants in certain assembly occupancies, there are certain other regulations that may affect the use of the building, the business it houses, or a combination of the two. Liquor licenses or health code and sanitary code criteria are examples of such broad-use provisions. The courts may issue an injunction barring a violation and may even order a noncomplying business to shut down until corrections are made, or in a worst-case scenario, a nonconforming structure to be demolished—for example, see *Stewart v. Finklestone,* 206 Mass.28, 92 N.E. 37 (1910). The unsafe structures provision in building codes gives code officials extraordinary power to take drastic action when a building is deemed an imminent threat to health, life, or property. However, general restrictions may not be enforced where the neighborhood has changed (e.g., from residential to commercial), where numerous violations of general restrictions have occurred (e.g., failure of administrative enforcement), where there has been a delay in enforcing restrictions (e.g., lack of staffing or funding), where the party who seeks to enforce the restrictions has committed violations, or where the restrictions may have expired because of the passage of time (regulatory sunsetting of restriction). These circumstances may be further compounded in the event of "adverse possession," whereby real property is held in a manner that conflicts with the true owner's rights. In these cases, a long-term violation concerning a land use or right-of-way access may have simply existed for so long that it is has come to be treated as acceptable because of the passage of time.

Under a zoning ordinance, a municipality is divided into residential, commercial, industrial, or manufacturing districts. Generally residents may be permitted to live in residential sections. Stores and residences may be permitted in commercial districts, and virtually any use may be permitted in a manufacturing zone. In addition, residential districts may be classified according to more specific uses. As an example, some zoning ordinances provide for single-family and multiple-family dwelling zones. Some zoning ordinances are even more restrictive and keep residences out of zones that are classified as commercial or industrial. Many municipalities also have ordinances that determine everything from minimum lot size requirements for particular buildings to curb cuts to the number of entrances.

The Role of Building Codes

Building codes are enacted and enforced under a state's police powers, that is, the general power to enact laws that promote the health, safety, and general welfare of its citizens, and that authority, including the authority to supplement the building code, is sometimes delegated to local government. Building code provisions must be reasonably related to the purpose or objective of the state's obligation to protect the welfare of its citizens. However, the government agency often enacts its code provisions while

granting broad power and discretion to the enforcing body or entity. The governmental agency's judgment will generally not be reversed by a court unless the judgment is clearly erroneous or unreasonable. For this reason, building and fire codes establish a formalized appeals process to provide a method for resolving a dispute over an application or interpretation of the code or other regulation. This appeals process is directed at the local level and is used by exception for situations in which the owner/developer and the AHJ reach an impasse that may delay progress on the project. Court involvement is possible, but is normally reserved as a measure of last resort.

Building codes sometimes apply to buildings and structures constructed prior to the adoption of the codes. The courts have permitted retroactive application of building codes because of their importance in protecting the public health and safety. More typical, however, is the concept of "grandfathering," whereby buildings constructed before the establishment of applicable codes are allowed to remain in use provided there are no imminent hazards.

The duty to comply with building codes is generally placed on the owner of the building or structure. The building codes typically assess fines for noncompliance. Inadequate design, improper application of code provisions, or outright disregard for the code-specified criteria are examples of noncompliance. Deviation from approved plans by the contractor without the benefit of a supplemental review by the code official may also result in noncompliance. Corrections of such violations are often disputed between the responsible parties and not easily resolved in some cases. In addition, some states and municipalities permit criminal prosecution of persons who knowingly violate building codes.

Most communities have adopted building codes. Some states have statewide building codes. Usually, before a building or structure can be built, the owner must apply for a building permit. A reviewing authority will analyze the plans and specifications to determine whether the proposed building complies with the appropriate zoning ordinance and the relevant requirements from the applicable building code. Most zoning and building ordinances provide that a new building may not be occupied until a code official has inspected it and issued a certificate of occupancy.

The Role of Fire Codes

Fire codes are a critical subset of general building codes and are key to protecting the public health and safety under a state's police powers. Fire codes may vary in their applicability but in many cases, they contain requirements that influence not only the construction of new buildings, but also criteria for ongoing protection for the life of the building. Probably the most well-known example of the importance of both the establishment and enforcement of rigorous building and fire safety codes is illustrated by the 1911 Triangle Factory fire in New York City. This fire triggered a review of not only existing rules and regulations in effect at the time of the fire, but also of the need to consider additional safety precautions. The trial included arguments on the factory owners' compliance and adherence, or lack thereof, to certain provisions of New York state labor laws and fire codes. Table 1.4.1 explores some of the code and compliance issues.

TABLE 1.4.1 1911 Triangle Factory Fire

Fire Protection Feature	*1911 New York State Law*	*Triangle Shirtwaist Company Compliance*
Doors	"All doors leading in or to any such factory shall be constructed as to open outwardly, where practicable, and shall not be locked, bolted, or fastened during working hours."	Door direction was fiercely debated at trial.
Staircases	Buildings with more than 2500 square feet per floor, but less than 5000 square feet per floor, require two staircases.	The Triangle Shirtwaist Company floors had 10,000 square feet of space. Any additional floor space would have required a third staircase.
Fire escapes	Required at the discretion of building inspectors. The building inspector insisted that the fire escape proposed for the building "must lead down to something more substantial than a skylight" (as specified by the architect).	The building architect promised "the fire escape will lead to the yard and an additional balcony will be put in." In the final construction, however, the fire escape ended at a second floor skylight. During the fire, the fire escape collapsed under the weight of the fleeing workers.
Non-wood surfaces	Metal trim, metal window frames, and stone or concrete floors required for buildings more than 150 ft high	The ten-story building was 135 ft high.
Sprinklers	Not required	Not installed
Fire drills	Not required	Not conducted

As with many building tragedies, the reaction of the professional design community was to attempt to address the underlying factors and remedy problems. Improvements to codes, including both incremental and sweeping changes, oftentimes follow such events. Even with improved codes, failure to design per the code or failure to properly enforce the provisions of the code may result in a catastrophe. Subsequent investigations to determine how and why a failure occurred may result in negligence claims against a building owner/operator, designer, contractor, or in rare instances, the entity responsible for enforcement and oversight of the code.

KEY LEGAL CONCEPTS FOR THE ENGINEER AND ENFORCER

The concepts of tort law, negligence, intentional tort, and strict liability are central to the engineer's and enforcer's understanding of their legal responsibility and exposure.

Tort Law

Tort is a generally defined and understood term in all jurisdictions and occurs when a person interferes with another person or his property. *Tort* is a legal term that is applied to a civil wrong that occurs and that may lead to a civil lawsuit. Basically, a tort is a "civil wrong, other than breach of contract for which the court will provide a remedy in the form of an action for damages," according to *Blacks Law Dictionary* (6th ed., 1990). Torts fall into one of three broad categories: (1) negligence, (2) intentional tort, and (3) strict liability.

Negligence

Negligence involves an unreasonable breach of duty by one person to another. The most common and likely tort encountered in the design and construction of a building involves negligence; thus, it will be discussed in more detail.

Intentional Torts and Strict Liability

Intentional torts are conditions reasonably foreseeable to cause harm to an individual and that do so. *Strict liability* is generally used to hold an individual responsible for errors, omissions, or other acts that cause damage or loss to another person. Intentional tort and strict liability will usually emanate from the action of, for example, a building owner who locks the exit doors (intentional tort) or installs a faulty product in a building (strict liability), rather than the engineer or enforcer. This chapter will not offer further discussion on intentional tort and strict liability.

THE ENGINEER AND NEGLIGENCE

As a result of performing professional services, the engineer may become liable for injuries or damages caused by negligence. A consulting engineer working in the construction industry may make an error in a plan that could result in a building failure. For example, the error could relate to the design of a structural system or component, fire protection system, fire wall, or any number of related systems like stairs, means of egress, or electrical systems. Likewise, an engineer working for a fire protection system component manufacturer could make a design error, resulting in a defective product. Lack of a rigorous quality control program at the manufacturing site may also contribute to a product that does not perform as intended. In either case, property may be damaged or someone may be injured, causing a claim to be made or a lawsuit to be filed against the engineer, the designer, the contractor, or the manufacturer.

The law draws a clear distinction between the rules applying to the engineer working in construction and other consulting areas (professional negligence) and the engineer working in manufacturing (strict product liability). The law places significantly different burdens on a plaintiff suing an engineer working as a consultant than on a plaintiff suing the manufacturer of a defective product.

A consulting engineer may be liable for negligence to clients or even to third parties. Similarly, a manufacturer may be liable for negligence to customers and subsequent users for damages caused by defects in the design or manufacture of its products. Suits for negligence fall under tort law. A suit for a tort must be distinguished from a suit for breach of contract. In a breach of contract lawsuit, the plaintiff seeks to recover damages for a breach of an agreement the defendant made with, or for the benefit of, the plaintiff. As an example, consider a designer who fails to deliver contract documents in the agreed-upon time. This may cause construction financing to be impacted, critical phasing or scheduling timelines to be missed, or start of construction permits to be invalidated. Tort law, on the other hand, has created an independent concept of a duty which one person owes another person, a duty not to injure or damage him, and is unrelated to the law of contracts.

Negligent Actions

English common law initially held that a person could be liable for injuries or damages they may have caused to another person, even though they were not at fault. However, by the early nineteenth century, the doctrine of negligence had become accepted. Accordingly, a person could be held liable for causing injury or damage to another person only if the person was negligent. At first, this concept was applied to certain tradespeople or professionals, such as blacksmiths or surgeons. The courts reasoned that such persons represented themselves as having certain skills in which the public could place their confidence. Accordingly, the courts determined that they owed the public a certain degree of expected service, and that if any of them breached this concept of expected service by being negligent, the service provider could be held liable for damages. Negligence could take the form not only of a positive act, such as a careless surgical procedure, but also of an omission (e.g., failure to meet the standard of conduct or performance).

Eventually, courts in England and the United States developed numerous rules governing negligence suits or actions. Among those rules are the following four elements that the plaintiff must show in an action to prove a negligence case against the defendant:

1. A duty that the defendant owed to the plaintiff to conform to a certain standard of conduct as established by the law
2. A breach of a legal duty by the defendant
3. The breach of duty must have a causal connection to the injury sustained by the plaintiff; the law requires that the breach of duty (the defendant's actions or failure to act) must be the "proximate cause" of the harm suffered by the plaintiff
4. Damage suffered by the plaintiff, since clearly, if the plaintiff has not sustained any personal injury or damage to his property, he is not entitled to recover any money from the defendant

These four elements can be connected to the work product expected to be provided by the architect or engineer. Was the conduct of the designer consistent with accepted practice? Did the project specification meet the prevailing requirements of the codes in effect in the jurisdiction? Did the design provide a safe and functional building that would not cause bodily injury or property damage? At the end of the project, did the designer deliver a useable, functional, and safe building suitable for the intended purpose?

Code Compliance

Frequently, professional service agreements provide that the design professional will prepare the design and specifications in compliance with "all applicable codes, regulations, and laws." Those codes, regulations, and laws include building codes, fire codes, zoning laws and ordinances, and federal and state statutes. Such "all applicable codes" contract provisions can be problematic. With the ever-expanding number of construction regulations and laws, the typical engineer may not be an expert in all applicable rules and may therefore not want to agree to broad statements of legal compliance. Thousands of laws, codes and regulations that relate to construction are on the books; all are subject to change, and some are open to interpretation. During both the design and construction phases of a project, an engineer is often called on to interpret codes and regulations, and the engineer's interpretation may differ from those of government officials. Government officials may insist that certain aspects of the design or construction be performed in a certain way, although this is not clearly called for by the applicable law.

In other instances, codes and ordinances may seem to be in conflict. In more cases than not, such conflicts may be nothing more than differing objectives. For example, property distances in the zoning law may have to more to do with encroachment and privacy issues whereas in the building code, such separation distances may have more to do with fire spread. These competing regulations may place the engineer in the untenable position of having to comply with two differing contractual obligations. A commonly encountered example of this provision involves the installation of sprinklers in electrical equipment rooms. Nationally recognized model standards and codes include stipulations that sprinklers are to be installed throughout the building unless a specific exception is granted. These standards and codes recognize the need to provide sprinkler protection in electrical equipment rooms. A local or state rule may explicitly state that sprinklers are not permitted to be installed in such rooms. In this case, the designer must choose between two provisions that cannot be met simultaneously.

In addition, there are additional issues to consider. Who will pay for design changes required to reflect a new code or regulation put in force during the course of a project? Although most permitting processes preclude the imposition of revised code-based requirements once the project is under way, there may be extraordinary circumstances when such changes must be made midstream in the construction process. Framed initially as an issue of who pays, this changes into an issue of what happens when the rules change in midcourse. If the change is at the request of the customer, they would be expected to modify the contract and allow for amendments to contract dollar amounts and an adjustment to the design and construction completion schedule. Also, if a project is suspended at any stage of development for an extended time, who will pay for design changes necessitated by new regulations when the project is resumed? If a professional service agreement does not provide for such circumstances, the engineer may need to provide extensive redesign services without compensation to bring the project up to code.

Accordingly, the engineer may want to meet with the client and the client's attorney prior to executing the agreement in order to reach an understanding on which legal statutes, ordinances, and regulations of law will apply to the project. If possible, the engineer should attempt to limit the language of the agreement to a statement that the engineer will comply with those codes, ordinances, regulations, and laws to which the parties have specifically agreed. In this conversation, it is important for the agreement between the engineer and the client to contain an appropriate cutoff date that states when the engineer's responsibility to adhere to new codes and/or regulations terminates. A reasonable cutoff date might be on submission of the plans and specifications to the appropriate code authorities. Any additional design changes deemed necessary after that date should be considered an additional service. In the written agreement, the engineer should make clear, if possible, that any conflicting interpretations by government agencies with which the engineer or the owner must comply may result in additional costs to the owner for which the owner should be responsible.

Standard of Care

What is the standard of care? Was it met? These are the first questions asked when an engineer is accused of professional negligence. As stated, the elements of professional negligence include (1) the owing of a duty, (2) a breach of that duty (e.g., failure to meet the professional standard of care), (3) causation (e.g., proximate cause) and (4) damages or harm. All four elements must be demonstrated in order to prove professional negligence. For example, although an injured party may suffer damages or harm resulting from the actions of an engineer, there may not be negligence because the engineer did not breach a duty (e.g., the engineer did not fail to meet the professional standard of care). Also, the legal interpretation of the professional

standard of care may vary from the public perception and the client's perception.

As a general rule, what is expected or required of the engineer is that the engineer render services with an ordinary degree of skill and care that would be used by other reasonably competent practitioners of the same discipline under the same circumstances, taking into consideration the contemporary state of the art and geographic considerations: It may be stated as follows: "The standard of care for all professional engineering and related services performed or furnished by Engineer will be the care and skill ordinarily used by members of the subject profession practicing under similar circumstances at the same time and in the same locality."

The standard of care has also been referred to as the "reasonable person" approach. What is reasonable and what is ideal or optimal may be two different things. It is reasonable to provide two exit stairs in a 20-story office building if that is all that the code requires. Compliance with codes, if those codes are accepted in the profession as the standard of care, is strong evidence that the designer is acting reasonably. This evidence is especially strong if the codes are nationally accepted, such as those published by the NFPA.

The "reasonable person" concept dates from the English common law doctrine that held that the public had the right to expect those providing services to so do in a reasonably careful and prudent manner as established by the actions of their own peers under like circumstances. This doctrine does not contemplate perfection or flawlessness. Performing to perfection is not the standard to which professional engineers or other professional service providers are held under the U.S. system of jurisprudence. Instead, the standard is whether the engineer's actions are reasonable, normal, appropriate, and prudent under the specific facts and circumstances. An engineer or designer cannot be expected to design for an unknown or unforeseeable hazard. The delicate issue and debate of what, if anything, codes and standards should do to address hostile or malevolent acts is a prime example of this. Events such as terrorist attacks are neither predictable nor symmetrical and are difficult to design for.

As noted earlier, it is not uncommon for some clients and members of the public unfamiliar with the standard of care to view professional engineering as an exact science rather than a licensed profession whose practitioners use ordinary skill, care, professional judgment, and discretion to address the needs of the client and the public. Sometimes these expectations are generated and are a result of unfortunate statements in the professional engineer's promotional materials or exaggerated comments included in proposals submitted to the client. For example, some clients will attempt, through the professional services contract, to augment the tort-based duty of reasonable care with a standard of care that requires the professional engineer to "perform to the highest standard of practice," to "warrant" or "guarantee" a result, or to "certify" that a result will be or has been achieved. Acceptance of these or similar provisions sets a far higher standard of care and subjects the professional engineer to a far greater liability exposure. Such provisions will also void most professional liability insurance, which is written based on the customary standard of care.

THE ENGINEER AND THE AMERICANS WITH DISABILITIES ACT

Accessibility Provisions for Newly Constructed and Altered Buildings and Facilities

The Americans with Disabilities Act of 1990 (ADA), also known as Public Law 101–336, became effective in 1990 after being signed by President George H. W. Bush. In general terms, the ADA is a wide-ranging civil rights law that prohibits, under certain circumstances, discrimination based on disability. Designers and owners/operators of buildings have, under ADA provisions, an obligation to provide reasonable accommodation for persons with disabilities. These provisions are now mainstreamed into the code requirements and criteria. The provisions are a mix of somewhat subjective measures (such as what constitutes reasonable accommodation) and technically specific and prescriptive rules that give precise performance measures (dimensions, numbers, etc.). The ADA provisions are also somewhat unique in that they must oftentimes be applied to the stock of existing buildings in certain circumstances. Voluntary compliance is an important component of an effective strategy for implementing Title III of the ADA. Private businesses that voluntarily comply with ADA accessibility requirements help to promote the broader objectives of the ADA by increasing access for persons with disabilities to the goods, services, and facilities available in communities.

Title III of the ADA authorizes the Department of Justice to certify that state laws, local building codes, or similar ordinances meet or exceed the ADA Standards for Accessible Design for new construction and alterations. Title III applies to public accommodations and commercial facilities, which include most private businesses and nonprofit service providers. Examples of covered businesses are restaurants, banks, commercial lending institutions, movie theaters, stadiums, groceries, convenience stores, health care facilities, and professional medical offices, to name a few. Congress, by authorizing the certification of state and local accessibility requirements under Title III, recognized the important role that state and local building codes and standards may play in achieving compliance with the building-related aspects of accessibility. State and local building officials who are involved in plan approval and construction inspection processes may provide important assistance to construction and design professionals through their oversight of the accessibility requirements of a certified state or local code. In any legal challenge that might be brought under the ADA to facilities constructed in compliance with an ADA-certified code, compliance with the certified code constitutes evidence, albeit refutable, of compliance with Title III of the ADA.

Importance of ADA Certification

The benefits of certification are not limited to potential ADA lawsuits. Certification facilitates ADA compliance by ensuring that certified state and local accessibility requirements meet or exceed ADA requirements. In this regard, business owners, builders, developers, architects, engineers and others in the de-

sign and construction industry are benefited because, once a code is certified, they can refer to certified code requirements and rely on them for equivalency with the ADA.

Certification of a state or local accessibility code also allows business owners, builders, developers, and architects to rely on their state or local plan approval and building inspection processes for assistance with ADA compliance through the implementation of certified accessibility requirements. Should a mistake occur in the design or initial construction phase of a project, the mistake can be identified early through the plan approval and inspection processes and corrected at a time when adjustments can easily be made and the costs for doing so remain low. In this manner, state and local building code officials in jurisdictions with an ADA-certified code can play an important role in checking to determine whether accessibility requirements have been met. Finally, jurisdictions that provide accessibility "checkpoints" such as those described above through the implementation of a certified code provide a significant benefit to private industry and an incentive for growth and development.

Engineer Responsibility Under ADA

Engineers are expected to use reasonable professional efforts and judgment to interpret applicable ADA requirements and other federal, state, and local laws, rules, codes, ordinances, and regulations as they apply to the project. However, as noted earlier, engineers should not be expected to warrant or guarantee that the client's project will comply with all interpretations of the ADA.

ENGINEER AND ENFORCER INSPECTIONS

Engineer's Role in Inspection

An *inspection* can be any kind of activity involving a visual or physical examination of work in progress or the results of work. It is important that the engineer, the client, and other involved parties have the same understanding of what observations and evaluations the engineer will perform and what scope and degree of error detection and quality assurance such activities can be expected to deliver. For example, unless an engineer is being retained specifically for the purpose of construction management services that entail inspection, the engineer will more typically agree only to "observe" or "review" a contractor's construction work for "general conformance" with the contract documents. It is not uncommon, however, to see contract language for general design services which transfer to the design professional significant responsibility and risk for inspection even though that is not within the scope of services for which the design professional is being paid. One example of how this responsibility may get formally transferred to the designer is contained in *NFPA 5000®*, *Building Construction and Safety Code®*, Chapter 40, "Quality Assurance during Construction."

The term *inspection* is sometimes used in contracts generated by owners when "monitoring," "reviewing," or "observing" might be more appropriate. When used to describe monitoring of the contractor's work, *inspection* may imply a greater responsibility than the engineer intends to provide. The client may think that the engineer is committing to police the project and through the inspection ascertain all instances where the contractor's personnel did not comply with the detailed plans and specifications and other contract documents. Some clients may even state in the contract that the purpose of the inspection is to assure the client that all problems are discovered and promptly reported to the client. The engineer is not inspecting the contractor's work to guarantee that it has no defects. The engineer can only "observe" the work and exercise reasonable care to determine that the work generally conforms with the contract documents. This is the industry standard and should be understood by the client. After all, the engineer is not being compensated for the man-hours it would take to watch everything done by the contractor to ensure no defects or deficiencies exist. Moreover, the contractor should be held accountable for those defects and deficiencies rather than the engineer.

The Role of Quality Assurance

If the intent of the owner was to raise the level of scrutiny or involvement of the engineer or architect of record, (also known as the registered design professional, or RDP) on daily progress and oversight of the project, then a much higher level of inspection, referred to as a quality assurance (QA) plan or program, may be called for. By their nature, QA programs establish another level of review. This supplemental compliance is not a substitute for, and does not in any way usurp the powers of, the AHJ. It does work to ensure that both routine as well as complex construction features are completed in accordance with the contract documents as well as with the specified code provisions. Quality assurance plans and programs do raise the level of surveillance and involvement of the engineer—specifically the RDP. In the realm of *NFPA 5000,* the following terms apply:

- *Quality assurance.* The procedures conducted by the RDPs responsible for design and the RDPs responsible for inspection that provide evidence and documentation to the RDPs, the owner, and the AHJ that the work is being constructed in accordance with the approved construction documents.
- *Quality assurance plan.* Written documentation of the tests, special inspections, and observations to be performed in the quality assurance program.
- *Quality assurance program.* A predefined set of observations, special inspections, tests, and other procedures that provide an independent record to the owner, AHJ, and RDP responsible for design that the construction is in general conformance with the approved construction documents.
- *Quality control program.* The operational procedures provided by the contractor to control the quality of the work and ensure compliance with the approved construction documents.

Agreeing to observe whether the contractor's work is in "general conformance" with the design concept is realistic. This is a manageable risk, whereas "inspecting" whether the work meets the details of the plans and specifications creates much greater

risk. The latter type of inspection needs to be clearly established as to the span of control, level of detail, and additional costs that would be involved.

LIABILITY OF CODE ENFORCEMENT OFFICIALS

Under the U.S. system of civil jurisprudence, it is generally recognized that any individual may sue any other individual in a court of law. Most state constitutions contain an "open courts" provision that seeks to limit any encroachment on an individual's right to sue another individual or entity. Having said that, the U.S. system of civil jurisprudence also recognizes the doctrine of sovereign immunity, a fundamental principle of English common law. Based on the divine right of kings ("the King can do no wrong"), today sovereign immunity remains as a means of protecting the public official as well as those who are employed or work on behalf of the government. The scope of protection includes building and fire code enforcement officials and other government employees involved in the code enforcement process. In some jurisdictions, the scope of protection may extend to consultants or contractors retained to perform a governmental function.

In recent decades, the sovereign immunity doctrine has been somewhat eroded as a result of court decisions and legislation waiving the application of sovereign immunity to certain governmental functions and activities. For example, under the Federal Tort Claims Act (and similar state laws), so-called "discretionary functions" (policy-making activities) of government continue to have sovereign immunity protection whereas so-called "ministerial functions" (day-to-day operational activities) of government do not have sovereign immunity protection. Since each state law may vary, depending on statutory language and court interpretation, it is critical for code enforcement officials to be familiar with the scope of sovereign immunity in the jurisdiction in which the official is employed.

SUMMARY

Professional engineers and code enforcement officials play a critical role in protecting the public health, safety, and welfare. Both groups must have a full understanding and appreciation of their respective roles in the design and construction process, recognizing general land use and building regulations, risk management considerations, ethical obligations and liability exposure that may arise in connection with the rendering of services to clients, members of the public, and others involved in the design and construction process.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on legal issues for the designer and enforcer discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Fire Investigation
Public Fire and Life Safety Education
Other Enforcement Agencies

Key Terms

dwelling fire safety survey, enforcement, fire inspector, fire investigator, fire marshal, fire prevention, inspection, plans examiner, public fire and life safety educator

Fire prevention includes any fire service activity that decreases the incidence and severity of uncontrolled fire. Usually fire prevention methods used by the fire service focus on inspection, which includes engineering, code enforcement, public fire safety education, and fire investigation. Similar methods and activities may also be provided by the private sector in large industrial or storage type occupancies, airports, and large assembly venues.

Inspection, including enforcement, is the legal means of discovering and eliminating or correcting deficiencies that pose a threat to life and property from fire. Education informs and instructs the general public about the dangers of fire and about fire-safe behavior. Fire investigation aids in fire prevention efforts by indicating problem areas that may require corrective educational efforts, inspection emphasis, or legislation. Good engineering practices, including plans review—another fire prevention method—can ensure compliance with codes and standards before construction or installation of built-in safeguards begins.

Historically, fire prevention was encouraged only after a large disaster. As an example, in the early years of the development of U.S. cities, following fires where a portion of a city burned down, laws were enacted prohibiting thatch roofs, thus preventing fire spread. Even though the fire service has attempted to be more proactive, major fire prevention efforts, in many cases, don't take precedence today until after a large event. This is supported by looking at past fire and life safety codes as they relate to postevent reviews and subsequent changes in codes, standards, and inspection methods or through redirection of code-enforcement priorities.

The full value of fire prevention was not realized until fire departments and agencies began to compile meaningful information concerning the causes and circumstances of fires. Such information highlighted problem areas and led progressive departments to initiate more effective fire prevention efforts. The results of such efforts are borne out statistically every year, confirming the effectiveness of fire prevention programs. Fire prevention, as the most important priority in cutting fire losses, received an endorsement in 1973, when the United States National Commission on Fire Prevention and Control published the results of its in-depth study on U.S. fires. In its report *America Burning,* the commission emphasized that increasing efforts toward fire prevention would measurably affect the U.S. fire loss picture. Statistics validate this position for areas in which fire prevention activities have been implemented.

See also Section 1, Chapter 3, "Codes and Standards for the Built Environment"; and Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety."

FIRE PREVENTION PERSONNEL

Effective fire prevention depends on the adoption and use of up-to-date codes and standards and a personnel network to support the enforcement of these codes and standards. Adoption of model codes and standards with modifications for local conditions provides the basis for fire prevention

Ronald R. Farr is fire chief/fire marshal with the Kalamazoo Township Fire Department in Kalamazoo, Michigan. A member of NFPA and the International Fire Marshals Association, he serves on several NFPA technical committees and the NFPA Standards Council.

Steven F. Sawyer is the executive secretary of the International Fire Marshals Association and a senior fire service specialist at NFPA. He has more than 30 years of fire service experience, including service as a deputy fire marshal and deputy fire chief.

programs. The personnel assigned to fire prevention should be technically capable and motivated to enforce fire codes, educate the general public, and investigate fire causes. Those who manage these responsibilities must be proactive and must be backed up with the appropriate resources—financial, training and staffing. This network of people is usually organized at the state, county, and/or local level. Some industries, such as colleges and universities, hospitals, and chemical and large manufacturing facilities may also have on-site fire prevention personnel.

Because of the importance and diversity of fire prevention activities, when possible, certain members of the fire prevention department should specialize in specific fire prevention functions. Staff size of a fire prevention division, bureau, or fire marshal's office will depend on the needs of the jurisdiction and the department size. In many cases the fire marshal must perform all duties of the fire prevention division and is the only member of the fire prevention staff. This office may be divided into specialized subsections addressing administration, fire prevention, code inspections, code enforcement, engineering, public fire and life safety education, data collection, and fire investigation. Other areas of expertise may be provided by specialists in a particular type of occupancy such as health care. These subsections may be headed by subordinate officers or specialists.

The fire prevention division personnel should consist of those department members best qualified for this work. In addition, qualified technical specialists should be available when possible. The department's overall effectiveness depends on the technical skills that the fire prevention personnel possess. It is also important that such personnel be able to properly communicate technical requirements to building owners, architects, engineers, other code-enforcement personnel, and other professionals involved in the construction industry as well as the general public.

State, county, municipality, or fire district laws or administrative regulations often delegate responsibility and authority for fire prevention to the fire chief or fire department head, who may then delegate this authority to an individual or division. In some states, the local fire marshal's authority and area of enforcement responsibility is derived from state laws, independent of or in addition to the powers and duties of the fire department chief. Personnel assigned to the fire prevention division should be knowledgeable about their authority. For example, the span of oversight for new versus existing buildings and the ability to make on-site inspection visits may vary from jurisdiction to jurisdiction

State and Provincial Fire Marshal/Commissioner

Most states have offices to oversee certain phases of fire prevention. The state's chief fire prevention administrator is usually called the state fire marshal. The organizational structure of state fire marshal offices differs from state to state. Most state fire marshals receive their authority from the state legislature and are answerable to the governor, a high state officer, or a fire commission. In some states, the state fire marshal's office may be a division of the state insurance department, state police, department of public safety, commerce department, or other state regulatory agency. Some offices are organized as independent state agencies.

State fire marshals' offices normally function in areas beyond the scope of municipal, county, or fire district organizations. Depending on the authority outlined in enabling legislation or administrative regulations, state fire marshal offices may have combined responsibilities in the following areas: code enforcement, fire prevention inspections, plans review, product approval, fire and arson investigation, fire data collection and analysis, fire service training, public fire and life safety education, fire legislation development, explosives and other hazardous materials regulation, manufactured housing regulations, electrical inspections, and state agency and public fire protection consulting.

State fire marshals may share responsibility with local fire officials, or each may have specifically defined areas of concern. Local fire protection officials are sometimes delegated the authority to act as agents for the state in stipulated areas of inspection, enforcement, and investigation.

At the national level in Canada, Human Resources and Social Development Canada (HRSDC) is responsible for fire safety enforcement in all nonmilitary federal government properties and for gathering national fire statistics. The Canadian Forces Fire Marshal (CFFM) oversees properties of the Department of National Defence, where fire protection facilities include a number of operating fire departments.

In Canada, each of the provinces has a provincial fire commissioner or fire marshal, whereas the three territories have territorial fire marshals. The provincial/territorial fire officer's responsibilities vary with each jurisdiction but may include code enforcement, fire service training, operation of fire-reporting systems, and fire investigation, as well as support of local fire departments. The Canadian Council of Fire Marshals and Fire Commissioners consists of the previously mentioned HRSDC and the CFFM, plus each provincial and territorial fire commissioner or fire marshal. The association exerts a major influence on fire safety policy in Canada.

County or Local Fire Marshal

In each county or community there is usually an individual assigned the duties of fire marshal. In smaller communities this individual may be the fire chief or another fire line officer with additional duties. In larger departments this may be a staff position or line position with only fire prevention duties. The chief officer for fire prevention activities may be called fire marshal, chief of the fire prevention division, or chief fire inspector.

The fire marshal should be well versed and knowledgeable in all aspects of the department's responsibility. He or she should also have knowledge of management, public relations, budget preparation, human resources, and other administrative functions.

Fire Inspector or Fire Prevention Officer

Fire inspectors or fire prevention officers should be selected for these tasks based on their technical training, expertise, and their ability to motivate people. Individuals in this position are

responsible for conducting fire inspections and also may be responsible for other division duties, including fire investigations, public education, or plans review, among others. An inspector conducting an inspection should be able to convince property owners or occupants to maintain or improve fire-safe conditions. The inspector who relies only on police power cannot accomplish as much as the inspector who relies on a proactive approach by showing the benefits and advantages for the employees and the business when fire safety elements are maintained. Strict enforcement of the fire law of the jurisdiction is necessary to achieve compliance and to ensure fire-safe conditions in the community are maintained.

Plans Examiner

The review of plans and specifications is a code-enforcement process intended to ensure compliance with the fire protection and life safety provisions of the building code, as well as the fire code prior to installation or construction. Individuals in plan examination must be technically proficient in both the intent and the letter of the applicable codes. The fire plan examiner reviews site plans, building and fire protection system plans, means of egress, and other fire and life safety plans and specifications and may prepare recommendations or consult with individuals involved in building construction, remodeling, or renovations. The plan examiner must regularly interact with other public safety officials and agencies at the local, state, and federal levels, including building, public works, zoning, health, and others, to ensure the construction of fire-safe, code-conforming buildings.

Fire Protection Engineer

Due to the complexity and magnitude of some fire protection problems, the services of fire protection engineers (FPEs) can be beneficial. Fire protection engineers may be employed by fire departments on a consulting or contractual basis or as full-time staff. The staff fire protection engineer contributes a high level of technical ability to the plans review process, interpretations, consultations, and the preparation of recommendations for a broad range of fire protection problems. Due to increasing interest in performance-based building and fire codes, the fire protection engineer is often in the best position to evaluate such proposals and assess the equivalent level of fire and life safety. The fire protection engineer's credentials, based on professional training, licensure, and registration as a professional engineer (PE), are recognized by architects, builders, and other professionals involved in the building process.

Public Fire and Life Safety Educator

The public fire and life safety educator creates public awareness of fire as a personal, family, business, and community concern and then strives to motivate the general public to do something about fire risks, based on proper fire-safe behavior. Today, many communities have expanded the role of the public fire and safety educator to other risks such as water, bike, firearms, motor vehicle, poison, fall, choking, natural disaster, and weather safety. Personnel selected for this function should be knowledgeable in a wide area of fire technology and other risks and be able to develop and present effective fire prevention, fire safety and other hazard prevention programs. This job requires someone with the imagination, creativity, motivation, communication skills, and adaptability needed to develop and convey fire and safety programs to all segments of the community. Program outreach may start at the kindergarten level and extend to the older adults community.

All levels of fire department personnel should participate in presenting the fire safety, fire prevention and other risk message to the community. Nonuniformed personnel, advocacy groups, older adults, teachers, and others with education backgrounds are also being used successfully by fire departments in this area of fire and risk prevention.

Fire Investigators

Fire cause determination and subsequent investigation can be the responsibility of the fire department alone or in cooperation with other agencies such as the police department. When a fire department is responsible, fire cause determination and investigation may be assigned to the fire chief, fire marshal, battalion chiefs, company officers, fire inspectors, or other personnel specially trained as fire investigators.

Investigative personnel should be perceptive, inquisitive, and thorough in determining facts and conducting an investigation. Investigation experience should be supported by training in areas such as chemistry, criminal law, forensics, and criminal investigation. An increasing number of progressive departments have fire investigation personnel trained in appropriate fields of criminal justice and provided with police powers. NFPA 921, *Guide for Fire and Explosion Investigations,* provides a guide to assist individuals who are charged with the responsibility of investigating and analyzing fire and explosion incidents and rendering opinions as to the origin, cause, responsibility, or prevention of such incidents. Although origin and cause are crucial to understanding how the fire started, an investigation can also analyze other factors such as performance of built-in fire protection systems and building construction assemblies, egress systems, and when appropriate, response by building staff for certain types of occupancies such as health care.

National Professional Qualifications

Professional qualifications standards for fire service career positions are the responsibility of the NFPA Professional Qualifications Correlating Committee. Four of the 15 standards are of particular interest to the fire prevention community: NFPA 1031, *Standard for Professional Qualifications for Fire Inspector and Plan Examiner;* NFPA 1033, *Standard for Professional Qualifications for Fire Investigator;* NFPA 1035, *Standard for Professional Qualifications for Public Fire and Life Safety Educator* and, NFPA 1037, *Standard for Professional Qualifications for Fire Marshals.*

Certification to the career levels defined in these standards is accomplished by agencies based on third-party accreditation. Accreditation for the fire service is currently available through the National Professional Qualifications Board of the National

Board on Fire Service Professional Qualifications (NBFSPQ) and the International Fire Service Accreditation Congress of Oklahoma State University.

Programs such as the NFPA Certification Program for Fire Inspector Certification to Level I and II and Fire Plan Examiner Level I are available on a national level. Many states also have their own certification program, require a national certification, or certify individuals to nationally recognized standard.

FIRE PREVENTION INSPECTIONS

Fire inspections can be classified into three types: installation and new construction, ongoing compliance, and re-inspection. These inspections are usually conducted by state or local fire prevention or fire department personnel. The type of inspections, frequency, occupancy types, and other factors that fire prevention personnel are permitted to make are based on state or local regulations. In addition to mandatory inspections, the fire department may also conduct voluntary fire inspections, such as home fire safety surveys.

Installation and new construction inspections ensure compliance with adopted codes and standards and help to eliminate problems before the building is occupied, a new process or hazard is introduced, or a new fire protection system is placed in service. These inspections also benefit the fire service by helping them to become familiar with the building before it is occupied and with the fire protection systems that have been installed.

Ongoing compliance inspections are needed to ensure that the occupancy, fire protection systems, and hazards protection are intact. These inspections ensure compliance with prior approvals, ordinances, and adopted codes and standards. Ongoing inspections should be performed at regular intervals based on legal requirements, hazards presented, and life safety issues. These inspections are often carried out yearly, based on licensing requirements. The frequency of other inspections is based on state or local laws.

One of the most important inspections is the re-inspection. If during an inspection, fire and life safety violations have been found and notices sent, a re-inspection is mandatory to ensure compliance. Violations that go unchecked place a liability on the inspecting agency for not following up on the original violation. It is also imperative that re-inspections be performed to ensure that unsafe conditions are corrected. Adequate time should be made available to inspection personnel to perform re-inspections.

The organization and operation of fire prevention inspection programs vary. Inspections required under the fire prevention code traditionally have been conducted by personnel from the fire prevention division. However, this responsibility is being shared increasingly with fire company personnel. The department's training program must train all its members in fire prevention.

Fire Prevention Inspection Objectives

Inspections conducted as part of code enforcement help to ensure compliance with mandated life safety conditions within a structure. The condition of and usability of means of egress, interior finish, emergency lighting, exit signs, and all fire doors should be inspected. Inspection of means of egress should include inspection of the exit discharge area.

Inspections, which are intended to prevent fires from occurring, are effective because the inspector identifies potential hazards that could cause a fire, allow a fire to develop, or allow a fire to spread. In addition to locating and correcting potential fire causes, the fire inspector should check any accumulation of combustible trash and debris, storage practices, maintenance procedures, and safe operation of building utilities.

Inspections determine that processes, high-hazard contents, hazardous materials, and flammable and combustible liquid installations and operations are installed correctly and hazards are properly protected. Inspections also determine the proper installation, operation, and maintenance of fire protection features, systems, and appliances within the building. The inspection process should ascertain whether each fire protection system is tested and maintained regularly and that records are kept for inspection and maintenance by the building owner or others.

Fire detection equipment, alarms, annunciation and notification systems, sprinkler-valve operation, supervisory switches, and fire pumps all should be tested and maintained regularly as part of the overall inspection process. Other fire protection features, including standpipes and fire escapes, should be tested and maintained or closely examined to detect possible malfunctions due to deterioration from weather, corrosion, or overall lack of preventive maintenance. Portable fire extinguishers should be checked as to proper type, placement, maintenance, testing, and distribution in the structure.

Technical information on a building and its processes should be recorded during the inspection. When used in prefire planning, such information can be valuable to the fire department in case of a fire at the property. The type of construction, vertical openings, utility type and placement, fire protection systems, fire department access, occupancy, hazardous materials, or special life-hazard conditions are the kinds of information that should also be noted during inspections and used to develop fire-fighting plans. This information also helps to ensure that the proper system or system component has been selected for the hazard. For example, a warehouse commodity may not be permitted to be stored over a certain height or in a certain configuration because of the type of sprinkler system that was installed.

In addition, the fire inspector should review written fire safety emergency procedures to ensure they are adequate and up-to-date with respect to the type of occupancy involved and the various types of fire protection features available. In many cases, it may be necessary to witness an actual drill or planned exercise of the emergency plan to properly evaluate its effectiveness. This should be coordinated closely with the facility manager.

Inspections provide an opportunity to educate the owners or occupants of a building about fire-safe behavior and the need for adequate fire and life safety conditions in the areas under their control. "Selling" fire prevention is the key to success in obtaining code compliance, and how fire prevention is "sold" should be an important consideration in training programs for inspection personnel. When inspection programs are properly

designed and put into practice, inspectors may achieve more through public education and persuasion than through exercising their enforcement authority. A bonus is that many of the concepts discussed at the workplace can be translated to fire-safe practices at home. The persuasive effect of the inspector's presence, coupled with the inspector's ability to spot and see that hazards are corrected, enhances the effectiveness of the inspection program.

Fire Company Inspections

In many communities, in-service fire suppression personnel conduct most or all regular or routine inspections. Company fire inspection procedures may include conducting building surveys, recognizing common problems concerning life safety conditions, locating fire hazards, and determining the operability of fire protection systems. Inspections also may include checking use and storage of hazardous materials, which may require issuing a hazardous-use permit. The inspection process helps familiarize fire company personnel with individual buildings and locations in their jurisdiction at which they may have to fight fires or perform other emergency duties. This information can be used in formulating prefire plans.

Company inspections are usually conducted in the fire company's first-due response area. Inspections and re-inspections may be scheduled by the company officer, by the battalion or district officer, or by the fire prevention bureau, according to requirements of the department. Before fire fighters perform inspections, they should receive proper training and be qualified and authorized to conduct inspections as fire prevention officers.

The inspection may uncover some situations that are easy to correct or others that require more technical skill. In either case, follow-up responsibilities should be assigned to the fire companies, fire company officers, and district chiefs according to the department's resources. The fire prevention division may help to obtain compliance by building owners after violations are located by fire companies, so it is essential for fire prevention personnel to coordinate their activities closely with those of fire company personnel.

Fire Prevention Division Inspections

In some departments, inspection personnel from the fire prevention division are solely responsible for conducting fire prevention inspections. The objectives of their inspections, like those of the general inspections performed by in-service fire suppression personnel, are to ensure compliance with applicable fire and life codes and to locate conditions that can cause a fire, cause a fire to spread, or endanger life and property. Each inspection must be thorough. The owner or occupants of the property being inspected must be notified when unsafe conditions are found. Inspections usually are required by law in order to locate any violations and to see that they are corrected. Legal direction by the municipal attorney or state attorney's office is available when a building owner does not cooperate. To perform such work competently, the inspector should have appropriate technical education, specialized training, and experience.

Even when in-service fire suppression personnel perform some or all regular or routine inspections, fire prevention division personnel may be concerned with the initial inspection, follow-up inspections, or enforcement actions necessary to correct fire code violations. Fire prevention division personnel may perform inspections associated with the issuance of permits as required by the fire code and may be concerned with buildings and premises that require a high level of code application. The inspector may need to confer with the property management or with fire department officers to prepare comprehensive reports, recommendations, or orders.

Both in-service fire suppression personnel and fire prevention division inspections may reveal conditions hazardous to the health and safety of owners, occupants, and the general public. Even when these hazardous situations are not specifically covered in the fire code or laws, such conditions must be brought to the attention of the owners or occupants; when necessary, other inspection authorities should be notified for the record. This mutual assistance in the inspection of buildings or premises can greatly enhance the level of life safety for the general public. Close cooperation among responsible inspection authorities should be encouraged and, where possible, recognized in municipal ordinances or interdepartmental administrative agreements.

The time of day and the actual day an inspection is conducted should be taken into account in an effort to identify conditions that may not be found during normal working hours. For example, night inspections of public assembly and mercantile occupancies should be part of routine inspection procedures to ensure compliance with occupancy load requirements and to demonstrate that the means of egress are in good operating order. Evaluation and knowledge of staff in a health care occupancy should account for the three shifts that provide care to patients on a 24-hour basis. Inspections based on citizen complaints should be conducted by the fire prevention division in a timely manner. An informed and interested public can be an important asset in uncovering unsafe conditions that might develop between routine inspections.

Dwelling Inspection Process

Nearly 85 percent of loss of life occurs in residential occupancies; approximately 75 percent occurs in one- and two-family dwellings. Residential inspections traditionally have not been mandatory because of unfounded concerns associated with the rights of citizens to ensure the sanctity of their homes or dwelling units. For years, however, many fire departments have inspected dwellings on a voluntary, by invitation, or planned basis and have been successful in reducing residential fire loss. Some departments test smoke alarms at homes where they have responded to medical calls. Inspections of this nature, whether conducted by career or volunteer fire department personnel, should be supported by a strong publicity program. Adequate training must be provided for all personnel involved. Voluntary inspections can be conducted either as a separate part of the fire inspection program or as part of fire prevention programs that include occupant fire escape planning and such practices as Operation EDITH (exit drills in the home), smoke alarm or

residential sprinkler drives, spring cleanup, burn prevention programs, heating fire safety, and so on. In some cases, banks or mortgage companies may require a dwelling inspection to verify the presence of smoke and carbon monoxide alarms when existing homes are sold and even when homeowners refinance their property.

For further information on dwelling inspections, see NFPA 1452, *Guide for Training Fire Service Personnel to Conduct Dwelling Fire Safety Surveys.* The Annex of NFPA 1452 includes sample materials for use during a dwelling fire safety survey (Figures 1.5.1 and 1.5.2).

CODE ENFORCEMENT

Fire Prevention Codes

The fire laws of the state, county, fire district, or community delegate general responsibility and authority to the fire officials involved in fire prevention activities. A fire code adopted into law that outlines specific fire prevention requirements and enforcement procedures is essential for an effective fire prevention program.

State law or local ordinances may outline how a fire code is written or adopted. The fire prevention official may have authority to write a local fire code or to adopt a nationally developed model code by reference. Using a model fire code is preferable to using one that has been developed locally. Nationally developed consensus codes are based on a broad spectrum of accepted fire prevention experience and may prevent a fire prevention official from being accused of developing a fire code that is biased, ultra-conservative or unreasonable.

There are additional advantages to adopting a model fire code. A model code provides a document that may be recognized as authoritative by architects, engineers, and builders who already are familiar with code requirements; provides an interpretation process by which the local official may determine the intent of the code-developing body should a question arise; and allows for periodic revision to reflect new technology and current thinking.

Several organizations publish model fire codes that jurisdictions may adopt by reference for enforcement use. NFPA publishes NFPA 1, *Uniform Fire Code*™, which incorporates many NFPA standards by reference. The International Code Council has developed its own model fire code, the International Fire Code. This code references codes, standards, and other NFPA documents. NFPA 1, *Uniform Fire Code*, and referenced NFPA codes and standards are found in the volumes of the NFPA *National Fire Codes,* published yearly and considered to be the most authoritative set of fire and life safety regulations in the world. Highly specialized topics, hazards, and occupancies are governed by the NFPA *National Fire Codes*.

Code Administration

Most fire codes specify similar enforcement procedures and contain similar requirements. A typical fire code contains an administrative section that establishes the legal framework and organization for the fire prevention program. This section usually

FIGURE 1.5.2 Sample Follow-Up Correspondence from Fire Department to Homeowner (Source: Figure A.10.2(c), NFPA 1452, *Guide for Training Fire Service Personnel to Conduct Dwelling Fire Safety Surveys,* 2005 edition)

outlines the code's applicability to occupancy types and specifies whether it applies to new or existing buildings, or both.

The code may define the enforcement authority of the fire prevention official and assistants, including lawful right of entry for inspections, the right to issue orders to correct hazardous conditions, and the right to order evacuation of an unsafe building or premises. The code may further assign duties that require the investigation of fires and the maintenance of fire records. Permit requirements, conditions, and procedures to issue notices of violation may be included.

The administrative section should be written in such a way as to provide the fire prevention official with as broad a scope of authority as possible. This facilitates enforcement of the fire code, other county or city ordinances, and state laws that pertain to the fire safety of buildings and premises, as well as to the control of hazardous materials within the jurisdiction. This section also may outline the owner's or occupant's responsibility for properly maintaining a structure, premises, permitted use and its fire protection features.

Subsequent code sections may define important code-related terminology, outline general fire precautions, and establish the proper installation, operation, testing, and maintenance procedures for fire protection systems and appliances within a building. Final sections of the code may outline the use and maintenance of specific types of equipment, processes, hazards, and occupancies, or they may describe handling requirements for various types of hazardous or explosive materials. Annexes may reference supplemental standards or other helpful data in the administration or application of the fire code.

Enforcement Procedures

The fire prevention process includes a number of enforcement procedures used to establish compliance with the fire code. They are described in the following paragraphs.

Permits. The permit is an official document issued by the fire prevention division to authorize the performance of a specific activity or event. Permits are issued in accordance with applicable codes by the fire official for the use, handling, storage, manufacturing, occupancy, or control of specific hazardous operations and conditions, installation of fire protection systems, special events, and other fire-related activities. The permit should be issued only if the condition of the approval meets code requirements.

The permit process provides the fire prevention official with information on what, where, how, or when specific hazards or fire protection systems are being installed, stored, or used within the jurisdiction or when special events will take place. The process allows cross-checking with building, zoning, public health, or other departmental requirements for the use outlined on the permit. Furthermore, it allows the fire official to review and approve devices, safeguards, and procedures that may be needed to ensure the safe use of hazardous materials, operations, special events, and fire protection systems. The lack of a required permit or failure to meet permit requirements constitutes a violation and is grounds for stopping an event, installation, operation, or use of a structure or operation.

The permit is the property of the issuing agency, not the permit holder. A license or permit authorizes, by law, the right of entry for inspection purposes to ensure compliance with the permit requirements. If an inspector operating under a fire code permit is refused entrance to perform a regulatory inspection, this refusal constitutes grounds to halt operation in, or use of,

the structure involved. Permits are usually issued for the place, process, and operator and are nontransferable so that the notification function of the permit process is maintained.

Certificates. A certificate, which is a written document issued by the authority of the fire official to any person or business, grants permission to conduct or engage in any operation or act for which certification is required. Depending on the needs of a jurisdiction, certificates of approval may be required before smoke or heat detectors, fire extinguishers, fireproofing materials, or other fire protection devices are offered for sale to the general public. This procedure is designed to ensure that only those fire protection appliances that will function in a satisfactory manner are offered for sale to the public.

Certificates of fitness are issued to individuals or businesses with demonstrated proficiency in skills, training, and testing in areas that affect fire safety. This includes pyrotechnics and persons who handle explosives; persons who install fire protection equipment and systems, including sprinklers; and persons who maintain fire extinguishers and fire detection systems. Certification requirements may include a financial bond or liability insurance if conduct of the regulated activity is inherently hazardous.

Licenses. A license is a permission granted by a competent authority to individuals about to engage in a business, occupation, or other lawful activity. Licenses are issued to provide knowledge of specific business locations, ensure compliance with particular standards, and add a source of revenue to the community. The fire prevention division may issue some licenses directly and may be involved in the checkoff process for licenses issued by other regulatory authorities.

Enforcement Notices

When violations of the fire code or ordinances are discovered during inspections, the violations must be called to the attention of the owner or occupants. When the situation is not corrected during the inspection or is a recurring uncorrected violation, several types of enforcement procedures may be available to the fire inspection officer.

Warnings or Notices of Violation. The inspection official may issue these notices to the owner or occupant, stating that a specific violation of the fire code or ordinances has been identified during the inspection. Depending on the legal requirements of the jurisdiction, a notice of violation will be sent to the building owner or, much like receiving a traffic ticket, the owner may be required to sign a form and keep a copy of the document. The specific violation and recommendations for correction of the violation should also be noted in the violation notice. A reasonable period of time should be permitted for correction of some violations based on their severity; all imminent life safety violations, however, should be corrected immediately. Re-inspection after the allotted time is essential to ensure that the correction has been made. If it has not, further legal action should be taken. All violations noted during the inspection, even those corrected during the inspection, should be noted on the notice of violation for future inspections.

Red Tag or Condemnation Notices. These notices are usually attached to appliances, systems, or equipment that would be unsafe and dangerous if allowed to remain in operation. The red-tag process requires that a competent service technician repair or replace the item before the tag can be removed and the equipment returned to operation. This process also may require that the fire official inspect the completed work before granting approval to resume the operation of the equipment in question.

Citations or Summonses. Violations of the fire code requirements or other fire regulations are considered either misdemeanors or civil infractions. An authorized fire official may issue a citation or summons to an individual who is in violation of the fire code. These documents constitute a notice for the violator to appear before the appropriate court to respond to the violations.

Warrants. A warrant is an order issued by a magistrate or agent of the court that directs a law officer to arrest a violator of the law and bring the violator before the court to respond to the charges specified in the document. The person requesting the warrant must provide factual information to the magistrate or court officer issuing the warrant, showing sufficient "probable cause" of a violation.

When authorized by state law or local ordinances, fire marshals, fire investigators, and other fire officials may be empowered to issue summonses, serve warrants, and make arrests. Police or peace officer training, in accordance with the standards of the state, is required by most states before a fire official may serve warrants and make arrests.

Where violations represent a clear and imminent hazard to life or property, it may be necessary for the fire official to take immediate action to correct unsafe conditions. Entrance into private property, shutdown of an operation, evacuation of a building, and withdrawal of permits are actions that the fire official may find necessary to ensure the safety of the public. These powers may be explicitly stated or implied in discretionary powers and "duty to act" requirements of appointing laws or ordinances. In all cases, actions must be based on clearly demonstrable threats to public safety, showing that delay would provide an unreasonable danger to residents, occupants, guests, or the public and that this judgment is based on accepted standards or concepts of safety.

In some states local fire officials can apply for and obtain an administrative search warrant. An administrative search warrant permits the fire official or other regulatory official the right to enter a premise to perform duties required by law.

RECORD KEEPING

Keeping records and files on all actions taken by the in-service fire suppression personnel, fire prevention division, or the fire marshal's office is an essential part of code enforcement and administration. All records of code enforcement, all documents relating to inspections, violation notices, summonses, plans review comments and approvals, fire reports, investigations, permits issued, certificates issued, variances or modifications that

were allowed, and so on are to be handled as legal documents. Well-organized and well-maintained inspection files and building records are essential foundations for enforcement actions. Complete and accurate records also are needed to measure fire department effectiveness in accomplishing fire prevention goals and to provide department management with information for budgetary and administrative purposes.

Types of Records

For each inspected property, a file should be maintained that summarizes information about the inspected premises and contains copies of all inspection reports. Records and reports of fire prevention activities should be clear, concise, and complete. Every time an inspector or fire prevention officer inspects a location, information about that location should be included in a record or a report. The occupancy file of each building visited should include a complete history of the building site; building plans and specifications, if available; fire protection system plans; information on and permits issued for the use, storage, and handling of hazardous materials; a summary of the types of operations or transactions carried out on the property; correspondence; inspection reports; and records of fires at that location. These files should also be reviewed by inspection personnel before they perform an inspection. This gives the inspector information on past violations and newly installed equipment or permits.

Files are needed for properties where a certificate of occupancy, a license, or a permit has been issued. Files also should be maintained on properties with automatic sprinklers, standpipe systems, private hydrants, or other private means of fire protection. A special notation or key should identify any system or equipment that is legally required. With a well-maintained system of files, established data need not be recompiled for each inspection. Inspection work planning is expedited, and time is used more effectively in the field for the inspection itself.

Computer Applications

In recent years, the use of computer technology has helped fire prevention officials handle record keeping and manage fire prevention programs. The number of programs, devices, and options available has grown sharply. The use of computers installed in vehicles, personal digital assistants (PDAs), and other devices has made the job of inspecting and reporting much easier. Many communities have found their records are more accurate and complete when computers are used for processing, organizing, or managing a great deal of the information associated with the overall fire prevention activity. Fire prevention reporting systems should be designed to collect, store, and process data and to schedule periodic activities according to local policy. For example, all information, including occupancy description, activity, and violations, is collected on a standard form during an inspection. After the inspection, forms are completed and processed according to local needs. These data, to be useful, must be collected and maintained in a uniform and consistent manner.

Computers can produce management reports related to inspection activity and to fire prevention personnel resource allocation. In addition, separate master file listings can be provided of occupancies currently under inspection and all occupancies to be inspected. Inspection forms or schedule sheets can be printed to show when periodic inspections are required and indicate violations to be checked for correction during follow-up inspections. These management reports should document the following:

1. The occupancy inspected, the location, the time of day, the date, and the name of the inspector
2. The code violations that have been corrected, filed by type, number, and kind of occupancy
3. The manner in which the fire department used its resources to accomplish fire prevention program objectives

These systems save the inspector time and provide data in a form useful for decision making by operational management. Because they contain a current inventory of occupancies, the systems can provide information for fire protection fiscal and long-range master planning.

PLAN REVIEW PRACTICES

Traditionally, the building department has been active in the design, construction, and final occupancy inspection of buildings. The fire prevention division's role traditionally began when the building was occupied, and it was concerned with the maintenance of life safety conditions and fire protection systems, as well as fire-safe storage and handling of contents.

Today, a progressive fire prevention division's role in the building construction process is changing. An increasingly important and practical fire prevention function involves the participation of the fire marshal or a designated representative in the review of building plans and specifications and in the construction process. In most cases, plans review is conducted in cooperation with the local building, zoning, and public works departments or with state agencies that may have this review authority.

The review of building plans and specifications provides the fire service with its best opportunity to see that fire protection standards are met before construction is completed and the building is occupied. The type and depth of the review process depend on the community's needs and the functions of other local departments or state agencies with review authority.

The fire official should participate in preconstruction conferences; address questions relating to fire protection features in the planned building, to the building code, or to fire code requirements; and comment during the plans review process. If questions and issues concerning the effect of construction on fire safety are discussed at this time with the architect, engineers, contractors, and other code officials, misunderstandings and conflicts that could arise during or after construction can be prevented. The fire official can emphasize fire safety code requirements and coordinate responsibilities with other code enforcement officials. Design professionals and contractors benefit from this procedure as well, because problems that otherwise would cost them time and money are identified and eliminated before construction begins.

Site Plan Reviews

The site plan review provides the fire official with the first look at new construction and at additions or modifications to existing buildings. The site plan provides an overview of the intended construction in relation to existing conditions and includes information such as building placement, exposures, size, type of construction, occupancy, water supply from both public and private sources, hydrant placement, and access. The site plan also may provide information about existing conditions that must be modified, such as abandoned underground flammable liquid tanks or pipelines in the area. The contour of the land may be significant. The current and projected uses of adjoining properties, including zoning, also should be reviewed at this time.

Preliminary Building Plans

The review of preliminary building plans gives the fire official an opportunity to comment on those features of the building that significantly affect life safety and protection of the building from fire. The depth and scope of the review and comments will depend on local conditions.

The provision for required fire protection systems is a primary concern in plans review. Because an estimated 75 percent of the building code may relate directly to fire protection and life safety within the building, the review may include, among other items, the type of occupancy, allowable areas and heights, fire separations, fire resistance of construction, interior finish, occupant load, number, location and arrangement of means of egress, protection of vertical openings, fire protection system, and special hazards.

Final Building Plans and Specifications

When the final building plans are submitted, they should include modifications required by the review official and agreed to by the design professional submitting the plans. Plans may be approved if they agree with the applicable code requirements. A building permit can then be issued, and construction may begin.

Plans review and approval must be followed by on-site inspections to ensure that the fire protection features and systems are constructed and installed as planned and approved. All deviations from the approved plans should be documented and, in certain cases, approvals must be obtained for the deviations. All agreements reached on-site or by telephone should be documented for all parties in follow-up correspondence or file memos. This correspondence and a copy of the approved plans should be retained in an organized filing system, so a permanent record of building construction is available for future reference.

When practical, building construction information should be provided to the fire companies responsible for that location. Information provided in all of the plans discussed in this section can aid in fire department prefire planning. Walk-throughs of the building by first-due fire companies should be conducted at various times during construction to familiarize them with the building.

Certificates of Occupancy

If the fire marshal's office is not the primary issuing agency for occupancy certificates, then either the fire marshal's office or the fire prevention division should be involved in the final inspection process. Each agency should certify the building before the certificate of occupancy is issued. This certificate indicates that all requirements under the building, fire and other applicable codes have been met and that the building is safe and habitable. All fire protection systems should be tested and placed in service before occupancy is allowed. The building should not be occupied until inspection agencies have approved it. This final review helps to ensure the life safety of the occupants and to verify that any required corrections have been made before occupancy.

CONSULTATION

The public looks to the fire service for answers and advice concerning fire problems. Due to its unique ability to provide this information, the fire department should offer consulting services to the community. Fire prevention officers must be able to explain fire codes, fire-related sections of building codes, and the application of specific standards to design professionals, contractors, and members of the building trades. Consultation also should be available directly to property owners, managers, occupants, and members of the general public, who may not be as familiar with fire problems and their solutions.

To maximize this service, the fire department should inform and instruct citizens about the best ways to deal with fire hazards. When the fire prevention division receives frequent calls about the same problem, it may wish to develop standard recommendations for that problem. If an issue relates to a specific group or business, they may wish to have a meeting with those affected to explain or clarify the issue. The fire department should maintain a library of up-to-date reference materials. In addition, the chief and other officers should be acquainted with individuals outside the fire department who have specialized knowledge or experience and who could act as resource persons. These and other consulting services are usually based in the fire prevention division or the fire marshal's office. State, city, or town webpages might also include FAQ sections on such everyday items as the requirements for location and placement of smoke alarms in the home or the permit, plan review, and inspection procedure required by the jurisdiction.

FIRE INVESTIGATION

The thorough investigation of fires is an integral part of the fire department's commitment to public safety and fire reduction. Fire investigation includes two areas: (1) fire cause determination and (2) investigation of criminal actions that may have contributed to a fire.

Fire cause determination is of major importance to a fire prevention program. Analysis of the causes of fires in a community is the basis for establishing fire prevention program priorities and providing fire safety information to the public.

Maximum utilization of resources must be based on firm information about the local fire problem. As information is accumulated from fire investigations, data become available on which to base corrective programs. Over time, this data will indicate trends in the area's fire problem, and a fire prevention program designed to tackle priority areas can be implemented.

If it is determined that a fire is caused by arson or other unlawful burning of property, a full criminal investigation should be conducted. Other fires for which a cause cannot be readily determined, including those classified as suspicious or undetermined, should also be investigated. Assertive fire investigations by skilled, trained specialists can deter arsonists.

In communities and states where fire service investigators have police powers, personnel may conduct an investigation to the point of arrest and incarceration of perpetrators. Where fire department personnel do not have police powers, fire cause determination must be made by the fire department and the follow-up investigation conducted by the police, sheriff, state police, or investigators from the state fire marshal's office. In some instances, cooperation with federal agencies such as the Bureau of Alcohol, Tobacco and Firearms (BATF) brings additional investigative and law enforcement resources to the local investigation units.

NFPA 921, *Guide for Fire and Explosion Investigations,* provides guidance in performing fire and explosion investigations. For additional information on fire investigations, see Section 3, Chapter 2, "Fire Loss Investigation."

PUBLIC FIRE AND LIFE SAFETY EDUCATION

Public fire and life safety education is an increasingly valuable area of public fire protection. This function has undergone rapid change and growth, focusing increasingly on the importance of prevention in public fire protection management. In recent years the focus of these programs has expanded to include other risks such as water, bike, firearms, motor vehicle, poison, fall, choking, natural disaster, and weather safety.

Public fire and life safety education includes three facets: (1) fire prevention education, (2) fire reaction education, and (3) other risk hazards. All three areas are necessary to change fundamentally the way the general public views fire as well as other hazards and to encourage people to act in a safe manner. The public needs to be motivated and instructed in actions that minimize the dangerous effects of a fire, should one occur. The basic method of instruction is changing from "preaching" to "teaching." Information is best presented in short, interesting, even humorous messages that require thought and that place responsibility for action on the recipients. In addition to the preventive aspect, the all-hazards approach to public education can also include a preparation aspect. For weather-related hazards that may result in long-duration power outages, having a supply of nonperishable foods on hand or a means to provide alternative light and heat sources should be considered. Recipients relate most effectively to the fire and life safety message when it is presented in a dramatic context. Cultural and language factors should be considered when fire and life safety messages are prepared for communication throughout the community.

National fire safety campaigns can be matched to local efforts. NFPA's *Learn Not to Burn*® effort is one such national campaign with messages designed to supplement, but not supplant, local fire prevention education programs. NFPA also offers other risk prevention programs such as *Risk Watch*® and *Remembering When.* NFPA has many public fire safety materials and programs designed for general public use and for specific groups and fire safety concerns. Community programs can be developed using the *Learn Not to Burn* theme and applying it to priority local fire problems (see Figure 1.5.3).

Community awareness and participation at the grassroots level are the keys to encouraging people to adopt fire and life safety behaviors. Civic and service clubs, youth and fraternal organizations, neighborhood action groups, the business community, schools, and other groups are contributing to the growth of fire and life safety education. Highly effective programs in such areas as escape planning, smoke alarm installation, fire hazard inspections, burn prevention, juvenile fire-setting problems, fire safety for babysitters, and fire safety for the elderly have been conducted by community groups in conjunction with local fire prevention personnel.

Many fire departments and fire prevention divisions have appointed full-time fire and life safety education officers. As their numbers have increased, the level of talent and professionalism of fire and life safety educators has also increased. Many fire departments no longer require that fire and life safety education officers be trained fire fighters; rather, these departments recognize the value of hiring educators with teaching experience

FIGURE 1.5.3 *Risk Watch* Program Being Used in a School (Source: Cote, Arthur E., *Fundamentals of Fire Protection,* 2004, Figure 7.5. Reproduced courtesy of Jones and Bartlett Publishers.)

and skills to develop and present educational programs geared to all ages and groups.

For additional information on fire and life safety education see Section 5.

Groups with Special Information Needs

Groups with information needs similar to those of the general public but different enough to require specialized programs include, among others, educational, industrial, institutional, high-rise, civic, service, elderly, professional, disabled, and commercial groups. Many innovative ways are used to reach such groups with fire and life safety information. See Section 5, Chapter 5, "Reaching High-Risk Groups."

Seasonal Activities

Informative educational programs of interest to the general public often are built around the four seasons of the year. Public education programs include National Fire Prevention Week, which is always the week that includes October 9, and Operation EDITH. Many topical and effective materials are available from NFPA for use in public education programs, including some featuring Sparky® the fire dog, the symbol of personal and property fire safety.

OTHER ENFORCEMENT AGENCIES

Building Department

Building departments are usually responsible for a variety of items related to building construction, structural integrity, protection, and occupancy features necessary to minimize danger to life and property. They provide oversight of design regulations to safeguard life, health, property, and public welfare and to minimize injuries by regulating and controlling the permitting, design, construction, quality of materials, use and occupancy, location, and maintenance of all buildings and structures within the jurisdiction, as well as certain equipment.

Effective building safety depends on the adoption of up-to-date codes and standards and a personnel network to use and enforce them. Adoption of codes and standards with modifications for local conditions provides the basis for building safety programs. The personnel assigned to the building department should be technically capable and motivated to enforce the building codes. This network of people can be organized at the state, county, and/or local level.

Because of the importance and diversity of building safety activities, whenever possible, certain members of the building department should specialize in specific functions. Staff size will depend on the community's needs and the department size and level of involvement. This office may be divided into specialized subsections addressing administration, inspections, enforcement, engineering, plumbing systems, mechanical systems, electrical systems, and planning and zoning. Other specialties may include members with structural expertise or flood plain management. Often these subsections are headed by subordinate officers.

In addition, qualified technical specialists should be available when possible—the department's overall effectiveness depends on the technical skills that the building department personnel possess. It is also important that such personnel be able to properly communicate technical requirements to building owners, architects, engineers, and other professionals involved in the construction industry as well as the general public.

State, county, municipal, or district laws or administrative regulations often delegate responsibility and authority for building safety to a specific individual, who may then delegate this authority to an individual or division. In some states, the local building official's authority and area of enforcement responsibility is derived from or stipulated by state laws. Personnel assigned to the building department should be knowledgeable about what authority they have.

The resources may vary depending on the size of the community, the type and pace of construction projects and the complexity of the projects. Quality assurance programs, such as those found in Chapter 40 of *NFPA 5000®*, *Building Construction and Safety Code®*, provide another tool for the code enforcement officer to ensure that the proper materials, designs, and techniques are being applied. All inspection or enforcement authorities from building departments, fire departments, or other offices still have most of the same legal obligations for inspection and enforcement issues as discussed previously.

Planning and Zoning Departments

Planning and zoning departments and inspectors have responsibility for the use and community planning of structures, buildings, and lands. They are responsible for such things as building and land maintenance, land use, building use, and community development.

Plumbing Department

Plumbing departments and inspectors are responsible for the erection, installation, alteration, repair, relocation, replacement, addition to, use, or maintenance of plumbing systems. Plumbing systems typically include all potable water, building supply, distribution pipes, and all plumbing fixtures and traps. Systems also include all drainage and vent pipes as well as all building drains and building sewers, including their respective joints and connection, devices, receptors, and appurtenances within the property lines of the premises. Plumbing departments will also be responsible for medical gas and medical vacuum systems, liquid and fuel gas piping, and water heaters and vents.

Mechanical Department

Mechanical departments and inspectors are responsible for the design, construction, and installation of mechanical systems. They will review the quality of materials, location, operation, and maintenance or use of heating, ventilating, cooling, and refrigeration systems; incinerators; and other miscellaneous heat-producing appliances. This includes the addition to or erection, installation, alteration, repair, relocation, replacement, use, or maintenance of any heating, ventilating, cooling, and refrigeration systems; incinerators; or other miscellaneous heat-producing appliances.

Electrical Department

Electrical departments and inspectors are responsible for the safeguarding of persons and property from hazards arising from the use of electricity. Their duties include plan review, inspection and enforcement of the installation of electrical conductors, equipment, and raceways; signaling and communications conductors, equipment, and raceways; and optical fiber cables and raceways for public and private premises. This includes buildings, structures, manufactured homes, recreational vehicles, floating buildings, yards, lots, parking lots, and carnivals. Also addressed are industrial substations, installations of conductors and equipment that connect to the supply of electricity, and the installations used by the electric utility, such as office buildings, warehouses, garages, machine shops, and recreational buildings that are not an integral part of a generating plant, substation, or control center.

SUMMARY

Fire prevention and code enforcement on the municipal, county, and state/provincial levels encompasses a variety of functions that include code inspections and enforcement, plans reviews, public fire and life safety education, and fire investigation. The successful implementation of fire prevention functions relies on the adoption of up-to-date codes and standards and the presence of technically capable and motivated personnel. This chapter has examined the functions and personnel needed for effective fire prevention and control of related hazards, that is, fire service activities that decrease the incidence and severity of uncontrolled fire.

Security Threats
Department of Homeland Security
Security Program Development
Security Vulnerability Assessment (SVA)
Guidelines, Standards, and Codes
Architectural Security Elements
Technology Security Elements
Operational Security Elements

Key Terms

access control, crime prevention through environmental design (CPTED), Department of Homeland Security (DHS), intrusion detection system, mass notification system, operational security, risk management, security program, security vulnerability assessment (SVA), terrorist activity

Security is "an intangible quality" that is most easily quantified or defined when it is breached or lost. The dictionary defines *security* as the quality or state of being secure—that is, free from danger, fear, or anxiety, or free from risk of loss.[1] Security has as much to do with perception as with reality. It can involve many components, from prevention through detection to apprehension. Finally, it can be said that security does not mean the same thing to everyone.

Crime has the fundamental components of motive and opportunity. The motive can be deep seated and, if that is the case, difficult to eliminate. Some people are deeply motivated by need—whether financial, habitual, spiritual, or simply for power. In some extreme circumstances, this need may be elevated enough for persons to sacrifice their own lives for their cause, often resulting in an act we call terrorism. A political motivation normally accompanies this level of commitment.

The other component of crime is opportunity. This aspect of crime is easier to manage. A great deal of crime targeting is based on opportunity. Most police and security professionals will agree that the elimination of opportunity is the single most effective means for preventing someone from becoming the victim. Making it difficult to perpetrate a crime is, therefore, the most effective deterrent.

The elimination of opportunity requires its identification through methods discussed in the security vulnerability assessment (SVA) section of this chapter. Although the focus of business and corporate security programs may be limited to their specific sites, the section on the Department of Homeland Security discusses the role of these programs in identifying and eliminating the actions of terrorists and criminals on a global scale. Once the opportunities are identified, the security program should address their mitigation or elimination. The security program can include architectural, technology, and operational security elements.

For related topics, see Section 1, Chapter 7, "Protecting Against Extreme Events"; Section 1, Chapter 8, "Emergency Management and Business Continuity"; and Section 14, Chapter 10, "Security and Intrusion Detection Systems."

SECURITY THREATS

Eliminating all security threats is difficult, if not impossible, because security threats are varied and dynamic. As one security threat is eliminated, another may develop. Thus, security programs look at establishing priorities, estimating probabilities, and dealing in reasonable measures.

The targets of security threats can be either people or assets. Clearly, most people would feel that eliminating the threats against individuals or groups of individuals should have the higher priority. Assets can be prioritized based on their criticalness to the organization.

Role of Motive

As stated earlier, motive plays a key role in criminal activity. Individuals can unknowingly create motives for criminal activity against them. Conflicts at work or at home can motivate criminal activity—for example, denying a promotion or providing a negative performance evaluation can

Lauris V. Freidenfelds, vice-president of Sako & Associates, Inc. (SAKO), has more than 30 years of experience in security consulting, corporate security management, and law enforcement. He currently provides senior-level security program development, design, and project management for SAKO and has served as a subject matter expert for numerous security conferences and trade magazines.

motivate criminal activity. The criminal activity may result in attacks on the individual or on assets under the control of the individual or organization.

Security Tools

One of the core tenets of providing security for individuals, as well as for assets, is to deny unauthorized or unwanted access to them. Access control systems play an important role in this. Another security tool is surveillance. Most criminals do not wish to be identified so that they can avoid prosecution and continue their activity. Many will avoid areas where it is known that security has a surveillance program in place.

Jurisdiction of Responsibility

The scale of criminal activity usually determines the jurisdiction of responsibility. If planned criminal activity targets just one or a few individuals or assets in a private organization, then that organization's security entity is usually the lead in mitigating the threat. The organization's security department can request assistance from public law enforcement if it cannot handle the incident on its own. If the threat is large in scale and has the potential to impact the public outside the domain of the private enterprise, then the public law enforcement agencies usually take over. This type of threat is considered terrorism.

The United States government (both individuals and assets) are frequently viewed as targets of terrorism. For that reason, it is on the forefront of establishing standards and guidelines for the protection of government individuals and assets. The establishment of the Department of Homeland Security (DHS) indicates that there is a growing shift in priorities from programs addressing apprehension to those focusing on prevention activities.

DEPARTMENT OF HOMELAND SECURITY

Establishment of the Department of Homeland Security (DHS)

In the past, acts of terrorism and large-scale incidents (e.g., bombings and biochemical attacks) involving major office buildings, transportation systems, and the like were considered not likely to occur on U.S. soil. The 1993 bombing at the World Trade Center, the 1995 Oklahoma City bombing, and the September 11, 2001, terrorist attacks have, however, created a new paradigm that is at best difficult to quantify and at worst challenging to predict. The threat and reality of international and domestic terrorism has had a negative impact on the sense of security of our society. This has led to the establishment of the Department of Homeland Security (DHS), which is a large organization of 22 previously disparate domestic agencies coordinated into one department to protect the nation against threats to the homeland.

DHS's Vision, Mission, and Strategic Goals

DHS's vision, mission, and strategic goals are as follows[2]:

Vision
Preserving our freedoms, protecting America . . . we secure our homeland.

Mission
We will lead the unified national effort to secure America. We will prevent and deter terrorist attacks and protect against and respond to threats and hazards to the nation. We will ensure safe and secure borders, welcome lawful immigrants and visitors, and promote the free-flow of commerce.

Strategic Goals
Awareness: Identify and understand threats, assess vulnerabilities, determine potential impacts and disseminate timely information to our homeland security partners and the American public.

Prevention: Detect, deter and mitigate threats to our homeland.

Protection: Safeguard our people and their freedoms, critical infrastructure, property and the economy of our Nation from acts of terrorism, natural disasters, or other emergencies.

Response: Lead, manage and coordinate the national response to acts of terrorism, natural disasters, or other emergencies.

Recovery: Lead national, state, local and private sector efforts to restore services and rebuild communities after acts of terrorism, natural disasters, or other emergencies.

Service: Serve the public effectively by facilitating lawful trade, travel and immigration.

Organizational Excellence: Value our most important resource, our people. Create a culture that promotes a common identity, innovation, mutual respect, accountability and teamwork to achieve efficiencies, effectiveness, and operational synergies.

The DHS and local public law enforcement agencies are getting more involved in assisting the private sector with security. However, this involvement consists of activities primarily focused on sharing information about threats and activities that become known to the intelligence agencies of the United States government. Some of this information is provided as sensitive information to the security community at local, regional, or national levels as appropriate, whereas other information impacts the DHS "Threat Advisory" level (Figure 1.6.1).

An interesting phenomenon that has developed is that public police departments are becoming more sophisticated in the implementation and use of detection capabilities. Many cities are installing video surveillance cameras to assist police officers in the field. It is likely that this concept will continue to grow, at least in the public areas. The determination of what and how much security is necessary on private property is still in the hands of private business managers.

SECURITY PROGRAM DEVELOPMENT

Risk Management Approach

The concept of developing an appropriate security program can be daunting to even the most experienced security professional.

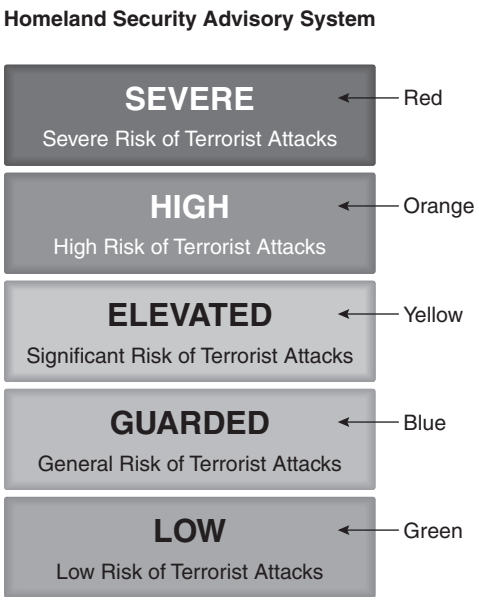

FIGURE 1.6.1 Department of Homeland Security's Threat Advisory Levels

Some people make the mistake of implementing security solutions without understanding the threats or vulnerabilities. This can lead to ineffective security programs, implementing programs that are too restrictive or, in the worst case, will not protect against a foreseeable threat. Alternatively, well-intentioned security programs can have the unintended consequence of inhibiting free and unencumbered egress for occupants. Security should be applied in a risk management approach that considers other factors such as fire safety and also maintaining a usable facility. The goal is a balance between security and other considerations in which every restriction is a minimally disruptive but effective response to a realistic threat. Implementing a program that is considered too restrictive can lead people to deride and resist the program. Implementing a program that does not address the foreseeable risks and vulnerabilities can be a waste of resources and lead to its failure.

How much security is needed can be driven by tort law—"reasonable measures" standard—that is, the foreseeability of crime. The security program should be able to address foreseeable incidents. The plan for implementing a security program should be based on performing a security vulnerability assessment (SVA); researching applicable guidelines, standards, or codes; and developing the appropriate strategy for the mitigation of security vulnerabilities. This process should be continually updated and modified because risks and vulnerabilities are dynamic and can often change. In addition, physical changes to buildings (e.g., tenant improvements, building renovations) will cause the plan to be evaluated and revised in many cases.

Security Program Elements

The security program should comprise architectural, operational, and technical elements (Figure 1.6.2). The appropriate interaction of these elements will be discussed in greater detail later, but the foundation of this concept is the coordination of technological and architectural elements to support operations. The technology aspects of security are but one element of effective security programs. Technology must be integrated with architecture and operations to form an effective security program. The appropriate use of each of the elements depends on the culture, style, and capabilities of the corporation. Overemphasis on only one or ignoring one of the other components can lead to a program that may be both inefficient and ineffective.

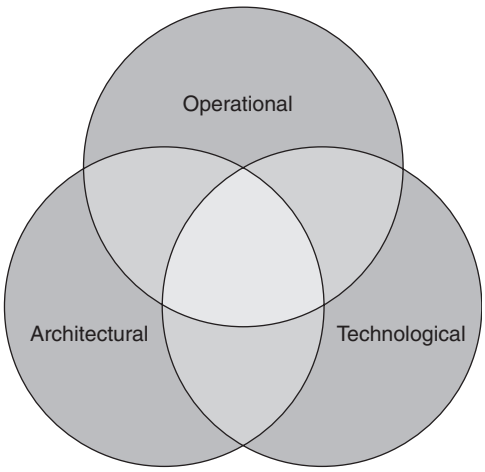

FIGURE 1.6.2 Security Program Elements

Technology is the tool that can make security operations more efficient. There are systems such as access control, video surveillance, intrusion detection, communications, contraband and weapon detection, asset monitoring, and others. It may not be economically possible to provide staff at each door to screen people entering and leaving the building. Security systems can execute that assignment with devices such as a biometric identity verification reader and other door controls. The effective security programs include technology systems that can adjust to the level of the known or potential threat.

Security can be considered more of an art than a science. Because the industry has evolved largely without standards until very recently, the methodology for achieving security can have many designs and options.

SECURITY VULNERABILITY ASSESSMENT (SVA)

Quantifying Types of Threats

There are many theories regarding the methodology of how to execute a security vulnerability assessment (SVA). Many are good, such as the FEMA 426, *Reference Manual to Mitigate Potential Terrorist Attacks Against Buildings.*[3]

Some threats to security are sufficiently common (e.g., fires or break-ins) that probability and severity estimates can be developed directly from historic data. Some threats to security are rare events (e.g., earthquakes or hurricanes) that can be characterized in terms of return frequencies using historic data, extreme-value statistical methods, and possibly scientific

understanding of the underlying physical phenomena that generate such occurrences.

Some threats to security, however, are so rare—or even unprecedented—that no predictions can be developed from experience. Expert judgment may have to suffice, and experts are often no better than anyone else at anticipating the truly unexpected (such as the September 11, 2001, attacks). Also, if the threats are the result of deliberate hostile acts—as they often will be in the security realm—it may be appropriate to base predictions on the attractiveness and vulnerability of the target. Military planning, which is based less on past frequency or current intent and more on current or future capability, may be relevant.

Prior to September 11, 2001, very few people in the United States would have believed that adversaries would commandeer commercial aircraft and sacrifice their own lives to commit an act of terror. Acts of terrorism on U.S. soil were not considered probable enough to justify a mitigation strategy to prevent them nor to determine building construction strategies to manage such hazards. Although the World Trade Center (1993) and Oklahoma City (1995) incidents might have elevated the notion of terrorist attacks, establishing criteria to deal with them simply did not occur. U.S. Department of State embassies located throughout the world have typically applied some very sophisticated security and deterrent strategies. The extent to which these elements could or should be applied to buildings on U.S. soil is now a topic of debate in all areas relating to the built environment.

Assessment Objective

The best approach is to develop a tool that will address the issues and factors important to the organization. The SVA should be organized to take into consideration the following factors:

- Foreseeable likelihood of the threat or incident
- Impact of the threat or incident
- Mitigation strategies

The objective of the assessment should be to answer questions such as the following and others that are more specific to the type of business:

- Does my building represent a potential target?
- Are we located near a target?
- Do tenants in my building elevate the risk by attracting an attack?
- Are we capable of dispersing critical operations or staff to backup locations?
- Can we separate screened from nonscreened people routinely or as part of response to an attack in progress?
- Do we have backup programs in place?
- Is my staff properly trained?
- Can we reasonably detect weapons, explosive devices, and biological or chemical agents at entries?
- Can we reasonably detect biological or chemical agents in air returns/intakes?
- Can we mitigate their effects?
- Is our voice-data infrastructure protected?
- Is our HVAC and electrical infrastructure protected?

The following impact questions should also be addressed:

- What would be the impact on operations if we were the target of an explosive, biological, or chemical attack?
- How long can we operate in this manner?
- What are the costs of operating in this manner?
- Can our operations be relocated efficiently?
- What would happen if a nearby facility were targeted?

SVA Process

As described in NFPA 730, *Guide for Premises Security,* Chapter 5, the SVA is a seven-step process.

Step 1: Formation of Team. The process should begin with the formation of a team of personnel from all organizational areas. Commonly, the individual responsible for an organization's security serves as team leader.

Step 2: Organization/Facility Characterization. Step 2 involves a characterization of an organization and the facilities to be protected. It includes identification of assets (i.e., people, property, information, and products); physical features and operations; laws, regulations, and corporate policies; social and political environment and internal activity (i.e., community resources, crime statistics, internal activities, and loss experience); and review of "current layers of protection" (including both site security features and safety measures).

Step 3: Threat Assessment. Step 3 is the conducting of a threat assessment. The process includes a classification of critical assets, identification of potential targets, consequence analysis (effect of loss, including any potential off-site consequence), and the definition of potential threats (by identifying potential adversaries and what is known about them).

Step 4: Threat Vulnerability Analysis. Step 4 is the conducting of a threat vulnerability analysis that identifies actual and potential threat scenarios and estimates a relative security risk level. The relative security risk level is a function of determining the severity of the consequences of an adversarial event, the potential for such an attack, and the likelihood of adversary success in carrying out the anticipated event or activity.

Step 5: Define Specific Security Countermeasures. Step 5 involves defining specific security countermeasures. All information from the previous four steps, including characterization, threat, and vulnerability analysis, is considered. An effective countermeasure is one that drives improvements in mitigating the defined threats and results in a reduction in the security risk level.

Step 6: Assess Risk Reduction. Step 6 involves taking into account the countermeasures defined in Step 5, reassessing the relative security risk levels developed in Step 4, and considering additional security risk reduction measures (security countermeasures) where appropriate.

Step 7: Document Findings and Track Implementation. Step 7 involves documenting findings and recommendations

in a report and tracking the implementation of accepted recommendations.

The process should be repeated as often as deemed necessary, but annually is usually a good minimum frequency.

GUIDELINES, STANDARDS, AND CODES

Governmental Guidelines

As stated before, the security industry has largely grown without the benefit of guidelines, standards, or codes. The earliest guidelines and standards evolved from the U.S. Department of Defense's mandating of security for defense contractor facilities as early as World War II. Terrorists have typically focused on federal government buildings or structures or objects that represent iconic or highly symbolic targets. This has prompted the federal government to establish guidelines that can be applied to certain federal facilities. Some organizations consider these guidelines applicable for their high-profile private corporate facilities.

On June 28, 1995, the U.S. Department of Justice published the *Vulnerability Assessment of Federal Facilities.*[4] The report recommended the formation of an Interagency Security Committee (ISC), which was formed by Executive Order 12977 on October 19, 1995, to establish long-term construction standards for federal buildings. The result was the publication of the *ISC Security Design Criteria for the New Federal Office Buildings and Major Modernization Projects.*[5] Additionally, there are many specific guidelines and requirements for specific federal agency facilities.

Commercial/Nongovernmental Guidelines

In the commercial, nongovernment sector there are fewer guidelines. The insurance industry has prompted the Underwriters Laboratories (UL) to establish some of the guidelines. Insurance companies noted that with respect to assets they insured there were no established standards for the prevention of loss. UL is one organization that developed standards and guidelines insurance companies found acceptable. To encourage implementation of these guidelines, insurance companies provided financial incentives for those who implemented and maintained these systems. Included are central station requirements, jewelry store protected property requirements, and others. Many industry associations provide standards or guidelines for specific components of a security program, such as glazing material, bank vault construction, and door hardware.

NFPA 730, *Guide for Premises Security*

On August 18, 2005, the NFPA approved NFPA 730 as an American National Standard. This guide provides construction, protection, and occupancy features and practices intended to reduce security vulnerabilities to life and property. Similarly, on the same date, the NFPA approved NFPA 731, *Standard for the Installation of Electronic Premises Security Systems.* NFPA 731 covers the application, location, installation, performance, testing, and maintenance of electronic premises security systems and their components. Using NFPA 730 as a guideline for establishing a security program, NFPA 731 can provide a minimum standard for applying security technology.

Concentric Circles or Layered Approach

No single feature or attribute can provide the total security package. Rather, the synergy of multiple features, systems, and policies work to provide an appropriate level of protection. Good physical security is built using a layered approach, with the perimeter being the first physical line of defense against a general threat level for any facility. Security is then applied in layers that are targeted to address specific threats. With respect to the development of security countermeasures, and in consideration of the defined threats, the SVA team's efforts should be to develop or strengthen the security by applying layers of protection beginning with a focus on the concentric circles of protection design methodology (Figure 1.6.3).

As described in NFPA 730, the concentric circles methodology provides for protection of defined critical assets by considering four primary protection elements. The primary elements of an effective protection plan design follow:

- *Deter.* Discourage an adversary from attempting an assault by reducing the likelihood of a successful attack or offense.
- *Detect.* Determine that an undesirable event has occurred or is occurring. Detection includes sensing the event, communicating the alarm to an attended location, and assessing the alarm.
- *Delay.* Impede adversary penetration into a protected area.
- *Respond*. Counteract adversary activity and interrupt the undesirable event.

Theft, sabotage, or other malevolent acts can be prevented in two ways: by either deterring or defeating the adversary. In the development of security countermeasures, it is important to

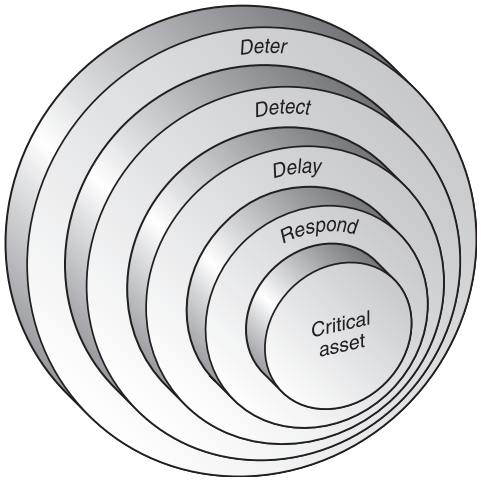

FIGURE 1.6.3 Concentric Circles of Protection (Source: NFPA 730, *Guide for Premises Security,* 2006, Figure A.5.2.5.)

understand that a properly designed and implemented security program integrates people, procedures, and technologies for the protection of assets. The use of technologies alone is not the solution.

The "new world" we live in poses a new challenge: the increased presence and threat of adversarial attack. Our journey now involves an important dual approach, the combination of today's security methodologies with traditional safety and risk management practices to strengthen security layers of protection. An effective security program, resulting from the completion and implementation of a comprehensive SVA, provides measurable benefits in the workplace for personnel (staff, guests, and visitors), in the protection of property, and in operations, resulting in enhanced business performance.

The security professional has the benefit of a plethora of available tools. The challenge is to select the correct ones and apply them appropriately. A growing popular concept is crime prevention through environmental design (CPTED). It is based on the premise that "the proper design and effective use of the built environment can lead to a reduction in the incidence and fear of crime, thereby improving the quality of life."[6] The goal of CPTED is to reduce opportunities for crime that may be inherent in the design of structures or of neighborhoods.

ARCHITECTURAL SECURITY ELEMENTS

Architectural security elements are elements that provide physical deterrence and prevention of intrusion/crime. In addition to the hard physical elements, architecture can play a role in creating segregation of buildings, staff, and traffic flow—a particularly important concept in the design of hospitals, where the people are unable to defend themselves against crime because of their physical condition, and in the design of courthouses, where the people are opposing each other in legal and criminal cases. These architectural elements, designed in conjunction with the appropriate technology elements, can provide a major contribution to an effective security program.

Lighting

Protective lighting is a valuable and inexpensive deterrent to crime. It provides visibility for checking badges and people at entrances, inspecting vehicles, preventing illegal entry, and detecting intruders both on grounds and outside and inside buildings. The recommendations for minimum lighting can be found in NFPA 730 paragraph 6.4.6.1 (Table 1.6.1). More information on recommended lighting levels for outdoor protective lighting is also provided in the *Lighting Handbook,* 9th edition, published by the Illuminating Engineering Society of North America (IESNA).

TABLE 1.6.1 Recommended Minimum Intensities for Outdoor Protective Lighting

Location	*Footcandles (on horizontal plane at ground level)*
Perimeter of outer area	0.15
Perimeter of restricted area	0.4
Vehicular entrances	1.0
Pedestrian entrances	2.0
Sensitive inner areas	0.15
Sensitive inner structures	1.0
Entrances (inactive)	0.1
Open yards	0.2
Docks/piers	1.0

Source: U.S. Army Field Manual 19–30, 1979; reproduced in NFPA 730, *Guide for Premises Security,* 2006, as Table 6.5.2.1.

Fences

Fences serve multiple roles in a security program. First, a fence line can be a barrier to prevent or minimize the chances for intrusion. The fencing material should be commensurate with the intended barrier protection required. Second, it can clearly indicate the outermost perimeter of an area that has access restrictions. This indication may require additional specific signage (to assist in prosecution) at designated locations to ensure proper warning. Checking with local ordinances to obtain proper installation and any related restrictions is advisable. It is also a good idea to see whether the local jurisdiction has recommendations or requirements for signage. The fence should be as straight as possible to provide for ease of observation. Clear zones should be provided on both sides of the fence to provide an unobstructed view. Utility poles in close proximity to the fence should be provided with a "security collar," a device that prevents climbing the pole to a height greater than that of the fence.

Gates and Barriers

The number of entrances should be kept to a minimum, consistent with safe and efficient operation of the facility. Entrances can be designed for vehicular traffic or for pedestrians and are usually closed by a gate or turnstile. Gates can be single- or double-swing for walkways, multifold for wide entrances, double-swing and overhead single- and double-sliding for driveways, cantilever single- and double-sliding for driveways where an overhead track would be in the way, or vertical-lift for special purposes such as loading docks. Any of these gates can be motor operated. When entrances are not staffed, they can be securely locked, illuminated during the hours of darkness, and periodically inspected. Semi-active entrances, such as railroad siding gates or gates used only during peak traffic flow periods, can be kept locked except when actually in use.

When the SVA dictates that the threat may be in the form of a vehicle attempting to gain access through force, vehicle arrest barriers or pop-up bollards may be recommended. These devices are designed to stop vehicles at the specified speed and mass (Figure 1.6.4).

Berms and Natural Elements

Within the perimeter fence and gates are several architectural elements that can add to the security program. Consistent with CPTED principles, natural features such as mature trees and

FIGURE 1.6.4 High-Security Road Block Barrier (Source: Courtesy of Delta Scientific)

FIGURE 1.6.5 Concrete Bollards (Source: Wausau Tile, Inc., http://www.wausautile.com)

elevation changes with berms and valleys can be used to prevent vehicles from gaining enough speed on the site to do damage. Drives and close proximity access roads should be designed with a serpentine-type route to again limit the speed that can be achieved.

Standoff Distance

When the threat or risk scenarios developed in the SVA indicate a need to consider vehicle-borne explosives, an effective means of providing security against this threat is to create a standoff distance from the building to a point where a threat vehicle is allowed to approach the building. The greater the distance, the less impact the explosion would have. The distance can be achieved by placing bollards (Figure 1.6.5), planters, or barriers at the distance where the explosion effect can be sufficiently dissipated. When designing for an explosives attack, an assumed explosives size (TNT equivalent) must be agreed on. The standoff distance is valid for that design assumption, but may not be as effective for a scenario that is greater than the design point. The same holds true for other interventions that address the explosives design scenario.

Walls/Glazing

Building perimeter construction should be sufficient to address the potential threats identified in the SVA. The threats may include explosives or intrusion attacks. When the standoff distance required to address the described potential explosive device cannot be achieved, the structural components of the building need to be reinforced to handle and mitigate the threat. The three types of materials presently listed by UL for use as burglary-resisting glazing materials are laminated glass, polycarbonate, and acrylic. Glazing materials that meet the UL requirements are listed under the category "Burglary-Resisting Glazing Material (CVYU)" in the *UL Security Equipment Directory.*

Component and cladding systems that are more robust when a proximate explosive is discharged can minimize the amount of airborne debris. Specially designed glazing systems actually restrain or retain glass panels in exterior windows.

Doors

As with gates, the number of doors into a building should be limited to only that which is necessary. In most commercial burglaries, the point of attack is a door, window, or other accessible opening. On doors with glass lites (i.e., glazing within a door) or doors adjacent to glazed panels, there is the concern of an intruder breaking the glass and reaching in to unlock the door. To protect against this type of attack, a double cylinder lock (i.e., a lock that requires a key to lock and unlock the door from either side) can be used under limited circumstances; however, this application can be in conflict with *life safety requirements.* (See NFPA *101*®, *Life Safety Code*®, 7.2.1.5.)

An alternative is to use a conventional single-cylinder deadbolt and either to replace the glass with burglary-resisting glazing material or to install a polycarbonate sheet behind the glass lite. When used to provide backup protection to a glass lite, the polycarbonate sheet is attached to the door with wood screws and countersunk washers. To allow for the expansion and contraction of the polycarbonate, the holes drilled in the polycarbonate sheet must be of a slightly larger diameter than that of the wood screw. This technique can basically be applied to any type of window.

Locks/Door Hardware

Door hardware is traditionally an architectural feature. Mechanical locks and door hardware should take into account the risks identified in the SVA and consideration should be given to security-type cylinders on the required doors. Nonduplicatable keys are typically a good idea. Higher-security keys are available from many manufacturers. Antipry devices can be applied where necessary, especially if door position monitoring is not provided at the door. The electronic door hardware needs

to be well coordinated with the security technology systems. Where building and life safety codes allow the use of electronic security door hardware, it should be *fail secure* as opposed to *fail safe,* with a mechanical or manual means of releasing the door to allow for egress. (Fail secure hardware remains engaged when there is no power, requiring power to unlock or disengage. Fail safe electronic hardware requires power to stay engaged; when power is removed, the hardware disengages.) In most cases, close coordination of the various failure mechanisms and scenarios and the manual releasing methods must be laid out to make it absolutely positive that the door can always be released via mechanical or manual means.

Signage

Utilize signage and site flow to prevent visitor frustration and anger. Focus on communicating with the unfamiliar visitor. Anticipate the questions unfamiliar visitors would have as they enter the facility to accomplish a common goal, such as paying taxes or visiting a clinic with two children in tow. Clearly communicate answers to those questions via coordinated signage. Design the signage based on the reality of how people prefer to access and use the facilities. Important components include consistent terminology, clear and consistent signage, multilanguage handouts, customer service or information centers in lobbies, and self-help kiosks. If handmade signs are necessary, make sure they are coordinated and consistent in production to ensure size and message constancy. Periodically review posted signs to verify their accuracy.

Signage should be posted from the entrance to the property all the way inward. Due to the number of functions at many of the facilities, signs may need to include the practical reason for visiting an office as well as the office name. This is sometimes the case, but frequently existing signs list the "official" name of an office, which is not the same as the colloquial name for it and does not indicate the functions performed there. Consideration should be given to having both listed.

Consider the use of "authorized entry only" signs or way-finding signage to prevent "wandering" or use of unauthorized or nonpublic areas. Color-coded strips on the floor are one example of a way-finding method.

Mailrooms

One vulnerability that may be identified in the SVA is the daily flow of mail and packages into the facilities. By their very nature, mailrooms, loading docks, and any areas that receive shipments are among the most vulnerable areas. Risks include improvised explosive devices (IEDs) (e.g., parcel bombs or vehicle bombs) and chemical or biological agents (e.g., anthrax). Because a criminal can remotely reach deep into a facility through mail and packages, an added level of precaution may be warranted. Typical detection provisions include using technology (X-ray machines and magnetometers) to screen mail and packages. Technology to monitor the air quality is much less mature. Attempts to mitigate the risk (reaction) through physical modifications, such as building separate mail handling areas with dedicated, separate ventilation systems, should be considered. Some federal government facilities actually process incoming mail at isolated, physically remote locations that are geographically separate from the primary facility or office.

TECHNOLOGY SECURITY ELEMENTS

Design Concepts

Today's design concepts involve multiple levels of integration and utilization of networks and sophisticated interfaces that result in simple and easy-to-use access control systems. The challenge that designers face is having a good understanding of specific system capabilities, interface options, and limitations. Too many video systems attempt to handle the access control requirements, and some access control systems attempt to become video switchers and controllers. Multitasking of this technology is now on the brink of utilizing video smoke detection apparatus. Although multifunctionality of this type of equipment may be desired, it may not be ideal. Specifiers of these systems and equipment must be aware of the intended use of the products, of the compatibility with other systems, and of the intended goal or objective the overall system is striving for.

Currently no standard can be considered a commonality conduit for system communication. In other words, no one system or communications protocol is the de facto standard. This "open architecture" term (a concept describing the capability of communicating universally with all system components on the market) has been a catchphrase picked up by the security industry based on a concept that has been effective in the building automation industry.

Although simple open or closed circuit devices can provide inputs to any and all systems, the concept of data communications is still a proprietary function. Security companies have developed their systems with proprietary concepts to protect their investments. Manufacturers do not build field panels that will communicate with their competitors and vice versa. Although there have been companies that built systems that could communicate with some third-party field panels, these are becoming few and far between. Some manufacturers of card readers sell their product to anyone, and these communicate via an industry standard output (defined as Wiegand) for use by all of those systems that desire to use their devices.

Many access control system manufacturers work with selected video surveillance systems to enhance their marketability. They share communication codes and work to provide as much feature compatibility as possible. When one system is required to communicate data to another, one of the systems must share its code and allow the other to write to it.

The effective security technology design for a door requires more than just an access control card reader. The typical configuration of security technology at a door can consist of the card reader to provide authorization screening into the protected space, the electronic door hardware, a door magnetic contact switch to monitor the position of the door (making sure that the door is closed after a legal opening), and a request-to-exit motion detector or other device to use to leave the protected space (Figure 1.6.6).

In large institutions and organizations, such as universities and multisite organizations, the implementation of security sys-

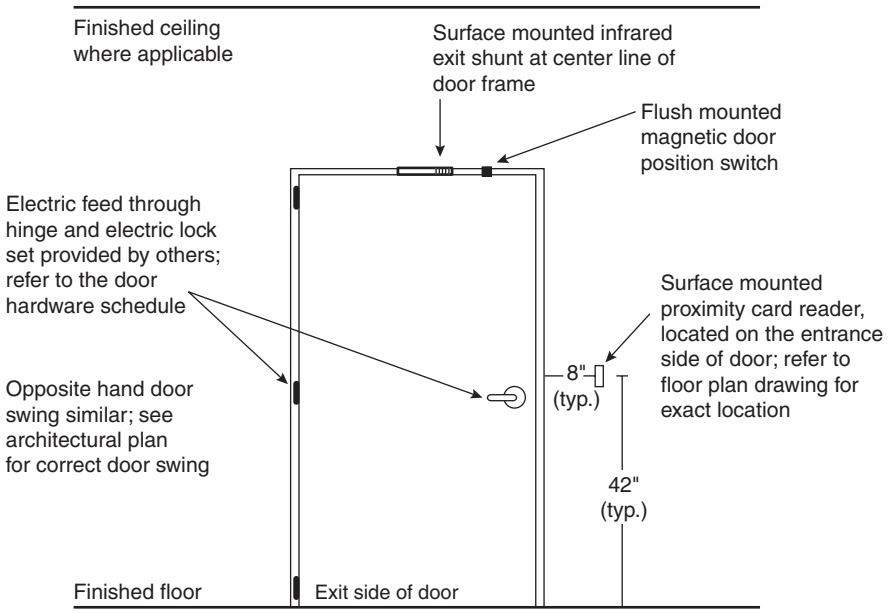

FIGURE 1.6.6 Single-Door Security Device Details

tems can be decentralized leading to multiple security systems and concepts. When possible, develop, publish, and support a security section to the organization's building standards document to codify the security standards applicable by category of facility.

Access Control

The backbone of most security systems is the access control system, which consists of a central processor or server with a graphical user interface (GUI) on one end and a microprocessor-based field panel controlling the card or identity readers at doors or portals. These systems have evolved into being able to process thousands of simultaneous access requests and allowing authorized people access through a door in under a second. The systems have the capability to matrix access authority levels and time/day zones to the level that each cardholder can have different access authority at every door dependent on the time/day and location of the reader.

The field panels provide most of the processing. These field-installed multiplex panels serve to multiplex data generated by multiple card readers and/or intrusion alarm devices for transmission to the file server and energize or de-energize power circuits to electric door locking devices.

The process that occurs can be described as follows. When entering an access-controlled door, the reader is designed such that on presentation of an access card, unique card identification data are transmitted to an associated multiplex field panel where the cardholder attributes contained within the cardholder database are analyzed, and access is allowed or denied accordingly. On authorization of access, the multiplex field panel temporarily unlocks the associated locking mechanism and shunts the associated door position switch or switches.

Identification

Cardholder Database. Most access control systems incorporate a database of information on the cardholder. The cardholder database includes some identification information, information about the unique card issued to that person, and usually a digitalized photo that is captured in the enrollment process. The photo can be printed onto the card for manual identity verification.

Access control has been performed by reader devices that would read the information on a card and base the go/no-go decision on the information about the cardholder stored in the database. The assumption has always been that possession of a card is restricted to the authorized user. Card readers have utilized technologies such as magnetic stripes, barium ferrite, Wiegand wires, and proximity (i.e., technology that utilizes radio frequency). Some of these technologies are no longer commonly used, such as barium ferrite and Wiegand wire; but all are still available.

Smart Cards. There has been some talk about the use of "smart cards" in security systems. These smart cards are small storage chips on a card, yet they are not processors. The cards may have a future in the security world in carrying the biometric characteristics for use by these systems. Smart cards have been used in the debit card market. These systems are capable of rewriting data onto the chip and thus lend themselves to systems that alter the information based on usage.

Biometric Devices. Recently a huge groundswell of interest has developed in biometric devices, which compare a unique physical characteristic, such as a fingerprint, hand geometry, iris, retina, facial features, or voice pattern, to a known characteristic in the database. These characteristics are presumed

to be unique to the individual, and any alteration or duplication attempt should be both difficult to reproduce as well as detectable.

The concept that is driving the biometric growth is the need to identify positively the individual attempting to gain access into an area. Security directors are no longer satisfied with the "possession of an authorized card" concept as the only means to allow access into secure areas. In the strictest of security environments, the access and identity verification process involves multiple tests: a valid card (what I have), a password or PIN code (what I know), and a biometric characteristic (what I am). This is commonly referred to as multifactorial identification.

The disadvantage of biometric readers is that until recently they have been stand-alone devices. Such a device requires that a stored template be called up for comparison to the presented characteristic. The device determines whether there is a match between the two of them, a decision that is not made by the access control system. The biometric device manufacturers have been independently developing these devices and have just recently started working with the access control system manufacturers to incorporate the biometric characteristics into the access control system databases.

Contrary to popular belief, the biometric readers are not tied into any national databases for identification purposes. Work is being done to develop biometric devices that will compare a presented biometric characteristic and identify that person, but as of now the only devices that can do that are limited to small databases (200 templates). The major obstacle is the processing speed; the comparison needs to be executed in a reasonable time frame, which typically is defined as under 2 seconds.

Intrusion Detection System (IDS)

Intrusion detection systems (IDS) are a fairly mature concept with few new developments. The systems have been designed to utilize field-installed devices, such as magnetic door position switches (door contacts), motion detectors, such as microwave or passive infrared (PIR), and other event initiating devices; process these inputs; and transmit the appropriate signal to a graphical user interface (GUI), central station, or other annunciating device.

Many access control systems incorporate the application software to handle intrusion detection processing as a subroutine. This capability allows the flexibility to manage these inputs and relate them to other inputs, information, or actions and create more intelligent responses. Intrusion detection systems are more frequently being integrated with video systems to provide visual information and confirmation of the event that occurred in the area of the initiating device.

Emergency and Duress Notification

Emergency and duress notification provide the ability to place security devices, known as duress or panic alarms, in critical areas such as cashier areas, emergency departments, psychiatric units, parking areas, executive suites, and so on, to notify the security department covertly of a security incident.

Video Surveillance

The major innovations in the video world have resulted from the digitalization of video signals, video recording capabilities, and the storage of these data in arrays of hard drive storage vehicles. Digital technology has been a part of video camera devices for some time, and the benefits of this technology are evident. One benefit of digital video cameras has been the reduction in the size of the actual video camera device and another is improved functionality. Color video cameras now are capable of operation at low light levels.

Digital video signals can be manipulated at the pixel level and hence the advent of digital video motion detection. The concept involves the ability to monitor the digital image and look for a pixel change in a designated area. If there is a change in signal, ostensibly due to movement, an output or alarm condition can be transmitted. This is a similar technology that can be applied in the previously mentioned video detection technology.

The video signals can be stored on digital video recorders (DVRs) and retrieved and viewed on PC graphical user interfaces (GUIs) as compared to the analog method of recording video signals onto VCRs, the digital methodology allows better management and manipulation of data (such as date and time) to be associated with the video image. This allows users to retrieve the desired video image based on the date and time stamp data. We no longer have to view the entire tape to find the recorded activity. The innovative systems can also provide for retrieval based on activity recorded with other parameters. The processing of video signals has seen much advancement due to digitalization.

A major new advantage of the digital video systems is the development of what some people call video analytics capabilities of these devices. Fairly sophisticated new capabilities are being designed into these systems, including the ability to discern motion in a particular direction, to detect packages left stationary for a prescribed length of time, to detect when the video image has been blocked, and to count the number of people or vehicles in the video scene. Some systems can read license plates on vehicles. With these capabilities, video systems can perform more than just security functions for the owner.

Communications

Incorporating emergency communication devices in parking garages and on university campuses is common. One of the newest critical security technology requirements is being driven by the DOD for facilities that house its staff. The DOD has developed a requirement for mass notification systems (MNS). This concept (at the request of the U.S. Air Force) has also been codified into the 2007 edition of *NFPA 72®*, *National Fire Alarm Code®*. A broad description of MNS is that it is both a communications and an emergency management tool that provides real-time instructions and information to building occupants or nearby personnel during an emergency event or situation. The unified facilities criteria (UFC), which superseded the Interim DOD Antiterrorism/Force Protection Construction Standards for Buildings, was issued on July 31, 2002. The UFC requires that antiterrorism features be included in all force protection

plans and that mass notification systems be installed in all DOD facilities worldwide by 2007. Commercial applications are beginning to appear as well. A mass notification system (MNS) is defined in the 2007 edition of *NFPA 72* as "a system used to provide information and instructions to people, in a building, area site, or other space."

Weapons/Contraband Screening

Depending on the results of the SVA, there may be a need for package screening and weapons detection devices at the entrance to a facility. Significant research and development is being done in this area. The devices are cumbersome, unattractive, expensive, and not very specific in terms of information they provide. Nevertheless, a good design should incorporate the physical space for these systems should the threats in the SVA warrant them. The number of devices should be coordinated with the expected throughput at the entrance. As detection devices, these devices cannot resolve problems without the intervention of security staff.

Asset Tracking

Some of the more sophisticated access control systems incorporate asset tracking or management subsystems. These systems utilize radio frequency or infrared technology-based transponders, which are typically attached to the asset, such as expensive merchandise or a laptop. This transponder is an active device that sends signals to a hardwired receiver, typically mounted in the ceiling. The reception of a unique code, transmitted by a transponder, is analyzed and can result in an alarm depending on the location of the receiver.

The newer asset tracking systems are active systems, in that they are constantly polling for known devices. When the transponder signal is lost, that event results in an alarm condition. The older retail-type asset tracking systems relied on a passive design, in which the transponder was required to send a signal to a receiver that was located at an illegal point and thus the signal would be interpreted as an alarm condition once received. If no signal were received, it was assumed the asset was in a legal location.

Infant Monitoring

It is becoming standard and customary in a hospital to have a computerized security system design to prevent infant/mother mismatching and deter abduction of newborn infants from protected nurseries and hospitals.

OPERATIONAL SECURITY ELEMENTS

Operational security refers to security practices and procedures as well as the security awareness of personnel (employees, faculty, administration, staff, residents, students, etc.). This component of the security program is the most effective and least expensive to pursue, but it is also the most difficult to quantify and implement. It may involve changing long-standing habits as well as changing the mind-set of the personnel involved. The security awareness of the general population in the facility can be just as important as the presence of a professional security force. The security for a facility can be supported by as few as a part-time security staff person with other responsibilities to as many as hundreds of dedicated security professionals. The appropriate application and quantity depends on the findings of the SVA and the services expected from them. The previously mentioned architectural and technology elements can provide the support for this operational element.

Security Plan/Policies

An effective asset protection program should include the development and implementation of a documented security plan and needs to have the cooperation and support of top management. This facility security plan needs to address the protection of all of an organization's defined critical assets, which can include people, property, information, and products. A security plan is a document that usually contains an organization's security-related measures and procedures, as well as information required to implement them. The objective of a security plan is to ensure that security measures and personnel respond in an integrated and effective way to mitigate the effects of an adversarial act in a manner that is appropriate for that particular organization or facility.

One of the security program elements that is often overlooked is physical key control. It is recommended that a designated person be responsible for centrally cataloging the keys in a database. Steps to establish key control include the following:

- Develop key control records.
- Designate a representative or representatives by name to be responsible for maintaining those records.
- Train these individuals on key control procedures and responsibilities.
- Centralize key duplication capabilities.
- Institute a method by which key controllers can request new keys.
- Institute limitations on who has the authority to request key duplication.
- Develop an audit schedule to monitor the system and compliance.

Traditional Security Staff

Security Staff Duties. In making a decision about whether to utilize a security force of any size, consider the following duties that security services can properly perform:

Entrance control. Operate and enforce a system of access control, including inspection of identification and packages.

Roving patrol. Patrol routes or designated areas, such as perimeters, buildings, vaults, and public areas.

Traffic control. Direct traffic (vehicular and pedestrian), conduct vehicle inspections, control parking, check permits, and issue citations.

Key control. Receive, issue, and account for certain keys to the building and its internal areas.

Security and fire systems. Monitor, operate, and respond to intrusion and fire alarm systems or protective devices. Do not assume it is a false or nuisance alarm.

Utility systems. Monitor, record data, or perform minor operations for building utility systems.

Lost and found. Receive, create a receipt for, and store found items.

Reports and records. Prepare reports on accidents, fires, thefts, and other building incidents.

Response to emergencies. In case of any emergency, such as fire, bomb threat, assault, or civil disturbance, respond, summon assistance, administer first aid, and assist public safety personnel.

Law and order. Maintain law and order within the area of assignment.

Hazardous conditions. Report potentially hazardous conditions and items in need of repair.

Other services. Handle service requests such as escorts and support of the business operations.

Proprietary Versus Contracted Security Services. The decision to hire employees versus contracting an agency depends on the organization's goals. Some basic elements should be considered when comparing the two services, as shown in Table 1.6.2.

Generally, organizations have chosen contracted security services over proprietary security services for economic reasons. This is particularly true for the nonspecialized security organizations, where tasks are not as complex as those found in health care, college campuses, museums, and so on. When the responsibilities and tasks are more specialized, a higher-quality security officer is required. This situation is particularly true in institutions or organizations that are standards driven, such as health care, which must adhere to the Joint Commission (JC) Environment of Care Standards. When those conditions exist, there is greater similarity in wages, making the decision less economical and more centered on quality of personnel and service to the organization.

Security personnel should be armed only when compelling reasons warrant this. Some security personnel are armed for a deterrent effect—that is, to prevent crime or other unauthorized activity—responsible officials must weigh that advantage against such disadvantages as the danger to innocent personnel if a firearm is used by a security person; the possibility of an accidental discharge; and the possibility, no matter how remote, of irrational behavior on the part of security personnel.

Most states require minimum training for nonproprietary security officers. Some states require training regardless of this statute. It is recommended that beyond the initial required training, continual education and specific topic training be conducted for security officers.

Nontraditional Staff

An often forgotten resource of security support is the nontraditional security staff. Utilizing receptionists and other observers

TABLE 1.6.2 Comparison of Proprietary Security Department Versus Contract Service Provider

Proprietary Security Department	*Contract Service Provider*
Higher quality, due to quality of institutional selection process and required training Higher rates for proprietary due to shift differential for second and third shift staff	Generally less expensive (especially true for the initial contract, as it is generally a competitive bidding process) Union dues, additional services, training, equipment, uniforms, etc. can mean additions to billing rate
More control Required adherence to institutional policies and procedures Direct supervision of proprietary supervisor	Flexibility in scheduling of replacements (i.e., sick time, vacations, terminations, etc.) Ability to provide special assignment personnel, usually not at premium rate
More loyalty as an employee of the institution, particularly in a largely proprietary institution	Impartiality when handling security incidents No perceived allegiance to employing institution
Perception among staff of higher prestige as an employee of a proprietary department/institution	Some loss of supervision of contract employee by institution (e.g., co-employment responsibilities)
Better institutional control over wages and benefits	Employed by "two masters" concept; similar to "co-employment" from the employee perspective Employees may have difficulty understanding who their boss is Many contract agencies are union employees
Trends indicate that attrition rate for proprietary employees is lower than for contracted services	May be some mitigation of negligent acts' liability on behalf of institution holding the contract Liability falls with contractor, depending on contract language, type of incident, etc.

provides a force multiplication concept. Simply put, doing so adds more resources to the security program, although these individuals may not constitute a dedicated security resource. They need to be trained to accept the responsibility for the security for their work areas as if they were at home. Security should not be a barrier; rather it should be appropriate to maintain accessibility and service.

Mandatory training should be provided for all employees on the goals of the security system and their role in it. Training should also become a mandatory part of employee in-processing for new hires. To meet the recommended requirement of annual updates, reinforcement training modules scheduled during annual milestones, such as employee performance reviews, benefits reviews, and so on, should be developed. To meet the recommended requirement, at least monthly security reminders should be included in the program, and articles (in industry publications, newsletters, pay stubs, etc.), email reminders, bulletin board entries, video vignettes, web-based quizzes, and so on should be developed.

Screening Employees

A policy to perform a criminal history background check on all new employees should be developed and implemented. It is in the best interest of the organization to ensure its employees have a demonstrated history of adhering to the law. Such policies have become industry norms in the corporate world for several reasons, such as security, liability, and risk management issues. Criteria for communicating, storing, and acting on the information should be developed. In-depth background checks (i.e., education verification, more comprehensive checks) on personnel in sensitive positions, such as managers, employees who handle contracts, employees who handle money, security personnel, should be conducted. The same concept should be required for all long-term contractors through the contracts with these vendors.

SUMMARY

A comprehensive security program incorporates architectural, technical, and operational security elements into an effective security plan. The appropriate application of each of the elements should be driven by the results of a well executed security vulnerability assessment (SVA). The security risks and vulnerabilities are dynamic and the SVA should be updated periodically. Security technology improvements and developments happen frequently, so consulting your security professional is recommended.

Mitigation Strategies

Key Terms

blast load, blast protection, continuity of business (COB), deliberate event, disproportionate damage, extreme event, extreme hazard event, mitigation, natural hazard, performance-based analysis, performance-based design, risk characterization, threat assessment

For centuries, the impact of significant fire and natural hazard events has driven changes to building design practice, technology, operations, and regulation. The Fire of London in 1666 was a driver for early building and zoning requirements, as well as fire-resistive construction. Conflagrations in U.S. cities in the late nineteenth and early twentieth centuries, as well as large industrial fire losses, led to the development of fire sprinklers, the beginnings of model fire and building codes, and the widespread construction of "fireproof" buildings.[1] Following the 1906 earthquake in San Francisco and the 1933 Long Beach earthquake, requirements for earthquake resistance began to be included in building codes.[2] Large life-loss events such as the 1911 Triangle Shirtwaist Company fire and the 1942 Cocoanut Grove nightclub fire were early drivers for emergency egress requirements.[3]

With each event, building and fire regulation, design practice, and building technology were reviewed, and if deemed appropriate, changes were made in an attempt to minimize the potential for repeat consequences of a similar nature. In determining what, if anything, needed to change, due consideration was given to the events, the response of the buildings, available technology, and societal risk tolerance. Over time, the need for significant regulatory changes lessened, and by the end of the twentieth century, the state of building and fire regulation, design practice, and available technology had combined to significantly reduce the loss of life from fire and natural hazard events as compared with the previous century. In fact, great effort in the latter part of the twentieth century was focused on finding ways to provide more flexibility in building design without compromising the safety record that had been achieved, much of which came under the general heading of risk-informed performance-based regulation and design.[4–8]

As the twenty-first century begins, attention is again focused on the impact of significant, or extreme hazard events. The consequences of the attacks on the World Trade Center Towers in 2001, the Station nightclub fire in 2003, and Hurricane Katrina in 2005 have been substantial enough to create considerable discussion as to whether or how building design may need to change to achieve more resilience against extreme events. The question of whether or not building regulation, design practice, or technology needs to change as a result of these events is beyond the scope of this chapter, as are emergency preparedness criteria, which are also crucial. However, there are a number of measures in regulation or in building-specific designs that can increase a building's resilience to extreme events.

Regarding mitigation of extreme events, some of the themes that recur throughout this chapter include redundancy, reliability, and tenability. In order to be highly reliable, most building systems require a degree of either redundancy or diversity of operation. The fundamental reason for having

Brian J. Meacham, Ph.D., P.E., FSFPE, is a member of the fire protection engineering faculty at Worcester Polytechnic Institute. Prior to joining WPI, Brian led the global risk consulting business for Arup, participating in several multi-hazard threat, vulnerability, and risk assessments. He is coeditor of NFPA's *Extreme Event Mitigation in Buildings: Analysis and Design* and coauthor of *Egress Design Solutions: A Guide to Evacuation and Crowd Management.*

Carl Galioto, FAIA, is the technical partner with the New York office of Skidmore, Owings & Merrill, LLP. He has been responsible for SOM's technical efforts for projects such as Tower One (Freedom Tower) at the World Trade Center, Seven WTC, Moynihan Station in New York, and the Zuckermann Research Building at Memorial Sloan Kettering Cancer Center. He was a member of the managing committee of the New York City Model Program that authored a new building code for New York.

two exits from a floor, even if one will suffice based on calculation, is to ensure a measure of redundancy and subsequent reliability. The need for structural redundancy has long been understood and the cost of such redundancy accepted, as the consequences of failure could be disastrous. Many owner-occupied buildings include redundant systems due to the potential cost of system failure and its consequent business interruption. For such facilities and features, systems are described as being "code plus" or optimum design.

The aim of this chapter is to outline a variety of measures available to help protect buildings and their occupants against the impacts of extreme hazard events. The chapter is structured so as to broadly outline extreme events, their assessment, issues of concern, protection objectives, and how the protection objectives can be met. A much more detailed discussion can be found in *Extreme Event Mitigation in Buildings: Analysis and Design*.[8]

HAZARD EVENTS

Hazard events are incidents that result in the possibility of physical harm or damage to buildings and their occupants. Section 1, Chapter 1, "Challenges to Safety in the Built Environment," provides an overview of losses that have occurred as a result of such events. In general, hazard events may be categorized as natural disasters, such as intense earthquakes, tsunamis, hurricanes, floods, and tornadoes, as well as human-caused or technological disasters, such as fires, explosions, and terrorist attacks. Extreme hazard events are incidents that make demands on a building, its systems, and its occupants that go beyond the usual design parameters imposed by codes, standards, and good professional practice.[9]

Natural Hazard Events*

Natural hazards are caused by geology, weather, and seismicity and are exacerbated by human behavior. Earthquakes, floods, and hurricanes are all examples of these types of events. Because many hazards are interrelated, they can occur as both isolated and combined events. Some of these types of extreme events are localized in nature, whereas others are regional. Natural hazards can impact structures and infrastructure, producing casualties and large financial losses.

*Much of this section is excerpted with permission from Thompson, A. C. T., Kammerer, A., Katzman, G., and Whittaker, A. S., "Natural Hazards," *Extreme Event Mitigation in Buildings: Analysis and Design,* B. J. Meacham and M. Johann (Eds.), National Fire Protection Asssociation, Quincy, MA, 2006.

Earthquakes. The earth's crust is composed of tectonic plates that move relative to one another, typically at tens of millimeters per year, accumulating strain energy. An earthquake occurs when the strength of the rock forming the crust is exceeded by the accumulated strain energy, which causes the rock to break. When the rock ruptures, seismic waves are propagated in all directions. In addition to the direct fault rupture and strong shaking that are typically associated with seismic events, other devastating secondary events are frequently triggered. Earthquakes can cause landslides, liquefactions, tsunamis, fires, and dam failures. Figure 1.7.1 illustrates a consequence of liquefaction.

Earthquakes are more prevalent at plate boundaries, although very large intraplate earthquakes also have occurred. Although earthquakes typically cause less annual economic loss than other hazards such as floods,[10] they have the potential to cause unanticipated regional devastation in just minutes, because there is currently no proven method for their short-term prediction. Earthquakes can affect all types of structures and infrastructures, including housing and commercial buildings, transportation elements (railroads, highways, tunnels, and bridges), utilities (water, gas, and sewer lines), industrial facilities, power plants, and dams. Globally, the risk of death and injuries from an earthquake varies greatly depending on local construction practices and the availability of emergency services. In addition to the short-term impacts, social, physical, and economic impacts result in long-term economic and social consequences.

Floods. Flooding produces extensive and costly damage to property. Floods are capable of damaging and undermining buildings and infrastructure, generating large-scale erosion, and causing loss of life and injury. Loss of life results principally from the sudden destruction of structures, washout of access routes, and motorists attempting to cross swollen streams. Flooding can be caused by a variety of events, particularly large weather systems that produce sustained and sometimes intense

FIGURE 1.7.1 Foundation Failure Due to Liquefaction in the 1999 Izmit, Turkey, Earthquake (Source: Photo by J. Stewart and J. Bray; courtesy of the Pacific Earthquake Engineering Research Center, University of California, Berkeley)

rainfall or storm surges. On a smaller scale, floods can be caused by local effects, such as intense thunderstorms and rapid snow melt. Seismically based hazards, such as tsunamis and dam failures, can also create flood conditions on rare occasions.

Riverine Flooding. River-based flooding is the most common form of flooding[11] and can occur in a wide variety of landscape types. Narrow channels may experience fast-moving, deep flooding, whereas flat areas may accumulate water and remain inundated with shallow water over long periods of time. In some cases, local heavy precipitation can produce flooding in areas other than known floodplains or drainage channels. Flash floods occur rapidly and without warning and are capable of significant damage due to high water velocities and large amounts of floating debris. Flash flooding is principally affected by the intensity and duration of rainfall and the topography of the affected area. Intense localized precipitation, dam brakes, ice-jam floods, and alluvial-fan floods can cause flash-flood conditions.

Coastal Flooding. In contrast to riverine flooding, storm surge typically occurs at a coastline due to large storms, such as tropical cyclones and severe winter storms. Storm-surge levels are strongly influenced by four factors: high wind speeds that drive large amounts of water onto the coastline; low barometric pressure that causes the water surface to rise; timing of landfall in relation to peak tides; and coastal shoreline configurations.[12] In addition to the storm-surge level, resulting damage is also influenced by the velocity of the storm center (with slow-moving storms doing the most damage); the nature of the coastal geology, vegetation, and slope; previous storm damage; and human activity. Storm surge can result in loss of life and in significant damage to structures, infrastructure, and the coastline.

Tsunamis. Tsunamis are large sea waves that usually are generated by underwater earthquakes that result in a rapid drop or uplift of the ocean floor. Tsunamis can also result from volcanic activity, submarine landslides, and, on very rare occasions, from a meteor or other space debris hitting the ocean. Tsunami waves can be more destructive than wind-developed surface waves, because they often have a pressure front that reaches deep into the water column. Most tsunami waves resulting from large seismic events have high speeds, long wavelengths, and low amplitudes as they travel across the ocean, making them difficult to detect. As a tsunami reaches coastal waters, the waves slow and pile up where the ocean bottom becomes shallower, causing the wave height to increase greatly. The damaging effect of the wave is increased significantly as waterborne debris is collected and forced to move with the water mass, battering objects in the path. Although damage from tsunami waves is often limited to the immediate vicinity of the affected coastline, large tsunami waves have damaged and flooded areas up to a mile inland.[13] Tsunami waves can travel very long distances with little energy dissipation. As a result, tsunamis can have significant impact on regions far from the source of the tsunami, as was the case with the 2004 Indian Ocean tsunami (See Figure 1.7.2).

Tropical Cyclones. Hurricanes, tropical storms, and typhoons are all classifications of tropical cyclone. Hurricanes and typhoons describe the same phenomena, with the appropriate terminology depending on the location of the event. Tropical

FIGURE 1.7.2 Damage from the 2004 Indian Ocean Tsunami (Source: Photo by J. Borrero; courtesy of the University of Southern California Tsunami Research Center)

cyclones affect coastal areas worldwide, often with devastating effect. Tropical cyclones are regions of atmospheric low pressure that originate over warm tropical waters and are characterized by winds circulating around an eye. Generally, the number of tropical cyclones varies seasonally and peaks as sea and surface temperatures peak. Tropical cyclones are commonly associated with severe winds, storm-surge flooding, high waves, coastal erosion, extreme rainfall, thunderstorms, lightning, and tornadoes. Storm surge and extreme rainfall cause coastal, riverine, and flash flooding; contamination of land, groundwater, and water supplies; agricultural, structural, and utility damage; coastal erosion and landslides; and loss of life due to drowning. High winds also impact utilities and transportation, cause fatalities due to downbursts and tornadoes, create large volumes of debris, and result in agricultural losses and building damage.

Tornadoes. A tornado is a rapidly rotating funnel of air that is typically spawned by a severe thunderstorm. Tornadoes are almost always accompanied by heavy precipitation and may be associated with large hail and lightning in some cases. Large fires may also produce local (usually small) tornadoes. The central United States is often particularly susceptible to tornadoes and is known as Tornado Alley. Although most tornadoes remain aloft, they are capable of great destruction when they touch the ground. Tornadoes can lift and move very large objects, including homes and cars, and can generate a tremendous amount of debris, which becomes airborne, causing additional damage. Tornadoes have also been known to siphon large volumes of water from bodies of water. The path of a single tornado is generally very localized, though it can range up to dozens of kilometers.

Wildland Fires. Wildland fires may be caused by lightning as well as by intentional or unintentional ignition. In densely populated areas, wildland fires can have significant impacts on the built environment, such as the Oakland fires of October 1991, which resulted in more than $1.5 billion in damage,[14] and the fires in New Mexico in 2000, which ultimately consumed part of the Los Alamos National Laboratory.[15,16]

Extreme Natural Hazard Events. Protection against natural hazard events is included in model building codes in North America and in most countries worldwide. This includes provisions for earthquakes, flooding, high wind, snow loads, and other natural hazards as appropriate to geology and climate. However, the protection measures included within the building codes are not aimed at providing the maximum level of protection possible for the most significant natural hazards that are possible. Rather, the general approach is that prescriptive code requirements provide for a level of building performance and occupant safety that reflect a level of performance for the most frequent and likely events, with some requirements for higher levels of performance against larger magnitude events in some areas (e.g., seismic protection in California, hurricane protection in Florida, or snow loads in Minnesota) for specific buildings with high social or public importance (such as hospitals, schools, and shelters).

Extreme natural hazard events can be considered those natural events that exceed the magnitudes (deterministically expressed) typically considered by building codes, or are considered very rare (probabilistically expressed) by the codes, which means that not all buildings are required to withstand the associated loads (e.g., not all buildings are designed to remain fully operational following a 2500 year seismic event). If a building or facility serves a critical economic, social, or public service function, houses very large numbers of people, or has other attributes that may result in the desire for continued operation during and beyond the occurrence of extreme natural hazard events, protection measures beyond those required by the code may be deemed necessary.

Fire

Although fire can impact a building as an external exposure, such as from a wildland fire or other external fire hazard, building fires are typically internal hazard events. As in the case of protection against natural hazard events, building codes include numerous provisions against the development and spread of fire, which have been added to the codes over time. Sometimes, however, fires can still become extreme events. This can happen when a fire overwhelms the egress system or fire protection systems, or because these systems do not exist or have been deliberately compromised, inadequately designed, or simply failed. Two examples of fires that became extreme events are The Station nightclub fire and the Windsor Building fire.

The Station Nightclub Fire. On February 23, 2003, a large crowd was gathered at The Station nightclub in West Warwick, Rhode Island (USA), where a live band was scheduled to perform. The band took the stage and began with a flash of pyrotechnics. The pyrotechnics ignited sound dampening foam material, which was installed on portions of the interior walls and ceilings of the unsprinklered club. The foam was highly combustible, and within minutes the entire club was engulfed in flames, overtaking the crowd before everyone could escape. This disastrous incident ultimately claimed the lives of 100 building occupants.

Windsor Building Fire. The Windsor Building, located in the heart of the commercial and banking center in Madrid, Spain, was one of the tallest in the city. At about 2300 hours on the evening of Saturday, February 12, 2005, a fire broke out on the 21st floor of the unsprinklered building. Although the fire brigade was reportedly on site by about 2330, the fire spread rapidly to most of the floors above the 21st, and by 0100 hours, the fire brigade had to retreat.[17] Soon afterwards, large pieces of the facade started falling off, taking the perimeter bay of the reinforced concrete slab with it in places. Eventually, the fire spread downwards as well, ultimately leading to the collapse of virtually all the slab edge bay above the 17th floor, as well as one internal bay on the north side. Although no lives were lost, the magnitude of the fire necessitated the building's demolition.

Deliberate Events

Events that are consciously instigated against buildings and their occupants are referred to as deliberate events. In the current en-

vironment, acts of terrorism, such as the 2001 attacks on the World Trade Center and the Pentagon come readily to mind. A variety of components, materials, and common platforms can be combined to create both the weapon and the delivery system.

Explosives. Explosives can be easily and cheaply obtained or fabricated and deployed. As such, their use can result in spectacular and fatal consequences, making attacks using explosives a preferred tactic of terrorists.[9,18] This was tragically demonstrated by the attacks using vehicle-delivered explosives on the World Trade Center in 1993 and the Murrah Federal Building (Figure 1.7.3) in 1995.

Like natural hazard or fire events, an explosion can have a significant impact on buildings and their occupants, such as the following:

- Blasts occurring near primary structural members could lead to catastrophic collapse, proportionate to the load and building design and construction.
- Even when key structural members are protected or designed to sustain blast effects, casualties are still likely from overpressures and from flying debris—especially glass.
- Blasts which occur within a building are magnified by reflected and reinforced pressures, which means that smaller explosive charges, such as those carried in a satchel or backpack, can be lethal and cause massive damage.

Chemical, Biological, Radiological, and Nuclear Events. The potential for mass casualties from chemical, biological, radiological, or nuclear (CBRN) attack have been an area of concern since the anthrax episodes in 2001. Although CBRN agents can be delivered to a population in a number of different ways, such as by food, water, and "dirty" bombs, airborne chemical and biological agents are often given the most attention.

The ease or difficulty with which terrorists could cause mass casualties with an improvised chemical or biological weapon or device depends on the chemical or biological agent selected. For example, a terrorist does not need sophisticated knowledge or dissemination methods to use toxic industrial chemicals, but will likely face serious technical and operational challenges when working with other chemicals or with biological agents.

Chemical agents of concern fall into five broad categories: choking agents, blood agents, blister agents, nerve agents and nonlethal (riot-control) agents.[19] Choking or pulmonary agents include chlorine (CL) and phosgene (CG). In sufficient concentrations, their corrosive effect on the respiratory system results in pulmonary edema, filling the lungs with fluid and choking the victim. Blood agents, or cyanides, are absorbed into the body primarily by breathing, preventing the normal utilization of oxygen by the cells and causing rapid damage to body tissues. Agents such as hydrogen cyanide (AC) and cyanogen chloride (CK) are highly volatile and dissipate rapidly in the gaseous state. Blister agents, or vesicants, are used primarily to cause medical casualties. Blister agents affect the eyes and lungs and blister the skin. Sulphur mustard (HD), nitrogen mustard (HN-2, HN-3), and Lewisite (L, HL) are examples of blister agents. Nerve agents are perhaps the most feared of all chemical weapons. Essentially, nerve agents affect the transmission of nerve impulses. Most of the agents in this category were discovered shortly before or during World War II and are related chemically to organophosphorous insecticides. Similar in action to many pesticides, nerve agents are lethal in much lower quantities than

FIGURE 1.7.3 Damage to the North and East Sides of the Murrah Federal Building (Source: FEMA News Photo)

the classic agents in the choking, blood, and blister categories. Nerve gases are effective when inhaled or when absorbed by the skin, or both, although there are differences in effectiveness. The rapid action of nerve agents calls for immediate treatment. Nonlethal agents, such as tear gas and other riot-control agents, are generally not considered chemical weapons because they are not life threatening in all but the highest concentrations. Examples of these agents include orthochlorobenzylidene malononitrile (CS), chloroacetophenone (CN), chloropicrin (PS), and bromobenzyl cyanide (BBC).

The principal biological agents of concern can be classified into three broad groups: bacteria, viruses, and toxins.[19] Bacteria are small free-living organisms, most of which may be grown on solid or liquid culture media. They reproduce by simple division. The diseases they produce often respond to specific therapy with antibiotics. Possible agents include anthrax, brucellosis, and plague. Viruses are organisms that lack their own cell membranes and so require other living cells in which to replicate. They are therefore intimately dependent upon the cells of the host that they infect. They produce diseases that generally do not respond to antibiotics. However, they may be responsive to antiviral compounds, although the few antiviral compounds that are available are of limited use. Possible viral agents include smallpox and the various hemorrhagic fever viruses. Toxins are poisonous substances produced by and derived from living plants, animals, or microorganisms. Some toxins may also be produced or altered by chemical means. Toxins may be countered by specific antisera and selected pharmacologic agents. Possible agents include botulinum and ricin toxins.

Radiological and nuclear materials can come from a variety of sources, including from approved medical materials and treatments, from fuel or waste from power generation or weapons manufacturing, or directly from nuclear weapons. Perhaps of most concern is the use of radiological and nuclear material in a "dirty bomb," which may have sufficient quantities of radiological and nuclear waste material to pose a significant hazard within a building or a larger area within a community.

ESTABLISHING PROTECTION AND PERFORMANCE OBJECTIVES

Several factors come into play in determining whether a building is at risk for an extreme event. For natural hazard events, the geographic location of the building is a primary concern. In the case of technological events, such as fire or accidental explosion, building design, construction, contents, use, operations, and maintenance are significant factors. With respect to terrorist attack, symbolic importance, service or mission criticality, and the potential magnitude of consequences from a successful attack can be critical factors. Even if some level of extreme event risk exists, however, building owners, developers, and design teams face a difficult task in designing buildings that provide an appropriate level of protection while retaining features that make them desirable spaces for working and living, including comfort, openness, and aesthetics, and meeting other important objectives, such as sustainability, usability, energy efficiency, and cost effectiveness.

This is not a new challenge, however, and even prior to the extreme events of recent years, efforts were already under way to help designers and engineers balance openness, aesthetics, and other design goals with safety and security.[20] In addition, over the past several years, there has been a slow shift from prescriptive-based to performance-based regulations and design (see for example, NFPA *101®*, *Life Safety Code®*; *NFPA 5000®*, *Building Construction and Safety Code®*; and the *ICC Performance Code for Buildings and Facilities*).[21]

Taken together, the combination of risk assessment and performance-based regulation and design provides a powerful approach for addressing extreme event analysis and mitigation in buildings.[22] The resulting risk-informed performance-based approach brings together concepts of risk characterization, building performance objectives, and mitigation strategy assessment and selection into a process that helps inform the overall design process.

Risk Characterization*

Risk characterization is a process that brings together analytical data such as statistics, risk analysis, historical data, computational modeling, test results, and cost data with stakeholder concerns in a way that allows agreement to be reached through deliberation on levels of tolerable risk.[23] It is a decision-driven activity, directed toward informing choices and solving problems.

A fundamental premise of risk characterization is that to adequately address a risk problem, one must develop a broad understanding of relevant losses, harms, or consequences to interested or affected parties. For extreme event mitigation in buildings, the stakeholders can include the government, facility owners/operators, occupants, neighbors, emergency officials, insurers, and the public. If a key perspective is omitted, the risk problem may be formulated improperly and the ensuing analysis may omit key parameters, resulting in further costs at a later date.

Bringing the stakeholders together, or at least anticipating the diverse perspectives of the stakeholders, is critical to the success of risk characterization. A singularly-focused view of risk and its tolerability may inadvertently miss important considerations such as technical, social, economic, value, or perceptual impacts. In addition, if some stakeholder views are not represented in the process, certain stakeholder groups may disagree with various parts of the process, from the problem statement to the risk measure selected. It is not necessary, however, for every stakeholder to be fully accommodated in the risk characterization process, despite the difficulties caused by a diversity of views. Involving as many views as feasible from the outset will help minimize roadblocks to gaining agreement throughout the process.

In addition to representing the views of the stakeholders, the success of the risk characterization process also depends critically on conducting a systematic analysis that is appropriate to the problem and treats uncertainties of importance to the decision problem in a comprehensible and reasonable way. Success

*This section draws heavily from Meacham, B. J., "Risk-Informed Performance-Based Analysis and Design," *Extreme Event Mitigation in Buildings: Analysis and Design,* B. J. Meacham and M. Johann (Eds.), National Fire Protection Association, Quincy, MA, 2006.

also depends on a deliberative process to formulate the decision problem, guide analysis to improve decision participants' understanding, interpret analytic findings and uncertainties, and improve the ability of stakeholders to participate effectively in the risk decision process.[6] In other words, good risk characterization requires the following components:

- A risk problem definition that stakeholders accept
- A sound scientific base for assessing the risk and developing acceptable mitigation strategies
- The proper use of analytical techniques with appropriate consideration of uncertainties and unknowns
- A good understanding of criteria to indicate acceptability of results such as mitigation effectiveness and cost effectiveness
- Sufficient discussion and deliberation to ensure that all parties understand all of the issues

Ideally, the process requires several iterations as new information and data become available, and as participants gain a better understanding and raise more issues. The process needs to be interactive, equitable, and free of ill-informed, ungrounded solutions. The iterative nature of the process just described is illustrated in Figure 1.7.4. In each stage of deliberation, multiple stakeholders interact to integrate key issues at the outset of hazard mitigation planning.

Essential to any risk characterization effort is the need to diagnose the risk and state of knowledge. The aim is to identify and characterize who or what will be impacted, and by what (e.g., threats, vulnerabilities, and risks). To help, certain diagnostic questions should be asked about the hazards and the risks, including the following:

- Who or what is exposed (e.g., people, property, and/or operations)?
- If people, what groups are exposed (e.g., vulnerable populations, including mobility impaired and those with cognitive disorders)?
- What is posing the risk (e.g., hurricanes, high wind, floods, earthquake, fire, terrorism)?
- What is the nature of the harm (e.g., sudden injury or death, morbidity, delayed mortality, property loss, operational losses, threat to community welfare, loss of critical functions, or legal issues)?
- What qualities of the hazard might affect judgments about the risk (e.g., dread, individual control, vulnerability, familiarity, immediacy, and/or degree of technical knowledge available)?
- Where is the hazard experience (e.g., local, regional, or national and in similar facilities)?
- Where and how do hazards overlap (e.g., are some classes of people or facilities disproportionately exposed to one or multiple hazards? Is there a geographical component to overlapping hazards)?
- How adequate are the databases on the risks (e.g., solid data, limited data with some judgment, few data with considerable judgment, or speculation)?
- How much scientific consensus exists about how to analyze the risks (e.g., is there agreement on analytical methodology, theoretical basis for analysis, and harms not analyzed)?
- How much scientific consensus is there likely to be about risk estimates (e.g., is epistemic [knowledge] uncertainty a serious problem, and how significant is variability in population)?
- How much consensus is there among the affected parties about the nature of the risk?
- Are there omissions from the analysis that are important for decisions (e.g., are possible harms, management options, or effects left unassessed)?

To provide focus to the diagnostic phase, a threat, vulnerability, and risk assessment (TVRA) approach is often employed.

Threat, Vulnerability, and Risk Assessment. The intent of a threat, vulnerability, and risk assessment is to (1) identify potential threats or hazards to people, facilities, operations, and finances; (2) evaluate the likelihood of specific threat or hazard scenarios occurring; and (3) assess the consequences (severity) should a threat or hazard scenario occur.[22]

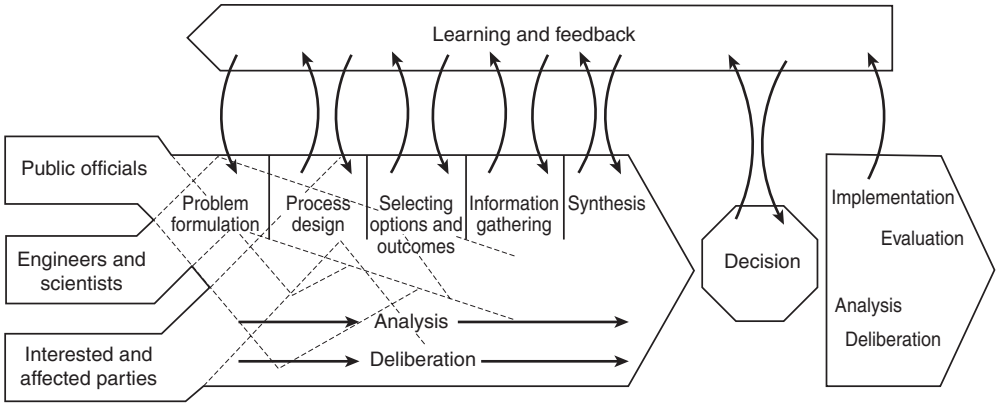

FIGURE 1.7.4 Risk Characterization Process (Source: Adapted from Stern, P. C., and Fineburg, H. V. (Eds.), *Understanding Risk: Informing Decisions in a Democratic Society,* National Research Council, National Academy Press, Washington, DC, 1996, p. 28)

Threat assessment focuses on identifying and understanding the potential sources of unwanted events. It should consider the full range of events pertinent to the building, from fire and natural hazard events to terrorist and other extreme events. *Vulnerability assessment* focuses on identifying potential weaknesses in a facility that could lead to impact from an event or aggressor (e.g., a potential weakness that might allow terrorists to access a building, such as a lack of building security, the ability to drive a vehicle close to a facility, and so forth). In some cases, vulnerability assessment is closely tied to consequence analysis in that it considers the response of a facility to an event of a certain magnitude, thus indicating the facility's vulnerability to that event (e.g., assessing the response of a facade to a certain size explosive load would both indicate the facade's vulnerability to a blast of that size as well as to identify potential consequences that may result should the blast occur). *Risk assessment* involves identifying events of concern, determining the likelihood of those events, and predicting the potential consequences should such events occur.

Although threat, vulnerability, and risk assessments can vary, a comprehensive TVRA should encompass the following components:*

- Asset identification and valuation
- Target potential
- Threat identification
- Threat scenarios
- Vulnerability assessment
- Consequence analysis
- Risk assessment
- Prevention and mitigation strategies
- Cost and effectiveness analyses
- Prevention and mitigation option selection

To help address these issues in a readily understandable and transparent manner, a variety of tools can be used, from simple spreadsheets to complex computer models. In many cases, a simple matrix may be sufficient to outline high-risk facilities, mitigation options, relative mitigation costs and effectiveness, and overall risk-cost-effectiveness assessment. A simple matrix of this type might include the following:

- Facility
- Location
- Event scenarios
- Life safety impact (relative impact on occupant life safety given an event)
- Damage potential (relative impact on the facility and systems given an event)
- Operational impact (relative impact on operations given an event)
- Relative risk (a relative measure of overall risk, incorporating the previous three factors)
- Mitigation options (a list of potential mitigation measures or strategies)
- Relative mitigation effectiveness (relative effectiveness of mitigation measures)
- Relative mitigation cost (relative cost of mitigation measures)
- Relative cost effectiveness (a relative measure of cost effectiveness given relative mitigation effectiveness and relative cost
- Relative risk/cost ranking (a relative measure of relative risk and relative cost effectiveness)

Such a matrix might take the form illustrated in Figure 1.7.5. From such a matrix, multiple mitigation options could be selected, based on their overall risk-cost-effectiveness ranking or other factors.

Establishing Target Building Performance Levels. Another key component in the process is establishing target building performance levels for the facility in question. In this context, a target building performance level reflects the expectation of how a building's systems will perform under the hazard scenarios of concern. The intent is to describe the target performance, using parameters that can be measured or calculated, as based on the tolerable limits of damage, injury, operational capacity, or other loss. The term "tolerable" is used to reflect the fact that absolute protection is not possible. Some possibility of damage, injury, or loss is currently accepted in structures. The exercise here is to determine how much additional risk (possibility of loss) is likely and tolerable from extreme events, as represented by the extreme event scenario chosen for evaluation. The term *impact* is used as a broad descriptor of loss.

An often-used approach to illustrate how events (design loads), impacts (consequences), and desired performance relate is through a matrix structure. For example, Table 1.7.1, from the *Department of Defense Minimum Antiterrorism Standards for Buildings*,[24] illustrates levels of performance for different building systems, as well as for occupants, under specific event conditions.

A similar approach is used within the building code environment as well.[21] In this case, four design performance levels are provided to bound the expected performance of facilities when subjected to various design loads (from hazard events). See Table 1.7.2.

The basis of this approach is the use of importance factors to assign buildings into performance groups, each of which will have its own target performance (tolerable risk) levels. This matrix display of target levels can be matched with a similarly configured matrix with predicted response of buildings for each performance group to a given severity of hazard as illustrated in Figure 1.7.6.

Regardless of the specific approach taken, key factors to consider include the following:

- What are the extreme event threat scenarios?
- Who and what are at risk?
- How are they at risk?
- What are the potential consequences?

*See Meacham, B. J., "Threat, Vulnerability and Risk Assessment," B. J. Meacham and M. Johann (Eds.), *Extreme Event Mitigation in Buildings: Analysis and Design,* National Fire Protection Association, Quincy, MA, 2006, for example, for a much more in-depth discussion on TVRA.

TABLE 1.7.1 Levels of Protection for New Buildings

Level of Protection	*Potential Structural Damage*	*Potential Door and Glazing Hazards*	*Potential Injury*
Below standards	Severe damage. Frame collapse, massive destruction, little left standing.	Doors and windows fail, resulting in lethal hazards.	Majority of personnel suffer fatalities.
Very low	Heavy damage. Damage results in onset of structural collapse. Major deformation of primary and secondary structural members, but progressive collapse is unlikely. Collapse of nonstructural elements.	Glazing will break and will likely be propelled into the building, resulting in serious glazing-fragment injuries, but fragments will be reduced. Doors may be propelled into rooms, presenting serious hazards.	Majority of personnel suffer serious injuries. There are likely to be a limited number of fatalities (10 to 25%).
Low	Damaged and unrepairable. Major deformation of nonstructural elements and secondary structural members and minor deformation of primary structural members, but progressive collapse is unlikely.	Glazing will break but will fall within 1 meter of the wall or will otherwise not present a significant fragment hazard. Doors may fail but they will rebound out of their frames, presenting minimal hazards.	Majority of personnel suffer significant injuries. There are likely to be a few fatalities (<10%).
Medium	Damaged and repairable. Minor deformation of nonstructural elements and secondary structural members and no permanent deformation in primary structural members.	Glazing will break, but will remain in window frame. Doors will stay in frames, but will not be reusable.	Some minor injuries, but fatalities unlikely.
High	Superficial damage. No permanent deformation in primary structural members, secondary structural members, or nonstructural elements.	Glazing will not break. Doors will be reusable.	Only superficial injuries are likely.

TABLE 1.7.2 Performance Levels of Impact for Buildings and Facilities

Impact Levels	*Mild*	*Moderate*	*High*	*Severe*
Structural damage	There is no structural damage and the building or facility is safe to occupy.	There is moderate structural damage, which is repairable; some delay in re-occupancy can be expected.	There is significant damage to structural elements but no large falling debris; repair is possible. Significant delays in reoccupancy can be expected.	There is substantial structural damage, but all significant components continue to carry gravity load demands. Repair may not be technically possible. The building or facility is not safe for re-occupancy, as re-occupancy could cause collapse.
Nonstructural systems	Nonstructural systems needed for normal building or facility use and emergency operations are fully operational.	Nonstructural systems needed for normal building or facility use are fully operational, although some cleanup and repair may be needed. Emergency systems remain fully operational.	Nonstructural systems needed for normal building or facility use are significantly damaged and inoperable; egress routes may be impaired by light debris; emergency systems may be significantly damaged, but remain operational.	Nonstructural systems for normal building or facility use may be completely nonfunctional. Egress routes may be impaired; emergency systems may be substantially damaged and nonfunctional.
Occupant hazards	Injuries to building or facility occupants from hazard-related applied loads are minimal in numbers and minor in nature. There is a very low likelihood of single or multiple life loss. The nature of the applied load (i.e., fire hazard) may result in higher levels of expected injuries and damage in localized areas, whereas the balance of the areas may sustain fewer injuries and less damage.	Injuries to building or facility occupants from hazard-related applied loads may be locally significant. There is a low likelihood of single life loss and a very low likelihood of multiple life loss. The nature of the applied load (i.e., fire hazard) may result in higher levels of expected injuries and damage in localized areas, whereas the balance of the areas may sustain fewer injuries and less damage.	Injuries to building or facility occupants from hazard-related applied loads may be locally significant with a high risk to life, but are generally moderate in numbers and nature. There is a moderate likelihood of single life loss and a low probability of multiple life loss. The nature of the applied load (i.e., fire hazard) may result in higher levels of expected injuries and damage in localized areas, whereas the balance of the areas may sustain fewer injuries and less damage.	Injuries to building of facility occupants from hazard-related applied loads may be high in numbers and significant in nature. Significant risk to life may exist. There is a high likelihood of loss in higher levels of expected injuries and damage in localized areas, whereas the balance of the areas may sustain fewer injuries and less damage.
Overall extent of damage	Damage to building or facility contents from hazard-related applied loads is minimal in extent and minor in cost.	Damage to building or facility contents may be locally significant, but is generally moderate in extent and cost. The nature of the applied load (i.e., fire hazard) may result in higher levels of expected injuries and damage in localized areas, whereas the balance of the areas may sustain fewer injuries and less damage.	Damage to building or facility contents from hazard-related applied loads may be locally total and generally significant. The nature of the applied load (i.e., fire hazard) may result in higher levels of expected injuries and damage in localized areas, whereas the balance of the areas may sustain fewer injuries and less damage.	Damage to building or facility contents from hazard-related applied loads may be total. The nature of the applied load (i.e., fire hazard) may result in higher levels of expected injuries and damage in localized areas, whereas the balance of the areas may sustain fewer injuries and less damage.
Hazardous materials	Minimal hazardous materials are released to the environment.	Some hazardous materials may be released to the environment, but the risk to the community is minimal. No emergency relocation is necessary.	Hazardous materials may be released to the environment with localized relocation needed for buildings and facilities in the immediate vicinity.	Significant hazardous materials may be released to the environment, with relocation needed beyond the immediate vicinity.

Magnitude of design event (Increasing magnitude of event →)	Increasing level of performance → Performance groups			
	PG I	PG II	PG III	PG IV
Very large (very rare)	Severe	Severe	High	Moderate
Large (rare)	Severe	High	Moderate	Mild
Medium (less frequent)	High	Moderate	Mild	Mild
Small (frequent)	Moderate	Mild	Mild	Mild

FIGURE 1.7.6 Relationships Among Magnitude of Design Events (Loads), Performance Groups, and Tolerable Impacts (Source: *Performance-Based Building Design Concepts,* © International Code Council, Inc., Washington, DC. Reproduced with permission. All rights reserved.)

- How likely is it for the consequences to be realized?
- What level of performance should be targeted for the facility?

Once this information is available, various mitigation options can be considered and assessed, on effectiveness in mitigating the events of concern, as well as on cost effectiveness. Such a process can be used for developing building code provisions for specific facility designs (Figure 1.7.7). To help in identifying potential mitigation options (solutions and verification methods) and their effectiveness, a performance-based approach can be quite helpful.

PERFORMANCE-BASED ANALYSIS AND DESIGN

In the broadest sense, performance-based analysis and design is a process of engineering a solution to meet specific levels of performance, where performance may be stated in terms of qualitative or quantitative objectives, criteria, or limiting states of damage or injury.[22] Performance-based analysis and design has gained momentum in recent years and is being used increasingly for structural engineering for natural hazards;[25] for fire protection engineering, as explained in the NFPA's *Introduction to Performance-Based Fire Safety,*[26] and the *SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings;*[27] and for multihazard mitigation design, including extreme events.[28]

Performance-Based Structural Design

The basic process for performance-based structural design is shown in Figure 1.7.8. In brief, the process consists of the following steps:

- Select appropriate performance objectives.
- Develop a preliminary design constructed to meet the objectives.
- Verify that the design can achieve the objectives.
- Iteratively revise the design until an acceptable design is achieved.

Performance objectives are quantified statements of the severity of a design event, its probability of occurrence, and the permissible damage given that the event is experienced.[25] The design event or its probability of occurrence is often defined as the hazard. Probabilities of occurrence may be expressed as mean annual recurrence intervals (the average period of time, in years, between repeat occurrences of an event of a given or larger magnitude) or annual probabilities of exceedance (the likelihood in any year that a given event will be experienced, calculated as the inverse of the mean recurrence interval). Note that the two expressions of probabilities of occurrence describe the same event. For example, using the mean-annual-recurrence taxonomy, a 100 year flood would be the level of flooding expected to occur, on average, once every 100 years. Using the annual probability-of-exceedance taxonomy, a 100 year flood would have an annual probability of exceedance of 0.01. Use of a particular taxonomy is often a combination of personal preference and industry norm.

Associated with a design event is the amount of damage that is tolerable (performance level). As discussed previously, performance levels may be qualitative or quantitative. As used in structural design, a qualitative performance level might relate to the effect of the damage from a design event on the state (also may be described as stability or capacity) of the building after the event is experienced—for example, whether the building remains safe for continued occupancy, whether it is

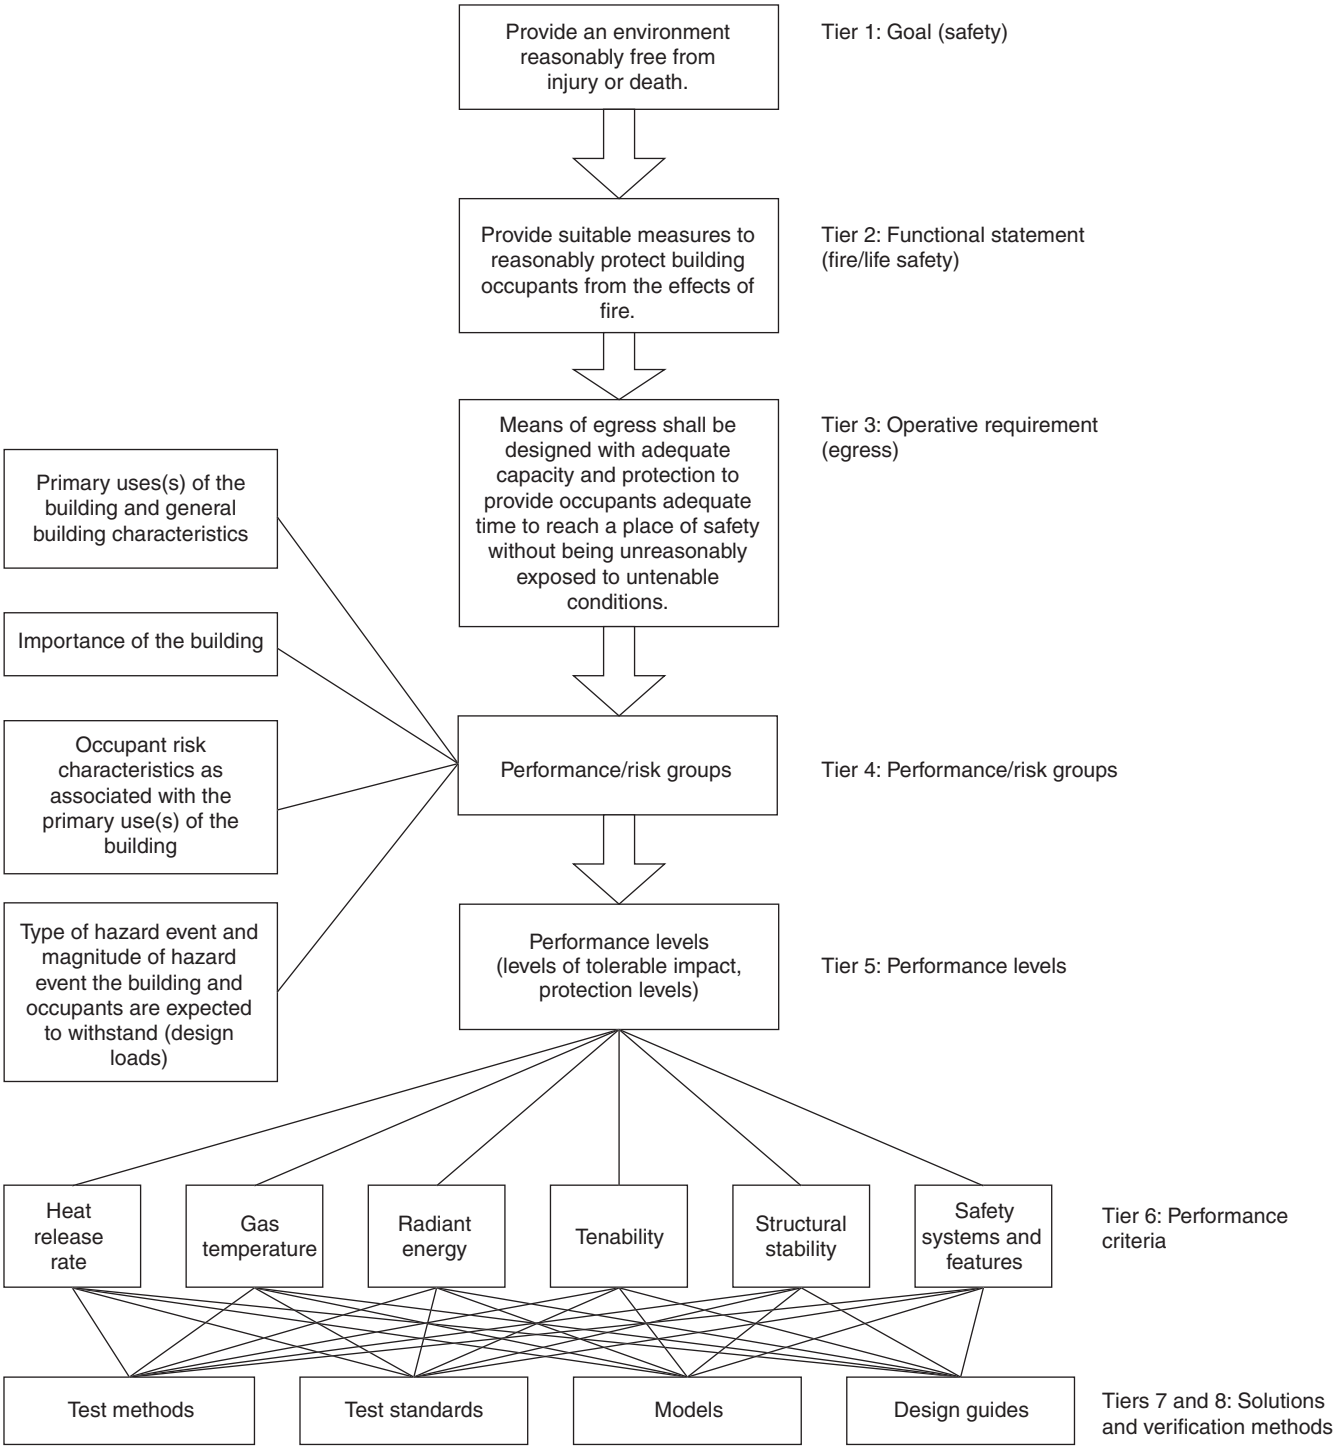

FIGURE 1.7.7 Going from Goals to Implementation in a Risk-Informed Performance-Based Environment (Source: Meacham, B. J., "Performance-Based Building Regulatory Systems: Structure, Hierarchy and Linkages," *Journal of the Structural Engineering Society of New Zealand,* Vol. 17, No. 1, 2004, pp. 37–51)

damaged but functional or operational in its intended service, or whether the safety of occupants is threatened. Quantitative expressions of performance levels, as used in structural analysis and design, relate to specific physical states, such as the extent of strength or stiffness loss, the amount of energy dissipated, and so on. Such expressions of performance are often meaningful only to structural engineers. Given that both qualitative and quantitative descriptions are used in practice, most authoritative

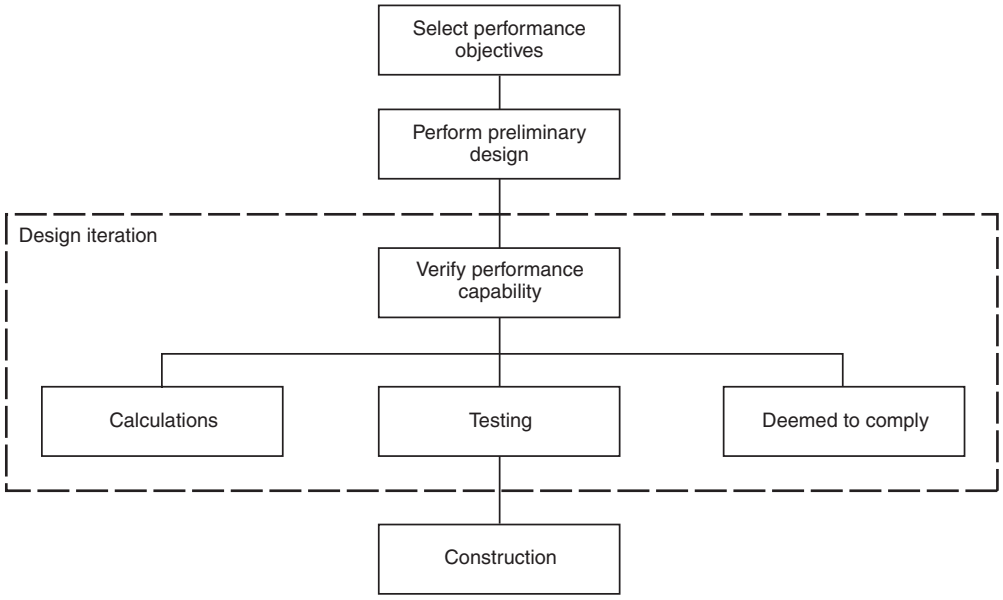

FIGURE 1.7.8 Performance-Based Structural Design Process (Source: *Performance-Based Building Design Concepts,* pp. 6-1–6-22 © International Code Council, Inc., Washington, DC. Reproduced with permission. All rights reserved.)

documents giving guidelines for performance-based structural design provide both qualitative and quantitative descriptions of performance levels to facilitate communication between structural engineers and others, such as the lay public.

Performance-Based Fire Safety Design

Following the structural engineering community, the performance-based concept has been adopted by the fire safety engineering community, where performance-based fire safety design has been defined in NFPA's *Introduction to Performance-Based Fire Safety* as follows:

> . . . an engineering approach to fire protection design based on (1) agreed upon fire safety goals, loss objectives, and design objectives; (2) deterministic and probabilistic evaluation of fire initiation, growth, and development; (3) the physical and chemical properties of fire and fire effluents; and (4) quantitative assessment of the effectiveness of design alternatives against loss objectives and performance objectives.

Although this definition is not universal, research conducted in the 1990s into the evolution of performance-based codes and performance-based fire safety analysis and design methods determined that the concepts are entrenched in more than a dozen performance-based fire safety analysis and design approaches under development or in use around the world.[4]

Development of performance-based design options has in some cases also resulted in a more clearly developed set of rules for prescriptive-based designs.[22] This is particularly true where performance-based design options require proposed solutions to be measured against the goals and objectives of the code. Codes such as NFPA *101* and *NFPA 5000* offer a detailed set of goals and objectives that apply to traditional prescriptive-based code regulations and the newer performance-based code regulations. The goals and objectives provide qualitative conditions to describe the level of performance, the intended perils considered by the code, and the expected outcome when the goals and objectives are met. This level of detailed performance goals and objectives did not exist in U.S.-based codes until performance-based design concepts were introduced into codes beginning in 2000.

Many of these performance-based design approaches, including the one described in the *SPFE Engineering Guide to Performance-Based Protection Analysis and Design of Buildings,* contain the following seven interrelated steps:[4,6,22,26,29]

1. Identify site or project information.
2. Identify goals and objectives.
3. Develop performance criteria.
4. Develop event scenarios, design scenarios, and design loads.
5. Develop candidate design options.
6. Evaluate candidate design options and select final design.
7. Develop final design documentation.

The basic flow of these steps is outlined in Figure 1.7.9 as a sequential process. In reality, however, it often involves several iterations, especially during the evaluation stage (step 6). The iterative nature of the evaluation, including the possibility of revisiting the performance criteria selected, is shown in Figure 1.7.10. (Figures 1.7.9 and 1.7.10 both illustrate the process without reference to fire, indicating its applicability to any engineering problem.)

The advantage of the performance-based analysis and design approach lies in the flexibility that can be achieved without

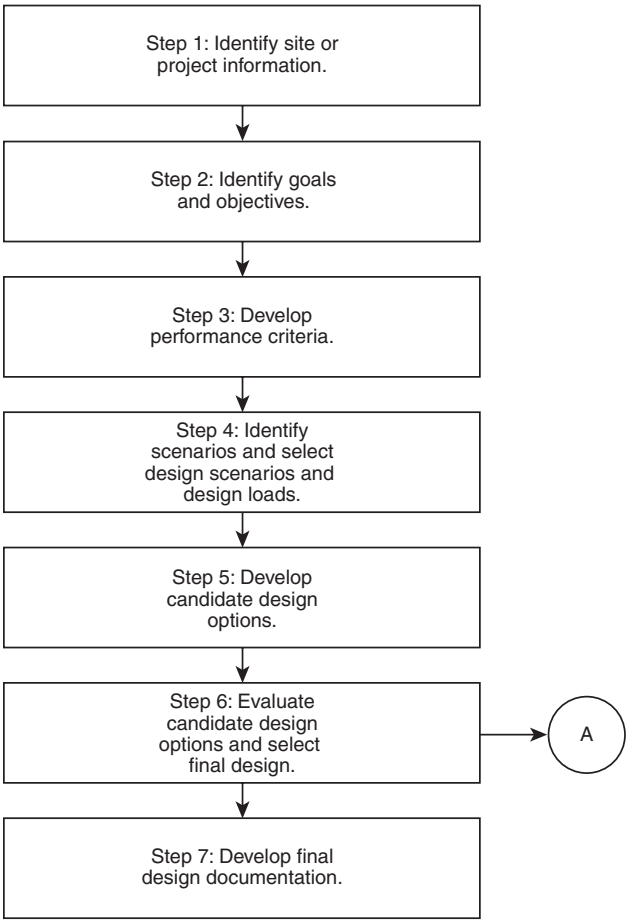

FIGURE 1.7.9 Seven Steps in the Performance-Based Analysis and Design Process (Source: Meacham, B. J., *Assessment of the Technological Requirements for the Realization of Performance-Based Fire Safety Design in the United States,* NIST GCR-98-763, National Institute of Standards and Technology, Gaithersburg, MD, 1998, p. 13)

compromising on safety, cost, or other important factors such as aesthetics, usability, and function.[22] The approach allows all parties involved to agree on the goals, objectives, criteria, and analysis and evaluation methods, resulting in a design that best fits all parameters—a performance-based design solution. A performance-based analysis and design approach can be used in conjunction with performance-based regulations or on its own. When performance-based regulations exist, issues such as goals, objectives, criteria, and performance requirements may already be identified and will not necessarily require development as part of the analysis.

MITIGATION STRATEGIES

There are a large variety of mitigation strategies available for addressing the potential impacts of extreme events in buildings. Detailed discussion can be found in NFPA's *Extreme Event Mitigation in Buildings, Analysis and Design,*[8] as well as other texts cited and listed under additional reading. For the purpose of this chapter, the focus will be on mitigating blast, CBRN, and extreme fire events.

Protection Against Blast Loads*

Implementing physical protection strategies against blast loads requires the active collaboration of engineers, architects, landscape architects, security specialists, and others to ensure the attractive integration of site and structure in a manner that minimizes the opportunity for attackers to approach or enter a building.[18] This protection includes such features as the following:

- Personnel involved in active site security and perimeter control
- Landscaping and earthworks that can function both as blast barriers and vehicle controls
- Appropriately designed street furniture and features such as planter boxes, bollards, and plinths that prevent vehicular access

It is also possible to design into a building itself a range of blast-resistant features, such as additional reinforcing details, composite fiber wraps to strengthen columns and slabs, and high-performance glazing materials. Figure 1.7.11 illustrates blast damage.

Based on experience with blast effects on buildings and people, several basic tenets of physical protection for buildings have evolved over time.[18] These basics are as follows:

- Prevent glazing and facade materials from shattering and entering occupied spaces.
- Keep the blast energy outside the building.
- Protect occupants from injury by fragments and larger objects, blast pressure, or physical translation.
- Prevent structural collapse—global, local, and progressive.

In support of these basic principles, the following should be considered when designing buildings to protect against terrorist attacks:[30]

- *Deflect* a terrorist attack by showing, through layout, security, and defenses, that the chances of success for the terrorist are small. Targets that are otherwise attractive to terrorists should be made anonymous.
- *Disguise* the valuable parts of a potential target so that the energy of attack is wasted on the wrong area, and the attack, although completed, fails to make the impact the terrorist seeks; the attack is reduced to an acceptable annoyance.
- *Disperse* a potential target so that an attack can never cover a large enough area to cause significant destruction, and thereby reduce impact. This protection strategy is suitable for a rural, industrial installation, but probably unachievable for an inner-city building.
- *Stop* an attack from reaching a potential target by erecting a physical barrier to the method of attack; this protective

*Much of this section is excerpted with permission from Hadden, J. D., Little, R. G., and McArthur, C., "Bomb Blast Hazard Mitigation," *Extreme Event Mitigation in Buildings: Analysis and Design,* B. J. Meacham and M. Johann (Eds.), National Fire Protection Association, Quincy, MA, 2006.

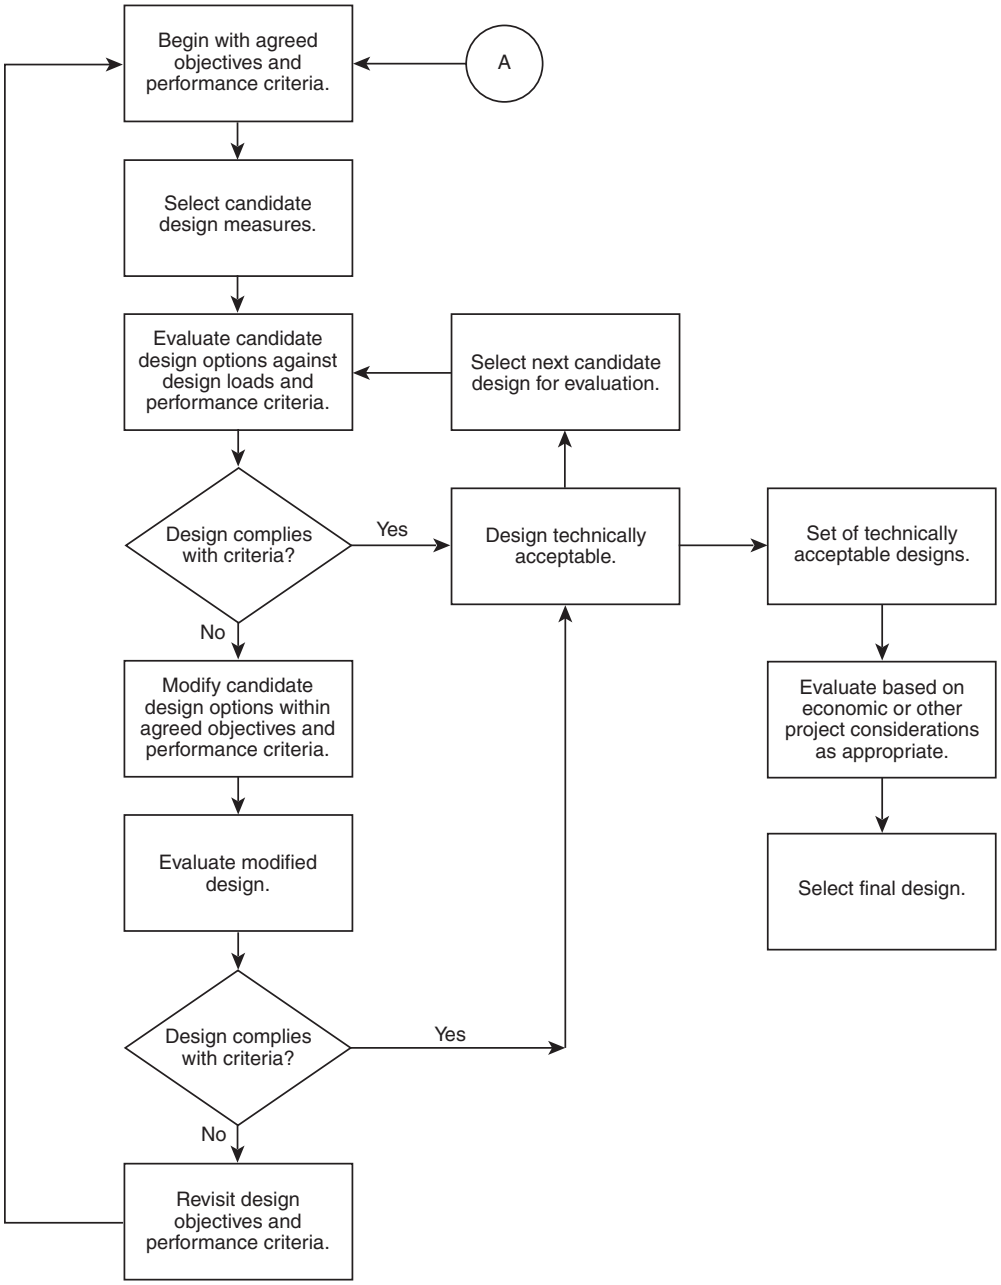

FIGURE 1.7.10 Iterative Nature of the Performance-Based Design Evaluation Process (Source: Meacham, B. J., *Assessment of the Technological Requirements for the Realization of Performance-Based Fire Safety Design in the United States,* NIST GCR-98-763, National Institute of Standards and Technology, Gaithersburg, MD, 1998, p. 14)

design approach covers a range of measures, from relatively large standoff distances to vehicle bollards and barriers to pedestrian entry controls. In particular, this is the only defense that will be successful against a large vehicle bomb.

- *Blunt* the attack once it reaches its target by hardening the structure to absorb the energy of the attack and protect valuable assets.

Despite the great strides that have been made in developing new materials and innovative techniques that will reduce building damage and occupant injury in the event of a bomb attack, the enormous amount of energy generated by even modest amounts of high explosives will still cause extensive building damage and personal injury if detonated at close range. If adequate standoff distance can be established and maintained, the other tenets of building protection become realistically achievable.

FIGURE 1.7.11 Blast Damage at the Chamber of Shipping, London, 1992 (Source: Arup)

The importance of standoff distance in the risk management equation cannot be overemphasized (Figure 1.7.12). If adequate standoff cannot be established, a combination of active site security, operational procedures, and building improvements must be provided.

Threat Assessment and Blast-Protection Objectives. As outlined above, the starting point in design against extreme events is for the designer and client (the developer, owner, or tenant) to agree on the level of threat to be considered and the objectives of any protection measures. This holds true for blast protection. Assessing the terrorist bomb threat to a particular building is not an exercise in precise mathematics or statistical analysis; the range of possible combinations of device type, size, and distance to which a building might be exposed is almost infinite. Despite the difficulties in carrying out such an assessment, however, it is an essential first step. Ultimately the objective of the bomb threat assessment is for the project participants to agree on one or more combinations of charge weight and location(s) to be protected against.

The blast-protection objectives must also be realistic. To expect any building, other than perhaps a hardened military facility, to withstand unscathed a large vehicle bomb immediately outside the front door is unrealistic. However, on a large facade it may be acceptable for the windows closest to the seat of the explosion to produce a certain level of hazard on grounds of economy, with the understanding that other windows, which are offset from the seat, remain intact. In other cases, fully protecting the exposed rooms at the closest range may be required. Building designers must decide whether to glaze the whole facade to the extent required for the most heavily loaded point at ground level or whether to adopt a graded approach to protection. Another consideration is whether the facade or other building components are expected to be reusable after the "design explosion" or whether a level of permanent damage and distortion is acceptable, necessitating replacement.

Conducting threat assessments and defining blast-protection objectives are part of a process of selecting a position on the scale of possible events from which to develop measures consistent with those objectives. This process should lead to the design of a building that offers greater protection—not only from the agreed-on threats, but also against a band of other possible scenarios—than would be the case if no added protection was provided. However, those involved in the process should never lose sight of the fact that the only certainty when designing counterterrorist measures for a building is that the event used for design will not be the attack to which the building is actually exposed. Some may view this caution as a reason not to design against a specific threat, because it will inevitably be the wrong one. A more appropriate reaction is to attempt an analysis that will (1) show that the design will achieve objectives and targets for a diverse range of extreme events and (2) identify the type and severity of events where objectives and targets will not be achieved and provide some insight into the performance expectations for those events.

Building Design and Layout. The threat assessment should be carried out before the design progresses too far, so that fundamental changes in the building can be implemented without substantial modifications. For example, as part of a threat, vulnerability, and risk assessment, one should ask if there is any way to increase the standoff distance, since as noted earlier, every meter added to the standoff distance contributes significantly to reduction in blast impact. At close proximity, and leaving aside local effects, the peak blast pressure is, broadly, inversely proportional to the square of the distance, so anything that can be done to maximize standoff, such as vehicle and pedestrian barriers, is of great value (see Figure 1.7.12).

Other features to be treated with caution and, if possible, designed out at an early stage are floors bridging over public roads, reentrant features such as partially enclosed courtyards, and even deep window recesses. All of these features exacerbate blast effects due to confinement and reflection of the blast wave. Another issue to consider during early planning is access and egress. Ideally, doors should be well dispersed around the perimeter to enable evacuation in the direction considered the safest, either before or after an explosion.

The most widespread cause of injuries and internal disruption from an external bomb blast is the fragmentation and inward projection of window glass. This has been observed in large explosions around the world, from London to Jakarta

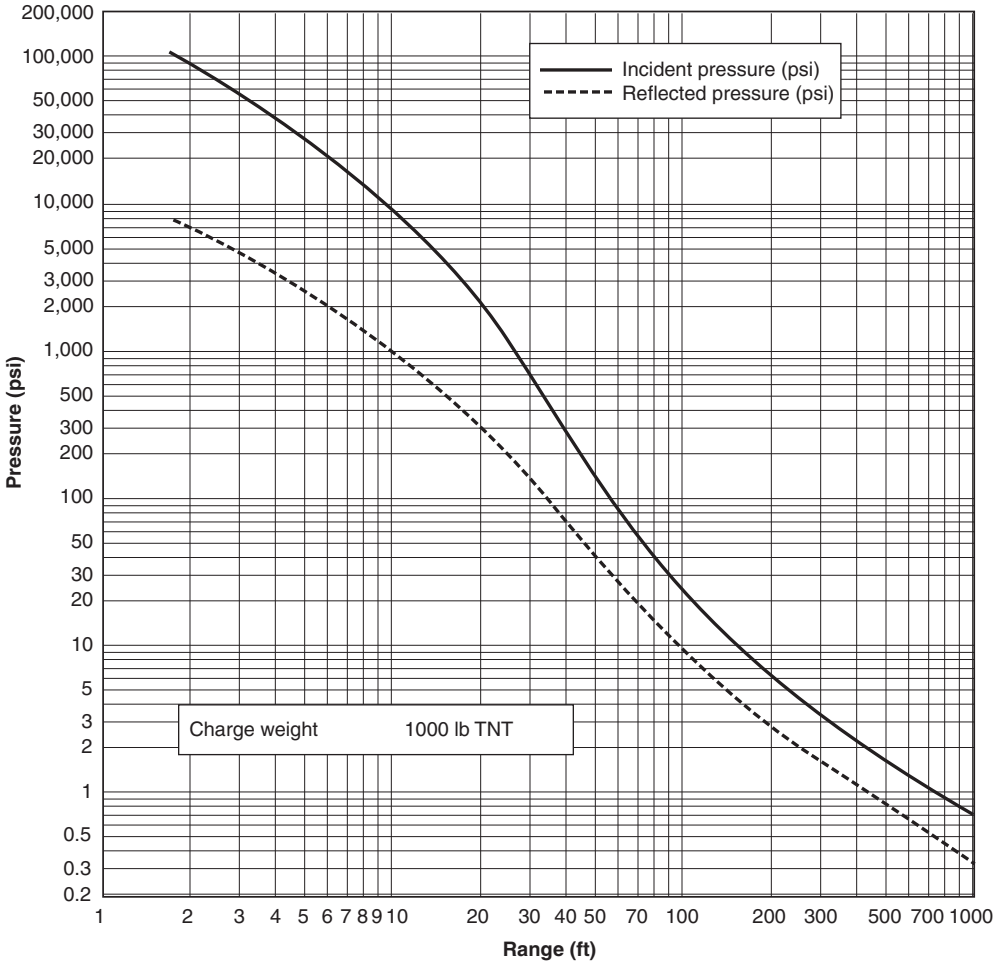

FIGURE 1.7.12 Comparison of Peak Blast Pressures on Surfaces with Incident and Reflected Orientations as a Function of Standoff Distance for a Given Charge (Source: Hyde, D. W., *ConWep Version 2.1.0.8,* USAE Engineer Research and Development Center, Vicksburg, MS, 2005)

to Oklahoma to Nairobi. Plain annealed glass, which is in the majority of homes, is the most hazardous type, because it breaks into dagger-like shards. During an explosion, these shards are thrown at high speed deep into the building, causing laceration injuries. Blast pressures entering through shattered windows can also cause potentially fatal lung damage or eardrum rupture and may throw people against walls and other solid objects. As noted above, standoff distance is a significant mitigation measure. In addition, there are a range of options available for reducing the hazard from glazing, from adding antishatter film to laminated glass, to means to better anchor windows and frames to resist the effects of explosions.[19] Figure 1.7.13 illustrates the relative effectiveness of various mitigation measures.

Bomb attacks on the Alfred P. Murrah Federal Building, Khobar Towers, and other buildings led to the introduction of measures to reduce vulnerability to disproportionate collapse in new U.S. federal facilities.[31] Investigation into this aspect of building design is continuing, and design guidelines are being developed by engineers and researchers around the world.

Most steel or in-situ concrete frames have the potential to perform well under blast loads from typical terrorist vehicle bombs. Local damage can be severe, with columns or slabs close to the explosion destroyed or badly distorted, but overall catastrophic collapse is relatively rare. Some simple modifications to normal construction practice[32] will improve the blast resilience of such structures, but even with these measures, repairs and member replacement may still be required. For all but the most mission-critical facilities, when striking a balance between expenditure and protection, the designer's aim should be to avoid disproportionate damage, not to eliminate damage completely.

In any framed structure, the beam-to-column connections are critical. In a concrete frame, reinforcing bars projecting from a beam can be anchored into the upper and lower sections of a column, rather than just into the concrete at the junction of the two structural elements, where damage may be severe. In steel frames, a simple low-cost "belt-and-braces" approach can be beneficial, with a bolted end plate backed up by a welded seating cleat below, each designed to support a full beam reaction on its own.

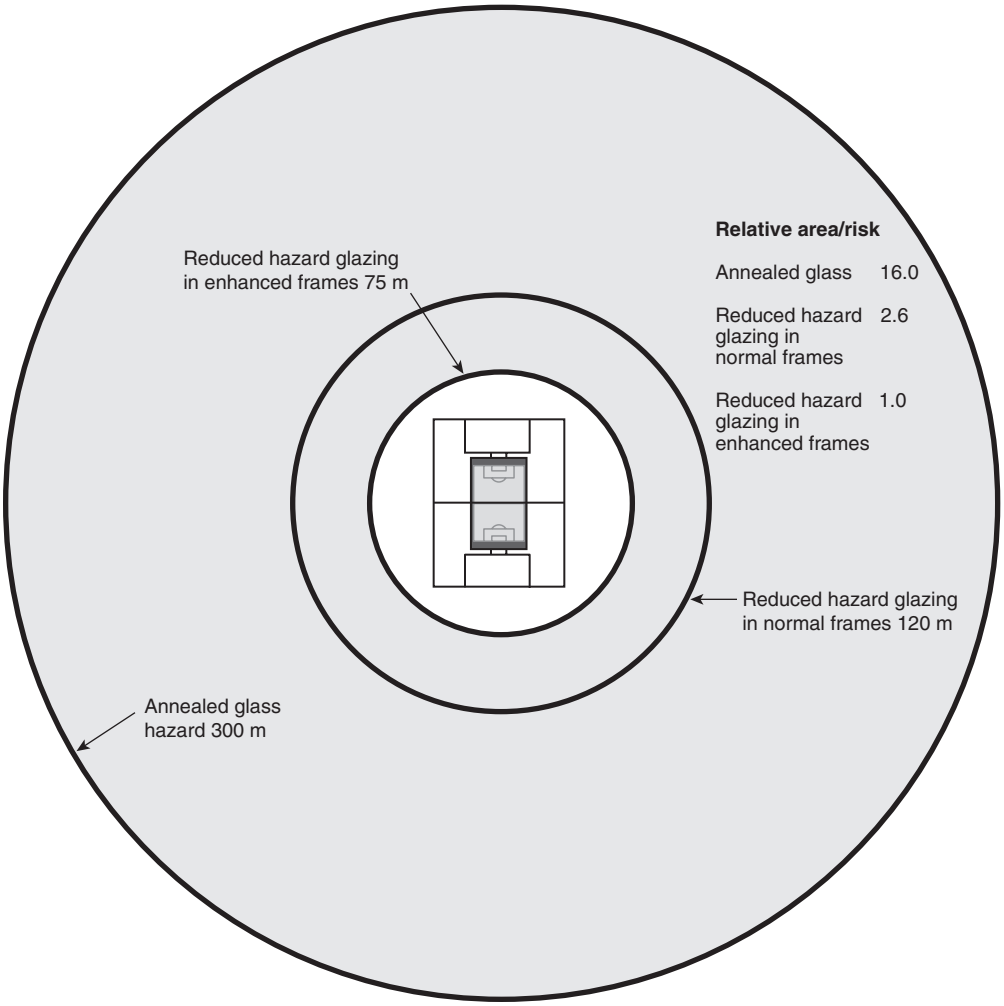

FIGURE 1.7.13 Effectiveness of Different Forms of Glazing After Large Vehicle Bomb (Soccer Stadium Shown for Scale) (Source: Hadden, D., "The Trade-Offs of Handling Risk and Resilience," *Proceedings of the Workshop on Lessons from the World Trade Center Terrorist Attack,* Technical Report, MCEER-02-SP08, Multidisciplinary Center for Earthquake Engineering Research, New York, 2002)

Structural designers may also need to consider the ability of floor slabs to resist upward loads from blast. Portions of a suspended floor slab may not actually need reinforcement on its top face to resist normal downward gravity loads. However, if blast pressures enter the ground level there may be uplift on the floor slab above, which could then fail in reverse bending if it has no top reinforcement and drop back down on the level below.

Computer Modeling and Other References. After settling on the threat, the protection objectives, and the building layout, more detailed engineering can follow. However, at this point opinions on how to proceed diverge. A topographical computer model of the building and its surroundings can be constructed. Sophisticated software can then be used to evaluate the blast pressures and impulses at points around the building for each of the agreed-on threats. However, the sheer complexity of modeling with confidence the influence of adjacent buildings, plus the uncertainties of bomb location and effective charge weight, may undermine the value of such an exercise. The response of the various building surfaces to the blast wave, which may include failure of some surfaces, can also affect the propagation of the blast wave. Merely representing these as rigid and unyielding surfaces may produce misleading results.

Alternative methods of deriving air blast pressures and impulses involve referencing published charts or tables,[33] using established, empirically based software, such as the Conventional Weapons Effects Program (ConWep),[34] or relying on advanced software, such as Air3d[35] or AutoDyne®[36] and the like, to model local conditions. In the end, however, designers should keep in mind that there are no exact answers when designing counterterrorist blast protection measures or universally established design codes to fall back on. In short, there is no substitute for a rational and realistic threat assessment backed by well-founded engineering principles and appropriate analysis.

Robustness and Protection Against Disproportionate Damage

Robustness is a fundamental concept in engineering design and is generally considered among the key public expectations for building performance. Simply, robustness implies a certain degree of "reserve" strength to deal with variations in loading that a building may see in its lifetime and that are not entirely predictable. Elements of robust design are built into codes and standards, but can also be addressed more explicitly in an engineered analysis and design approach, such as may be the case for design against extreme events.[37] The following are the simplest and most common principles of robustness:

- Allow for strength of materials to be variable, taking a statistically justified approach to the design strength.
- Enable imposed loads to be greater than codified values, adopting a margin for error based on experience/historical precedence.
- Allow for a limited amount of damage or failure of part of the structure and design for the subsequent redistribution of loads to the remaining structure.

When considering the robustness of a structure, consideration is given to the extent of damage that may occur from events of various sizes. As with robustness, many codes and standards contain some provisions aimed at assuring the level of damage from an event is proportional to the magnitude of the event (the building is robust against the expected events and associated loads), with the aim being to avoid disproportionate damage.

In brief, *disproportionate damage* occurs when the consequence of an event is far greater than expected. A key here is the link between the "expectations" and "realizations" of events and impacts. In general, "small" events are generally expected to have "small" consequences (i.e., "small" amounts of damage). Similarly, it is expected that for many buildings, "large" events can result in large amounts of damage, particularly if the event is rare or unforeseen. A "small" event resulting in "large" amounts of damage would be considered disproportionate.

In other words, many code-based design hazards will fit into the small event scenario. The resultant loss of structure or function is what may be expected or anticipated. Code-based designs that anticipate larger event scenarios resulting in larger losses may be deemed acceptable. Such a large event, which is considered highly unlikely, may impose such loading on the structure that mitigating factors are essentially impossible to apply.

If a certain class of buildings is expected to perform better under "large" events, additional protection may be mandated by code (e.g., building codes reflect higher performance requirements for critical facilities, such as hospitals as compared with garages associated with single-family dwellings, even for the same earthquake event) or developed as part of the design process. Where building codes do not already require mitigating measures against disproportionate damage, the topic should be considered by the design team based on building population, location, and other risk factors deemed important to the building or facility.

Protection Against the Spread of Airborne Contaminants*

The nature of mechanical systems is to use networks of pipes and ducts to connect various parts of the building. Even if the systems are off, these networks can provide routes through the building that allow the spread of fire, smoke, and biological or chemical compounds, causing the danger to spread beyond the hazard's origin. A number of building-design elements can limit the likelihood of such systems from spreading fire, smoke, or chemicals through a building:

- Smoke and fire spread can be addressed through the use of automatic dampers that seal ducts at certain points in their routes.
- The spread of chemical or biological agents, smoke, or fire can be limited by designing separate duct networks for different parts of the building.
- The risk of introducing smoke or chemicals into the systems can be reduced by careful location of the air intakes, monitoring of the air intakes, and stringent filtration.

Piping systems for heating, ventilation, and air-conditioning (HVAC) systems are generally closed loops; their contents do not come into contact with air, or people, at any point. The exceptions to this are domestic water systems and open-loop cooling tower systems. As such, most of the risks of spreading contaminants within a building are associated with duct systems. These systems are large and open to the air at many locations. However, many of the risks have been known for some time, and several mitigation measures related to ductwork are addressed within codes and standards of the National Fire Protection Association (NFPA) and of the International Code Council (ICC), including the following:

- *NFPA 5000*
- NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilation Systems*
- NFPA 90B, *Standard for the Installation of Warm Air Heating and Air-Conditioning Systems*
- International Building Code[22]

The American Society of Heating Refrigeration and Air Conditioning Engineers (ASHRAE) has developed guidance regarding HVAC design concepts to help mitigate and control spread of chem-bio agents by way of the ductwork.[38] is one such expert document on this topic.

Further details can be found in Section 8, Chapter 1, "Air-Moving Equipment," and Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems." In addition to circulating air within a building under normal conditions, HVAC systems can also be used for managing the impact of fire and other events. Considerable design guidance is available for the design of smoke control and management systems as well (see References).

*Much of this section is excerpted with permission from Cousins, F., "HVAC System Design for Extreme Events," *Extreme Event Mitigation in Buildings: Analysis and Design,* B. J. Meacham and M. Johann (Eds.), National Fire Protection Association, Quincy, MA, 2006.

Chemical, Biological, Radiological, and Nuclear Sources. The potential for an extreme event involving chemical, biological, radiological, or nuclear (CBRN) substances exists whenever a CBRN substance is present in a building. Triggering of such an event could be the result of anything from an accidental release to someone coming to work sick to a deliberate attack. As with consideration of other extreme events, the assessment and mitigation decision process should begin with a threat, vulnerability, and risk assessment, from which suitable mitigation measures can developed.

Accidental releases could come from spills of common chemicals (such as chlorine) inside or outside of a building as a result of anything from breaking a small storage container (dropping or shaking off a shelf during an earthquake) to a large transportation vehicle crash (truck or train car) in close proximity to the building. In a deliberate attack, agents can be delivered to buildings as packages, by intruders, through vehicles, and by projectiles. There also exists the possibility of airborne transmission of viruses, such as severe acute respiratory syndrome (SARS), influenza and related infectious diseases. To provide protection against CBRN spread, it is important to understand properties of the contaminants as well as release/delivery mechanisms,[19] as different methods of delivery will require different means of hardening the HVAC system.

Protection Against CBRN Spread Initiating Inside of a Building.[39] One of the key issues with HVAC systems is that they link multiple parts of the building together through relatively large pathways (the size of the connection depends on the type of system selected and the way in which the building is normally operated). If an agent is released within a building, then the HVAC systems can provide a path for dispersion to all areas connected to that HVAC system. The most effective way to prevent spreading of the agent is to isolate the systems serving the room in which the agent is released from those serving the rest of the building.[38,40–42] In most buildings, it is not practical to do this for every room within the building, because this would mean providing multiple, extremely large equipment rooms and distribution shafts.

Two scenarios that apply to most buildings, and for which mitigation measures are both inexpensive and effective, are the release of an agent in a delivery area and the release of an agent in a mechanical space. If the agent is brought in through the delivery of a package, then the area where the package is most likely to be opened should be protected. In most commercial buildings, this means that independent HVAC systems should be provided in reception areas, the mailroom, and the loading dock and adjacent receiving areas. These systems should be independent of other areas of the building. They should recirculate air within those rooms only, and all air leaving those rooms should be exhausted from the building. The exhaust outlet should be located well away from any air intakes. These measures will help to control the spread of any agent that is released.

An example of an independent exhaust system used in a reception area is shown in Figure 1.7.14. The figure shows a chemical and biological material released from the outside into the reception area. All air is recirculated within the room, and the room's system does not interface with any other building systems. Of course, management procedures are also required to ensure that all packages are delivered and opened centrally.

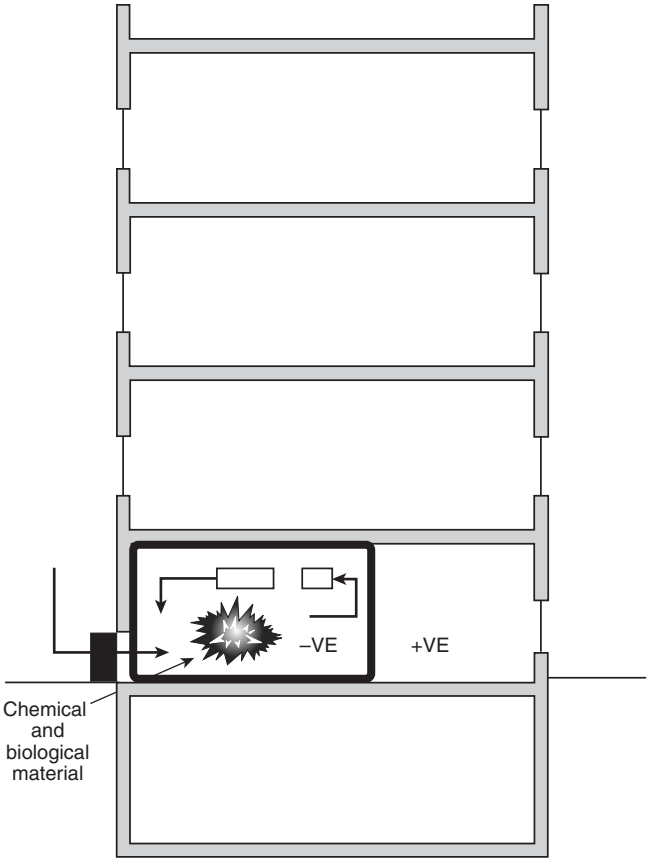

FIGURE 1.7.14 Example of an Independent Exhaust System (Source: Arup)

Another area of high vulnerability is the mechanical room. If an agent is introduced within an air-handling unit, it will be dispersed around the building very quickly. In this case, the risk can best be reduced by controlling access to the mechanical room. The level of access control required will depend on the use of the building.

Consideration should also be given to protection in main building lobbies and security screening areas, particularly if these locations serve as the point for detecting and controlling against introduction of agents into the building. Once access past these points is granted, then the spaces previously mentioned as well as exit stairs that connect the floors of the building can be entered to disperse any agent or substance.

Protection Against CBRN Spread Initiating Outside the Building. All buildings with mechanical ventilation have air intakes. In general, each air intake serves a large portion of the building. The air intake is more critical than the exhaust because it allows a contaminant to be drawn into the building. Air exhausts should also be protected, although to a lesser extent, because they provide weak points for contaminants to enter the building when the systems are off. Several strategies can be ad-

opted to minimize the risk of a containment being drawn into the building, depending on the level of risk associated with the building.

A number of mitigation measures can be provided at minimal cost as part of good-practice HVAC design.[38,40–42] These measures include the following:

- Restrict access to building system plans.
- Locate air intakes away from public access areas.
- Install air intakes at high levels.
- Require security clearance for maintenance personnel.
- Locate air intakes away from horizontal surfaces.
- Provide physical protection of mechanical rooms and air intakes.
- Control supply of air system components.
- Provide surveillance at air intakes.
- Provide multiple air intakes.
- Provide filtration at air intakes.
- Provide protection for incoming potable water supply.

Restrict Access to Building System Plans. Controlling who has access to HVAC system plans prevents an attacker from determining where the intake locations are. It also prevents a would-be attacker from understanding the interconnection of the various areas of the building and knowing the levels of protection that have been put in place. This lack of information makes planning an attack more complicated and increases the likelihood of failure. Information on the following should be restricted: mechanical and electrical systems; elevators; fire, life safety, and security systems; and emergency operations procedures.

Locate Air Intakes Away from Public Access Areas. Air intakes should be located in nonpublic areas. Placement in nonpublic areas prevents an attacker from easily releasing an agent adjacent to the air intake without entering a restricted area. Access management practices can be implemented to reduce the risk of attack.

Install Air Intakes at High Levels. Most chemical and biological agents are heavier than air. Locating the air intakes at high levels, even if they are on a publicly accessible street, reduces the risk of the agent actually entering the building. Figure 1.7.15(a) shows an example of a vulnerable system; Figure 1.7.15(b) shows an example of a more protected system. Figure 1.7.15(c) shows a best-case scenario.

Require Security Clearance for Maintenance Personnel. The mechanical systems of any building are highly vulnerable. All maintenance personnel should be security screened upon employment. Maintenance workers on external contracts should be supervised at all times or be subject to the same security clearances.

Locate Air Intakes Away from Horizontal Surfaces. If an intake is located at a high level, then the easiest way to release an agent into the system is to send a projectile up to the air intake. It is more difficult to do this if there is no horizontal surface on which the projectile can lodge and release the agent. Air intake and exhaust openings should therefore be sloped or vertical.

Provide Physical Protection of Air Intakes. Air intakes should be protected so that they cannot be penetrated by a projectile or other device. Air intakes are usually protected by steel louvers for weatherproofing and have a half-inch metal mesh to prevent birds and vermin from nesting within them. These physical barriers can be strengthened by using heavier gauge meshes and more protective louvers; however, these measures will also increase the required size of the air intake.

Control the Supply of Air System Components. Components that are to be introduced directly into the air system and that require frequent replacement, such as filters, should be bought from reputable manufacturers and inspected for tampering before being used within the system. Such supply management will prevent an agent from being introduced through system components.

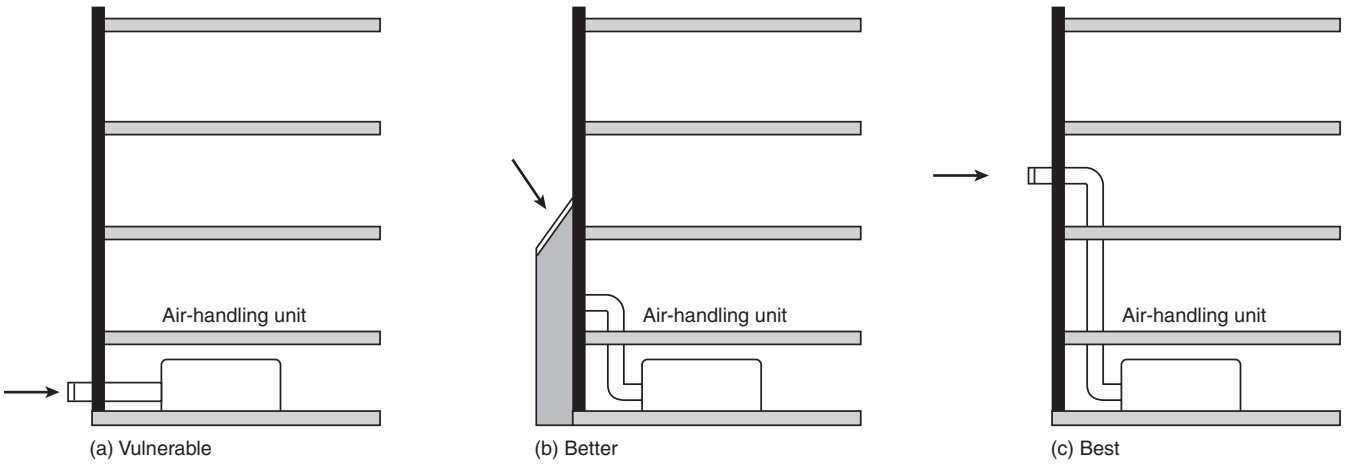

FIGURE 1.7.15 Protecting Air Intake from Airborne CBRN Agent (Source: Arup)

Provide Surveillance at Air Intakes. It is sometimes not possible to locate air intakes away from horizontal surfaces or to protect them from projectile attack. Many building intakes are located at high levels of the building, set back from the edge of the roof. This situation has the advantage of making them invisible to a casual street-level observer and meets the requirement to put them out of a publicly accessible area, but it does not meet the requirement to locate them away from horizontal surfaces. In these cases, the most practical approach may be to provide camera surveillance or motion detection at the air intake. This type of surveillance will shut down the system if suspicious activity is observed.

Provide More Air Intakes. Another strategy is to provide more air intakes, so that the portion of the building impacted by an event is reduced. However, this approach may lead to more complex HVAC systems and additional surveillance requirements, and thus it may not always be a practical solution.

Provide Filtration at Air Intakes. If a chemical or biological agent is released, then it may be possible to prevent the spread of the agent through filtration.[38,40–42] Such protection can be provided through physical filtration (using fibrous filters) or chemical filtration (using chemical reactions to eliminate gases), usually with activated carbon or through the use of UV light to denature bacteria and viruses. In general, a filtration-protection strategy should only be used for high-risk buildings or for high-risk areas within buildings, because it can lead to significant energy use increases and maintenance impacts. Energy consumption increases with the use of physical filters because the filters introduce a pressure drop that the fans within the mechanical systems must overcome. Filtration for chemical and biological agents should be suitable for particle sizes of 0.3 to 35 microns for bacteria and of 0.01 to 0.3 microns for viruses. These sizes are much smaller than the sizes usually filtered out using standard building filters. Filters are rated using the MERV system—a minimum efficiency reporting value. High efficiency particulate air (HEPA) filters are commonly used for this type of filtration.

Protection Against Extreme Fire Events

Protection against extreme fire events is not a new concept. In some respects, current building codes are a reflection of responses to past extreme events. In some cases, protection levels mandated by codes may be adequate for extreme fire events, whereas in other cases additional mitigation measures may be warranted. As with the assessment for disproportionate damage and other threats discussed previously, risk assessment will help inform the need for additional mitigation measures.

Regardless of whether code-based or a result of an engineering analysis and design, key factors for extreme fire event mitigation include redundancy, reliability, and tenability. Almost by definition, an extreme event will significantly stress building systems. As a result, consideration should be given to increased redundancy or diversity of operation, as appropriate given the outcome of a threat, vulnerability, and risk assessment.

Redundancy and diversity of operations are not new concepts in fire and life safety design. The fundamental reason for having two exits from a floor, even if one will suffice based on calculation, is to ensure a measure of redundancy and subsequent reliability. The need for structural redundancy for nonfire loads has long been understood and the cost of such redundancy accepted for essential facilities because the consequences of failure could be disastrous. Many owner-occupied buildings go even further, including redundant systems due to the potential cost of system failure with its consequent business interruption. This is one example of a facilities system that satisfies the "N+1" or even greater concept. For every building, however, building failure after people have escaped has been deemed tolerable for a wide range of hazards such as earthquake or hurricane.

An area that perhaps warrants more attention is fire detection, suppression, and control. The implementation of fire detection and suppression systems, in addition to having some level of structural fire resistance, is accepted for most building types because the benefits are widely understood. It is well known that fire alarm systems detect fire and smoke, that appropriately designed and installed sprinkler systems, coupled with appropriately designed, constructed, and monitored fire-rated systems (walls, doors, opening protection), are enormously successful in controlling fire with resultant savings to life and property. Currently, however, reliability and redundancy within or between these systems are not always required, and where provided, is not always well understood (i.e., sometimes the provision of different types of systems in a "defense-in-depth" approach is confused with redundancy of or within a particular system). Where questions exist, it would be wise to examine the potential implications of the failure of fire detection, suppression, and control systems in buildings, especially those whose occupancy and/or configuration, such as a very tall tower, could pose a greater impediment to successful evacuation and emergency response.

Protection Against Uncontrolled Fire Spread. As outlined in NFPA 550, *Guide to the Fire Safety Concepts Tree,* there are three primary approaches to manage the impact of fire: control the combustion process, contain through construction, or suppress by automatic or manual means (see Figure 1.7.16). Detailed discussion regarding these three approaches is provided elsewhere in this handbook. However, it is worth considering the issues of reliability and resilience of systems in the context of extreme events.

Because even small fires, if uncontrolled, can become extreme fires, it is preferable that fires be quickly detected and suppressed, thus minimizing threats to personal safety and to property. Most high-occupancy or otherwise important facilities are protected throughout by automatic sprinklers and standpipe systems. However, current codes permit the water supply for a sprinkler system to be carried by one sprinkler riser or combined sprinkler/standpipe riser. In an extreme event, it is possible that such a single riser can be compromised, cutting off all water supplies to the entire building sprinkler system, causing the building and its occupants to rely on fire barriers and fire-rated construction of the building structure and means of egress.

Having a backup for suppression systems in the form of redundant fire suppression systems, water feeds or storage, fire-rated construction, or other system is a good thing. However, it

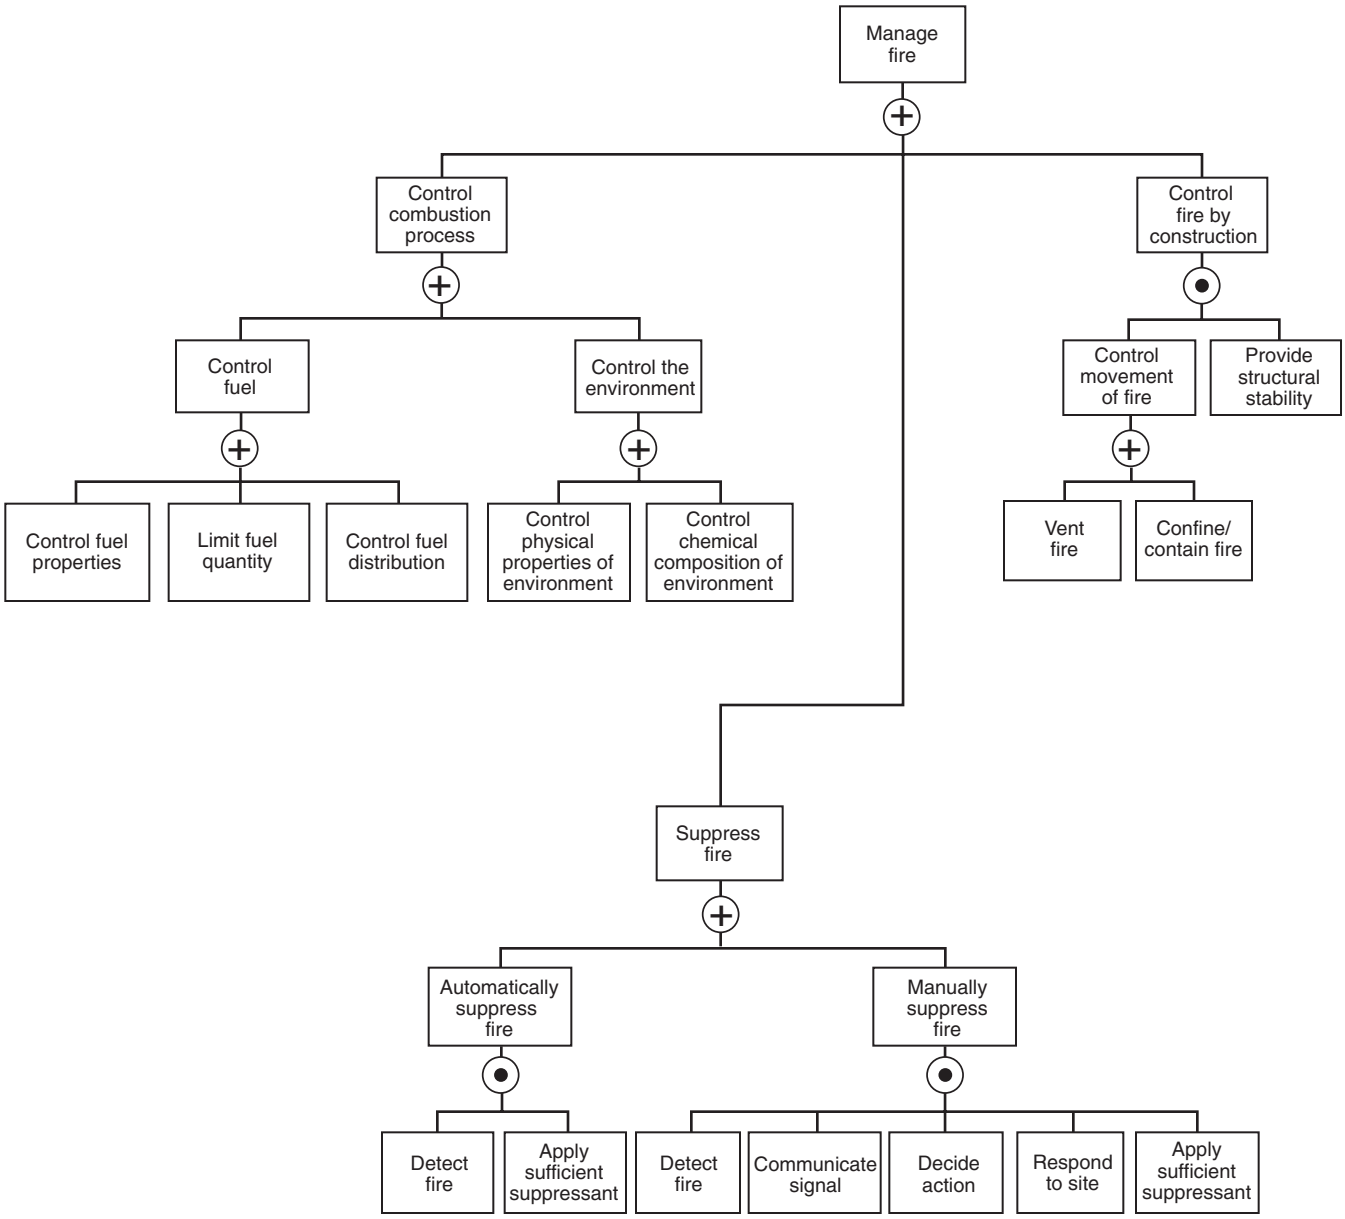

FIGURE 1.7.16 Manage Fire Branch of the Fire Safety Concepts Tree (Source: NFPA 550, *Guide to the Fire Safety Concepts Tree,* Figure 4.5.1)

is also worthwhile to consider increasing the reliability of the suppression system water supply as well, when warranted by a threat, vulnerability, and risk assessment. In buildings of significant concern, such as high-rise buildings, this can be achieved rather cost-effectively in many cases. For example, in most high-rise buildings, a minimum of two stairs are required for egress, and two fire standpipes are required to support fire-fighting operations. Although the stairwells and standpipe risers are already in place, it might be appropriate to increase the reliability and resilience of the sprinkler systems by changing both of the required standpipes into combined sprinkler/standpipe risers, thereby giving the sprinkler system two sources of water.

Protection of Occupants in Place. For many circumstances, especially in high-rise buildings, evacuating occupants on the floor where a hazardous event is occurring and on the floor above and below the event while isolating occupants elsewhere in the building from hazard is a recognized option. See Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies."

The design conditions in this scenario would be those occupants on the three affected floors and those on all other floors. The objective on the affected floors is rather obvious: to separate the occupants from the hazard as quickly as possible. This goal is achieved by maximizing flow through the doors to the vertical exits and down the vertical exits.

Many people who perished on September 11, 2001, in the South Tower of the World Trade Center were likely following directions to remain in place, and consequently it is possible that building occupants will now be less likely to follow directions to remain in place and will take initiative to evacuate a high-rise building in the event of a fire (or other) emergency anywhere in the building. Such a general self-initiated evacuation could impede the egress of people exiting affected floors, and occupants on nonaffected floors may need to be convinced that it is in their best interest, and in the general interest of those at risk, to remain in place. People may be much more likely to choose to remain in place if they are given enough information with which to make a decision and therefore believe that they have taken responsible initiative for their personal safety.[43]

Protection of Occupants by Partial or Full Building Evacuation. Protecting occupants during evacuation is an important role of the egress system, which may include corridors, stairs, and elevators.

Stairs. Quite obviously, one of the keys to a successful full building evacuation is the tenability and the efficacy of the stairs. To maintain tenability, the stair enclosures should remain intact and resistant to damage from fire and from fire-fighting operations in order to maintain fire resistance. The stairs should remain tenable so there is an environment that supports the vigorous physical activity of what can safely be assumed to be a sedentary population, who will require the opportunity to rest in the descent. Therefore, wide landings are advisable to provide such a rest stop.

The stairs also must remain smoke-free to maximize visibility. Visibility must be maintained by effective lighting so that the stairs are bright and remain illuminated under emergency conditions via generators and battery backup in the event of generator system failure. Optional installation of photoluminescent markings on handrails, stair nosing, and other prominent features can also aid in occupant descent.

From the standpoint of smooth flow, stairs should be of a sufficient width to accommodate two large adults walking side by side and therefore many experts believe that the minimum stair width should be increased from the current 44 to 66 in. (112 to 168 cm). At present, both NFPA *101* and *NFPA 5000* have addressed this issue in the interim by mandating stair widths of 56 in. (144 cm) when the cumulative number of occupants expected to utilize the stair is 2000. This moves toward the number previously noted. In addition, the 56 in. (144 cm) width is also expected to improve counterflow of first responders.

Fire Service Elevators. Dedicated elevators have been used for fire service access in the United Kingdom and other locations for decades and there is general interest in employing such elevators for certain classifications of high-rise buildings. Use of dedicated elevators for the fire service may warrant consideration when building-specific risk assessments indicate the need.

Occupant Evacuation Elevators. Unique building configurations could merit the use of occupant evacuation elevators. Such building configurations could be very tall structures with observation decks or other assembly occupancies at the building top. Some jurisdictions require refuge floors (such as Hong Kong) or refuge areas. These refuge areas can be served by occupant evacuation elevators to assist in their evacuation.

In the United States, an effort being coordinated by the American Society of Mechanical Engineers (ASME) is under way to make occupant use elevators a practical option in future tall building design. Task group efforts and work are expected to introduce basic provisions for hardened fire service elevators and occupant evacuation elevator concepts in the next editions of NFPA *101*, *NFPA 5000*, and the IBC.

Emergency Responder Considerations

When considering design for extreme events, discussions with the fire department and other emergency responders should be held early in the design process to assist in addressing their concerns and requirements as they may pertain to a building or facility, and to be able to incorporate these into the design early on. There are several building systems and features that can assist emergency responders in being able to conduct their work, including the following:*

- Fire department notification system
- Mass notification systems
- Site and building access
- Fire command center
- Internal communication systems
- Fire protection equipment
- Water supply
- Smoke purge systems
- Emergency response plans

Notification. Automatic fire department notification is helpful in giving the fire department and other emergency responders early and rapid notification of a fire or other event. Such a system will typically be triggered from an internal building system, such as fire detection or suppression system activation. In some cases, manual fire department notification may be used, particularly when internal alarms go to a central supervised location within the building (such as a security desk) or to a remote supervisory station.

Mass Notification Systems. These systems can be used to alert occupants in multiple buildings or campus-style compounds of a threat that may affect more than one building or area. The systems may direct the occupants to a safe area, such as an underground parking garage for an imminent hostile threat or to site-specific areas away from the threatened building or area.

Site and Building Access. Easy access onto the site, into the building, and to the area of fire origin should be provided for

*Much of this section is excerpted with permission from Marrion, C., and Custer, R., "Design to Manage Fire and Its Impact," *Extreme Event Mitigation in Buildings: Analysis and Design,* B. J. Meacham and M. Johann (Eds.), National Fire Protection Association, Quincy, MA, 2006.

the fire department and its equipment. Security gates, bollards, locked doors, and other security systems, which can help limit incidents, can delay response to the area of origin. Care should be taken to address these "competing objectives" during design, making sure security systems can be controlled as needed to facilitate emergency responder access into controlled areas.

Fire Command Center. A fire command center or area set aside as a control area is required in high-rise buildings. Depending on the building, its type of occupancy, susceptibility to various threats, and so on, it may also be beneficial to have a command center from which emergency responders can stage their operations. This area should contain appropriate equipment, including status indicators and controls for all appropriate fire protection equipment. The fire command center should be large enough to allow responders to undertake necessary operations.

Equipment. It may be necessary to provide equipment on site to assist fire fighters in their operations. This equipment may include standpipes and hose connections, internal communication systems, equipment storage cabinets, and so on. On-site access can assist emergency responders in reducing the time to get equipment to the area of origin, as well as assist them in undertaking their operations.

Water Supply. Adequate water supply should be provided on site. This includes not only a municipal supply but also may include on-site storage tanks. The equipment necessary to access the water supplies inside and outside of the building, including hydrants, siamese connections, and standpipes, should be accounted for in the design.

Smoke Purge Systems. In some buildings, it may be appropriate to provide means to clear the resultant smoke and heat generated during fire-fighting operations to facilitate fire fighting and search and rescue operations. Smoke purge systems may be appropriate in such cases.

Emergency Response Plans. Emergency response plans should be developed for the individual building. Planning and training internally, as well as with emergency responders, will help in managing an incident more effectively. This training may include pre-incident planning to assist emergency staff and building personnel in understanding the building, its fire and life safety systems, particular hazards, key structural elements, and events that could impact critical equipment.

A more comprehensive treatment of egress issues, including use of elevators for egress can be found in the text *Egress Design Solutions,*[44] the *Life Safety Code® Handbook,* the *SFPE Handbook of Fire Protection Engineering,*[45] and Section 4 of this handbook.

Protection Against Unauthorized Access

There are four primary strategies for protecting against unauthorized entry to a building: deter, delay, detect, and prevent.[23] Also see NFPA 730, *Guide for Premises Security,* NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs,* as well as Section 1, Chapter 6, "Premises Security," and Section 14, Chapter 10, "Security and Intrusion Detection Systems."

Deterrence focuses on providing a visible presence of security, with the aim of making a potential aggressor "think twice" about trying to gain entry. This presence can range from a security force to CCTV, bollards, lighting, or other measures that are visible to a potential aggressor. *Delay* reflects strategies that will slow an attack. Delay strategies include bollards or landscaping to hinder vehicle approach, access control, turnstiles, and similar measures aimed at slowing and restricting access. *Detection systems,* such as X-ray, gamma-ray and other screening tools, glass-break detectors, door contacts, smoke detectors, explosive detectors, and chemical detectors, are used to detect the presence of a threat within a facility. As a final measure, *prevention* means hardening; it is intended to mitigate consequences should a threat scenario be realized. Prevention can include a variety of physical measures, from structural hardening to fire protection systems to heating, ventilation, and air conditioning (HVAC) system filters, dampers, and controls, as described earlier in this chapter.

In many cases, it is appropriate to implement the concept of *concentric rings of protection* or *defense in depth,* with critical assets located in the core and layers of protection surrounding the asset, in concert with deter, delay, detect, and prevent strategies. This concept is illustrated in Figure 1.7.17. In all cases, the details of security design should be based in a comprehensive threat, vulnerability, and risk assessment focused on the building, its location, and its security needs. Section 14, Chapter 10, "Security and Intrusion Detection Systems" includes in-depth discussion of these concepts.

Providing for Business Continuity

In addition to considering the impacts from extreme events on buildings and their occupants, it is often important to consider the impacts to whatever business operations may be housed within a building as well. This is especially important for owner-occupied buildings and facilities, but should also be a consideration for those looking to lease space in a facility. It is important because building codes are typically focused on life safety issues, with some property protection components, but do not explicitly consider impacts to the businesses operating within the building.

For normal-hazard events, the protection afforded by meeting the code can usually provide some level of protection for the business operations as well. For extreme events, it may not be reasonable to assume protection is afforded at a related level. For example, in a severe earthquake, flood, or fire, the building may be designed to allow people to escape, but the building may verge on collapse and the contents totally lost. If this is unacceptable to the mission of a business, additional protection may be warranted.

For many organizations, the focus for business continuity is on the impact to the business in terms of loss of equipment and operations, loss of contents, and related factors associated

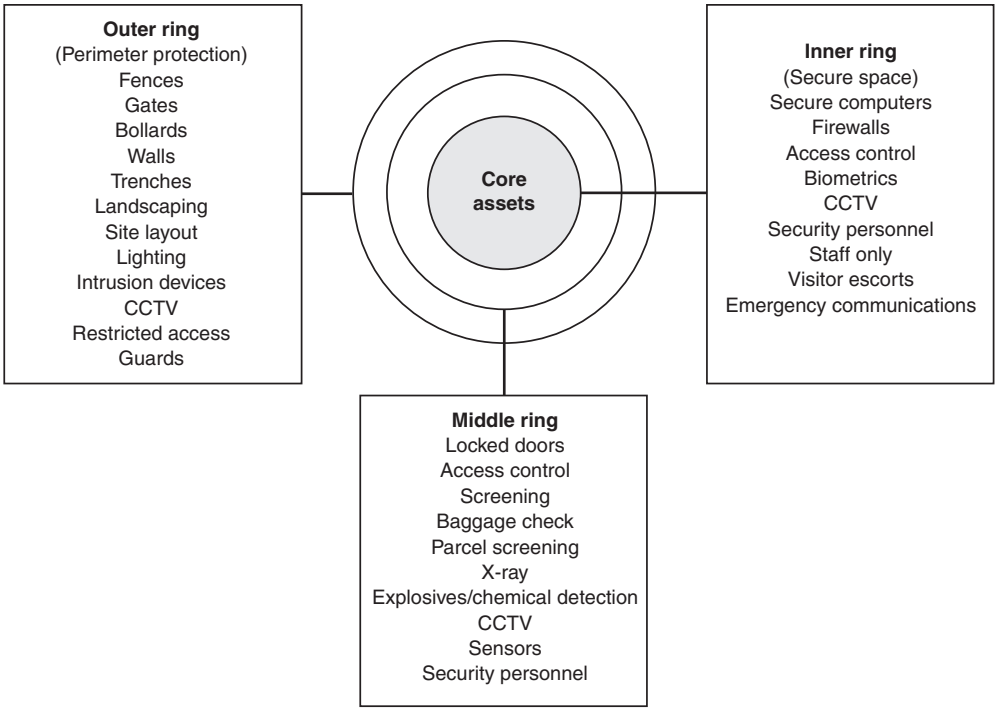

FIGURE 1.7.17 Rings of Protection/Defense in Depth (Source: Arup)

with total downtime and return to operations (in addition to life safety and property impact concerns). A core question for starting the process concerns how big a loss can be tolerated over what period of time. The answer will depend on the business and can be addressed in various ways, from interruption in activities, to loss of contents, to impact on the customer base. Some factors to consider include the following (these will vary by business type):

- Value of stored material (including how valued and by whom)
- Loss impact in terms of material worth (i.e., replacement cost)
- Impact of loss on supply chain (i.e., replacement time, end product cost)
- Loss impact of potential changes in market perception (i.e., reliability, continued service)
- Value of operations equipment (including how valued, replacement cost, and replacement time)

As part of establishing business continuity objectives for extreme event scenarios, decision makers should determine to what extent the organization understands and values the facility, its contents, and operations (i.e., where does the facility fit within the big picture of organizational goals and objectives), as well as how much impact the facility can have on the big picture if significantly damaged, which can then inform mitigation design and other risk management decisions. A more comprehensive treatment of assessment for business continuity can be found in NFPA 1600 and Section 1, Chapter 8, "Emergency Management and Business Continuity."

SUMMARY

This chapter has outlined a variety of measures available to help protect buildings and their occupants against the impacts of extreme hazard events. Given the nature of extreme events, issues have been raised for consideration and not necessarily for application in every situation. Societal expectations can further affect this process if an outcome of an extreme event is large life loss. Engineering methods, design approaches, and operational considerations are always under scrutiny to determine if the best and most appropriate measures are being considered.

Emergency management and business continuity planning is necessary for all entities public and private. Emergency response is typically a site-level function, whereas business continuity may permeate multiple levels of an organization depending on the nature of the business and the arrangement of critical business functions. A crisis management team comprised of senior managers will command the organization's response to enterprisewide threats including those that threaten an organization's brand, image, or reputation.

An emergency management and business continuity program requires an assessment of hazards to people, property, business operations, and the environment. Knowledgeable people, systems, and equipment are needed to detect threats, warn occupants to take protective action, alert response teams, and stabilize the incident. Threat-specific response procedures must be implemented to protect occupants at risk, emergency responders, facilities, operations, and the environment. An incident management system is required to manage the response and recovery effort and coordinate the efforts of internal and external responders.

A program requires training all personnel on basic protective actions including evacuation, shelter-in-place, and lockdown. Those with a role in the program must be trained to discharge their duties. Leaders must have the highest level of training to enable them to assess a developing situation, direct resources to stabilize the incident, and recover the organization. A combination of training, drills, and exercises is necessary to build and maintain the competencies necessary to carry out the program. Periodic evaluation and updates are necessary to keep the program current.

This chapter defines the essential elements of an emergency management and business continuity program. It also describes a process for development and implementation of a program that incorporates the essential elements.

For additional information on related topics, see Section 1, Chapter 6, "Premises Security"; Section 1, Chapter 7, "Protecting Against Extreme Events"; Section 4, Chapter 5, "Strategies for Occupant Evacuation During Emergencies"; Section 10, Chapter 1, "Emergency and Standby Power Supplies"; Section 12, Chapter 12, "Disaster Planning and Response Services"; and Section 12, Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response."

PROGRAM MANAGEMENT

Goals and Objectives

There are numerous goals and objectives for an emergency management and business continuity program. Many are interrelated. Some are optional, others are mandatory. At the very least, businesses must protect their employees and occupants within their buildings. Individual companies may decide that they cannot tolerate any downtime. As a result, they invest substantially to mitigate hazards and implement robust emergency response and business continuity plans.

Unfortunately, all hazards cannot be mitigated, and most companies cannot afford the redundancy necessary to prevent any possibility of business interruption. Choices must be made that are

Donald L. Schmidt is CEO of Massachusetts-based Preparedness, LLC. He is chair of the Technical Committee on Emergency Management and Business Continuity, which is responsible for NFPA 1600, and the editor of *Implementing NFPA 1600: National Preparedness Standard.*

mindful of business goals and objectives, financial constraints, corporate culture, management support for the program, geopolitical events, economic conditions, regulatory requirements, and industry practices. The following are typical objectives for an emergency management and business continuity program:

- Protect the health and safety of people, including emergency responders and the community surrounding the facility
- Stabilize an incident, or at least prevent a bad situation from deteriorating
- Support public emergency services and others who stabilize the incident
- Understand hazards and the potential impacts of hazards
- Identify prevention and mitigation opportunities and pursue them, if economically feasible
- Prevent or minimize damage to property, including buildings and their contents
- Prevent any business interruption, or at least minimize the impact of hazards on business operations
- Prevent environmental contamination
- Protect market share
- Minimize financial loss
- Protect brand, image, and reputation
- Comply with contractual or customer requirements
- Comply with regulatory requirements
- Act as a responsible corporate citizen

As a minimum, goals should include protection of people, property, and the environment from foreseeable hazards. This includes safeguarding people, including employees, guests, contractors, visitors, and the community that surrounds the facility as well as emergency responders. Protection of physical assets could include facilities, machinery and equipment, raw materials and finished goods, and operations within the facilities. Environmental protection includes the prohibition of any discharge into the air, ground, or bodies of water. Protection of an organization's image, reputation, market share, and shareholder value may also be included. Whether stated or not, all organizations must comply with laws, rules, and regulations promulgated by local, county, state, or federal governments.

Administration

Management's Role. The foundation of an emergency management and business continuity program is management commitment, direction, and support. Management must set policy, appoint a program coordinator and advisory committee, and provide funding for prevention, mitigation, planning, training, equipment, supplies, and other resources. Managers must be held accountable for development of the program and for keeping it current.

Policy Statement. Development of an emergency management and business continuity program begins with senior management endorsing the program and outlining goals, objectives, and their support in a policy statement. The policy should define the vision of the organization and vest authority in those responsible for the program so they can develop the program and keep it current. This includes the authority to take immediate action to protect the health and safety of people.

Laws, Regulations, and Industry Codes of Practice

Many laws, rules, and regulations have been promulgated at the federal, state, and local levels of government for risk assessment, prevention/deterrence, mitigation, emergency response, business continuity, and recovery. Many of these statutory requirements focus on emergency response and include requirements for protection of people and protection of the environment. The Occupational Safety and Health Administration's (OSHA) "Emergency Action Plans" standard prescribes basic requirements for evacuation planning and accountability. Numerous other OSHA standards prescribe requirements for risk assessment, mitigation of hazards to employees, and emergency planning.

Fire prevention codes including NFPA 1, *Uniform Fire Code*™, and the *International Fire Code* have been adopted across the United States and include basic requirements for emergency response planning. Many states and some cities have amended model codes to include more stringent requirements. Some cities have also adopted local ordinances under the name of "homeland security," requiring enhanced planning, training, or drills to prepare for acts of terrorism or other extreme events.

The National Commission on Terrorist Attacks Upon the United States (the 9/11 Commission) recommended that NFPA 1600, *Standard on Disaster/Emergency Management and Business Continuity Programs,* be recognized as the U.S. national preparedness standard.[1] The recommendation was adopted within the National Intelligence Reform Act of 2004.[2] The Canadian Standards Association has licensed NFPA 1600 for the development of a new voluntary Canadian National Standard. NFPA 1600 is also one of five international standards used as the source for the new International Standards Organization (ISO) Standard 223 "Societal Security—Guidelines for Incident Preparedness and Operational Continuity Management."

There are numerous standards, guidelines, and recommended practices published by industry groups for their members. Many industry groups have published standards for risk assessment and loss prevention/mitigation, including security, emergency response, and business continuity. For example, the chemical industry has published guidelines and best practices for emergency response for decades. Banking and financial services industries have an integrated, deep-layered plan to ensure that the U.S. banking system remains viable during any event—regardless of size and magnitude. Following the terrorist attacks of September 11, 2001, additional regulations were promulgated to protect privately owned and controlled critical infrastructure.*

*Critical infrastructure includes banking and financial services; energy (electrical power, oil, and gas production and storage); public health; information and telecommunications; water supplies; agriculture; and transportation (aviation, rail, mass transit, waterborne commerce, pipelines, and highways).

Emergency Management Codes, Standards, Recommended Practices, Laws, and Regulations. The following is a listing of various emergency management codes, standards, recommended practices, laws, and regulations:

Business Continuity Best Practices and Standards. The following is a listing of various business continuity best practices and standards:

- *Good Practice Guidelines, A Framework for Business Continuity Management,* 2005, The Business Continuity Institute, http://www.thebci.org/gpgdownloadpage.htm
- *Professional Practices for Business Continuity Planner*s, 2004, Washington, DC, DRI International http://www.drii.org/displaycommon.cfm?an=2
- ANSI/ARMA 5-2003, Standard for Records and Information Management; ANSI/ARMA 5-2003, Vital Records Programs: Identifying, Managing, and Recovering Business-Critical Records, Lenexa, KS, ARMA International

Organization

Development, implementation, and maintenance of an emergency management and business continuity program require personnel with technical knowledge of the organization, its facilities, operations, resources, and hazards as well as persons knowledgeable in emergency management, business continuity, and crisis communications. The organization should reach out to public agencies, solicit their input on plan development, and coordinate operational procedures. Advance planning and coordination is essential for effective incident management. Table 1.8.1 provides a listing of potential internal and external participants in the development of an emergency management and business continuity program. Key to a well-organized program is the appointment of a program coordinator, the appointment of an advisory committee, and sufficient funding for the development and maintenance of the program.

Program Coordinator. The organization should appoint a program coordinator to develop the program under the direction of the advisory committee. Often multiple persons are assigned to develop components of the program including environmental, health, and safety (EHS), medical, risk management (RM), and security staff. Separate emergency response, business continuity, and crisis management teams organized within different levels of the organization are common. However, all teams, organizations, and plans must be carefully coordinated for effective response.

Advisory Committee. An advisory committee should be appointed to provide direction for, and assist with, development of

TABLE 1.8.1 Program Participants

	Vendors

the program. The committee should establish objectives for the program consistent with senior management's vision as written in the policy statement.

The advisory committee should identify resources from all functional areas of the organization that may be needed to develop the program, mitigate hazards, or respond to or recover from an incident. The committee can assist with the coordination of intradepartmental activities and should oversee the periodic evaluation and revision of the program.

Finance and Administration. Sufficient funding is necessary for the development and maintenance of the program. Senior management must appropriate funding to meet minimum statutory requirements. The program committee should also recommend appropriation of additional funds for prevention and mitigation of hazards and enhanced planning commensurate with the organization's financial situation, risk profile, risk management program, and tolerance for risk. Success of the program in the long term depends on continued funding. The program coordinator and advisory committee must continually assess funding needs to keep the program current and inform senior management to ensure sufficient funds are appropriated.

Procurement and accounting procedures should be established to support the program. This includes establishing a budget that does not penalize any department that bears responsibility for developing the plan. The program benefits all, and costs should be allocated to all departments. Authority levels and procedures for approval of monetary expenditures should be established to support the program and to expedite procurement during an incident. Procurement procedures should comply with governance standards even during emergencies.

RISK ASSESSMENT

Understanding the hazards that could injure people, damage facilities, interrupt business operations, contaminate the environment, or injure the brand, image, or reputation of the organization is a prerequisite for further planning. A thorough risk assessment should begin with the identification of hazards; quantification of their probability of occurrence; and estimation of their potential impact on people, property, the environment, and the organization itself.

Hazard Identification

There is a long list of potential hazards, including naturally occurring, human-caused, and technological events. For most hazards, there are varying probabilities of occurrence and severity of impacts. The challenge of risk assessment is to identify credible hazards and realistically assess potential impacts. An assessment of vulnerability is necessary to estimate the impact of a hazard (Table 1.8.2).

Vulnerability Assessment and Impact Analysis

Vulnerability assessment and impact analysis are the next steps in the risk assessment process. The vulnerability of an asset to a specific hazard and the magnitude of that hazard will determine its potential impact. Prevention and deterrence may reduce the probability of hazard occurrence but do not reduce the impact or severity of consequences. Mitigation efforts can reduce vulnerability or reduce the impacts.

An assessment of assets at risk (e.g., people, including emergency responders; property; operations; the environment; and the organization itself) will identify opportunities for prevention/deterrence and mitigation. The impact analysis will also identify assets that may be damaged, disrupted, or interrupted, requiring business continuity planning.

The vulnerability assessment requires technical expertise to understand the characteristics and variability of each hazard and how each hazard can injure people and or damage buildings, equipment, and critical infrastructure (Figure 1.8.1). The analysis should also evaluate the impact of each hazard on business operations, the ability to deliver services, and potential financial consequences. Environmental contamination resulting from overpressurization, explosion, ruptured piping or tanks, spillage or release of materials, fire protection water runoff, flooding, or other means must also be considered.

The impact analysis should evaluate the loss of single or sole source suppliers, damage to raw materials, the interruption of utility systems, damage to machinery and equipment essential to production, and the loss of people and their technical knowledge. The analysis should also consider critical timing when a loss would have the greatest impact on operations and financial results. Critical times may be seasonal (in preparation for or during the holiday shopping season), at the end of accounting periods, or as a new product or service is launched.

The organization must also assess the scenarios that could injure its brand, reputation, or image. Consider loss of customers, lost market share, failure to meet contractual obligations, or regulatory fines or penalties. Allegations of a product defect, whether substantiated or not, can scare away customers. Misconduct or impropriety of senior management could result in fines or penalties and jeopardize the future viability of a company.

Natural disasters such as Hurricane Katrina or a significant act of terrorism can wreak havoc in a widespread area and impact commerce nationwide. The hazard assessment and impact analysis must look beyond the property line to identify scenarios that could damage more than one facility owned or operated by the entity or prevent suppliers from shipping critical raw materials or subassemblies. Also important is an assessment of the impact resulting from interruption of critical infrastructure including transportation systems, energy supplies, telecommunications, and financial services.

PREVENTION AND MITIGATION

Emergency management and business continuity planning is not simply reactive. Prevention/deterrence and loss mitigation are important elements of a successful program. The risk assessment process provides an excellent opportunity to identify opportunities for prevention/deterrence and mitigation.

Site Selection and Code Compliance

Prevention and mitigation begin with the selection of a site for a new building. Building in an area that is less prone to natural

TABLE 1.8.2 Hazards

Medical emergencies
- Injury
- Illness
- Foodborne illnesses (mass)
- Disease pandemic

Fire or explosion
- Explosion
- Bomb explosion
- Fire
- Wildfire

Buildings and equipment
- Structural failure or collapse
- Entrapment
- Mechanical breakdown

Transportation incidents
- Motor vehicle
- Railroad
- Watercraft
- Aircraft
- Pipeline

Hazardous materials
- Hazardous material spill/release
- Radiological incident
- Hazmat incident off-site
- Nuclear power plant incident
- Natural gas leak

Meteorological
- Severe thunderstorm
- Tornado
- Lightning
- Flooding
- Dam/levee failure
- Windstorm
- Hurricanes and tropical storms
- Winter storm (snow/ice)
- Drought
- Climate change

Geological
- Earthquake
- Tsunami
- Landslide
- Subsidence/sinkhole
- Volcano

Security
- Labor strike
- Demonstrations
- Civil disturbance (riot)
- Bomb threat
- Lost/separated person
- Child abduction
- Kidnapping
- Extortion
- Hostage incident
- Workplace violence
- Robbery
- Sniper incident
- Terrorism
- Arson
- Crime or theft
- Sabotage or vandalism

Utility interruption or failure
- Communications
- Electrical power
- Water
- Gas
- Steam
- Heating/ventilation/air conditioning
- Pollution control system
- Sewage system
- Other critical infrastructure

Supplier failure to perform
- Loss of key supplier/customer
- Loss of shipping or transportation

Computer systems
- Hardware failure
- Data corruption
- Power surge
- Lightning
- Loss of or lack of capacity
- Host site interdependencies
- Direct physical loss
- Systems outages
- Firewall, ID check
- Water damage
- Cyberterrorism
- Passwords, access, data backup
- Computer fraud
- Loss of encryption
- Denial of service
- Improper system use by employee
- Telecommunications interruption or failure
- Loss of use of critical equipment
- Vendor failure (single or sole source provider)
- Internet service provider
- Inadequate supervision
- Electricity brownout or blackout

Employment practices
- Privacy
- Harassment

Financial
- Investments and financial instruments
- Financial transactions

Product, professional, contractual liability, and directors and officers liability
- Product liability or warranty
- Contractual liability
- Architect/engineering
- Directors and officers liability
- Libel or slander
- Fraud

Intellectual property
- Copyright/patent infringement
- Trademark infringement
- Theft of intellectual property
- Theft of information

Strategic risk
- Mergers and acquisitions

Regulatory, societal, and technological change
- Regulatory changes
- Societal change
- Technological change
- Economic change

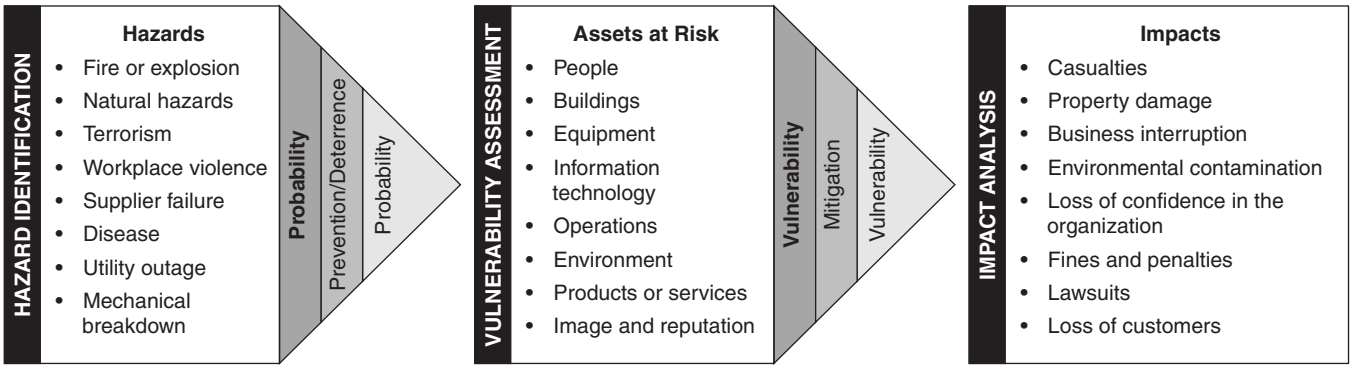

FIGURE 1.8.1 Risk Assessment Process (Source: Donald L. Schmidt, Preparedness, LLC)

hazards can reduce or eliminate damage from earthquake, hurricane, flooding, landslide, or wildfire. Constructing and operating buildings, systems, and equipment in accordance with applicable building codes, fire prevention codes, and environmental regulations will help protect people, property, and the environment. Replace hazardous materials such as flammable liquids and gases with less hazardous materials.

Physical, Operational, and Cyber Security Factors

Physical, operational, and cyber security should be addressed within a comprehensive program. Careful layout of buildings on the property and the arrangement of roadways, parking areas, landscaping, lighting, walls, and doors can reduce crime and limit exposure to some acts of terrorism. Concepts of Crime Prevention Through Environmental Design (CPTED) can be followed to reduce the incidence of crime. NFPA 730, *Guide for Premises Security,* provides general guidance for all types of facilities and specific guidance for individual occupancies. Section 1, Chapter 6, provides additional guidance on these subjects.

Surveillance of the perimeter of buildings and access points can detect potential problems allowing intervention. Surveillance technology can act as a deterrent and provide information to identify perpetrators and provide evidence for prosecution of criminals.

Buildings can be built with fire-rated walls to separate high-hazard operations from low-hazard operations, or high-hazard operations can be located in detached buildings. Hazards should be protected in accordance with the latest codes and standards. Protective systems should be installed to detect incipient problems, notify operators to respond, warn occupants to evacuate, suppress a fire or explosion, or contain runoff of hazardous materials.

Identify critical information sources including vital records and drawings as well as electronic data, and ensure backups are securely stored off site. Duplication or redundancy of essential personnel, critical systems, equipment, information, operations, or materials provides an immediate backup in the event of loss or damage.

RESOURCES

Resource Inventory and Constraints

Many resources are required to support the emergency management and business continuity program. These include people with expert knowledge; surveillance, detection, alarm, notification, warning, communications, suppression, and other systems; facilities including an emergency operations centers for managing an incident; information about hazards, systems, and equipment; and intelligence* about developing threats.

One of the most important resources is sufficient funding for all facets of the program. Senior management must be aware of resource needs and the cost to procure, prepare, maintain, and deploy resources.

Resource constraints must be understood and planning must be commensurate with the expected resource limitations. Will the resource be available when needed? Can a trained and certified medical team respond within 4 to 6 minutes with an automated external defibrillator (AED) to resuscitate a heart attack victim? How many trained medical responders and AEDs do you need to respond to all employees on all floors of all buildings? What is the cost for providing an AED and the annual training required to certify sufficient responders? Is the automatic sprinkler system properly designed to control a fire involving racked storage of flammable liquids? What liability could the organization accrue if personnel are injured in the performance of their emergency response duties?

Maintain an inventory of all resources and use the inventory when auditing the program to verify that all resources are available, immediately accessible, and reliable.

GAP Analysis

GAP analysis has become a common term to describe a review of a program or program element for the purpose of determining whether the program or an individual element is sufficient to meet the intended need. Applied to emergency management and business continuity program resources, a GAP analysis is used to identify any shortfalls in the quantity, response time, capability, limitations, cost, or liability associated with required resources. A strategy should be developed to acquire sufficient resources or adjust plans and procedures to overcome any limitations or shortfalls.

Mutual Aid

Mutual aid agreements with other organizations with similar facilities, systems, or equipment may be one means of responding to an emergency or restarting business operations while a facility is recovering from a loss. Neighboring facilities, businesses, or even an organization's competition may provide assistance by providing personnel, equipment, or supplies for response to fires and other emergencies. This is common with high-hazard industrial facilities located remotely from capable public fire suppression services. Mutual aid agreements can be used for continuity of critical functions by sharing facilities, use of machinery and equipment, or production of common products.

Mutual aid agreements should be in writing, reviewed by legal counsel, and signed by an authorized manager. Agreements should define liability and detail funding and cost arrangements. In addition, agreements should define authority, roles, responsibilities, procedures, communications, resources, and required qualifications.

PLANNING

Depth and Complexity of Planning

The depth and complexity of planning are dependent on the organization, the hazards and vulnerability of the organization's

*Information Sharing and Analysis Centers (ISAC) have been established to advance the physical and cyber security of the critical infrastructures of North America. ISACs provide and maintain a framework for valuable interaction within individual industries and with government. Information on the ISAC Council can be downloaded from http://www.isaccouncil.com/sites/index.php

facilities, the protection of facilities, the availability and capability of external resources, and the tolerance for interruption of business functions. The depth of planning also depends on regulations and the philosophy and culture of the organization. Planning is required at all levels, and coordination and connectivity of plans and organizations at each level are needed to ensure prompt, efficient, and effective response and recovery. There are four levels of planning: strategic, crisis management, emergency response, and business continuity.

Strategic Plan. A strategic plan is overarching and developed at the highest level of the entity. It includes the goals and objectives of the emergency management and business continuity program. It sets minimum performance standards for, and defines the role and responsibilities of, the corporate, business units, and individual facilities for prevention, mitigation, emergency response, business continuity, and crisis management.

Crisis Management Plan. A crisis management plan protects the entity from serious threats to brand, image, or reputation. A crisis may arise from a single event such as a serious fire, hurricane, act of terrorism, or widespread environmental contamination. It may arise from allegations of a product defect or product contamination. Acts of impropriety or allegations of systemic discrimination or harassment have been headline news for a number of major corporations. Financial and strategic risks, however, are often the leading cause of corporate crises. A crisis evolves when the scope of the event or series of events is widespread or the impact on the entity as a whole is significant.

Crisis communications is an important element of the crisis management plan designed for communications with internal and external audiences. Internal audiences include employees, and external audiences include the news media, stakeholders, customers, suppliers, and regulators. The crisis communications plan assigns responsibility to a spokesperson, includes scripts for potential scenarios, procedures for the release of information, and a system for tracking issues that develop over time.

Emergency Response Plan. Develop an emergency response plan for every facility. Since hazards vary by geography and facility, emergency response plans must be customized for each facility. The functions and level of response of the emergency organization should be commensurate with the magnitude of hazards, the availability and capability of internal and external resources, and the adequacy of funding. Every facility should have an emergency response plan with protective actions including evacuation and accountability of building occupants, shelter in place, and lockdown.

Business Continuity Plan. Business continuity plans include strategies, resources, and procedures for maintaining and restoring critical functions that enable the entity to fulfill its mission or achieve its business objectives. Information technology is central to many business continuity plans, but it is not the sole focus of business continuity plans. The impact analysis should identify critical functions and the time frame for restoration of functions before irreparable harm is done to the entity. Business continuity plans must define the alternate operating strategies, necessary resources, and procedures to overcome interruption or disruption of all critical functions.

Direction, Control, and Coordination

Incident Management System. Successful stabilization of, and recovery from, an incident requires effective management and direction of the organization's resources in coordination with external resources called to assist.

A small-scale incident can be managed by one person with the support of others. One person alerts the first aid team to respond to the location of the victim and dials 9-1-1 to request an ambulance. A first aid team responds to the victim and administers first aid and directs paramedics or EMTs to the scene. Larger-scale incidents require more resources, and management of additional resources becomes more difficult. A scalable incident management system is essential to effective management of the incident.

Within the United States, the National Incident Management System (NIMS) was developed following the terrorist attacks of September 11, 2001. NIMS is a national approach to incident management applicable at all jurisdictional levels and across functional disciplines. NIMS is applicable across a full spectrum of potential incidents and hazard scenarios, regardless of size or complexity, and it was designed to improve coordination and cooperation between public and private entities.

Small incidents may be handled solely by the business without any intervention from public agencies. Larger-scale incidents that overtax the resources of the business require the resources of local public agencies. Resources—public and private—will be managed by the public sector incident commander. Incidents involving or potentially involving mass casualties, widespread property damage, or widespread economic impact, such as natural disasters, acts of terrorism, and public health emergencies, most likely would be managed by a combination of state and federal agencies and resources. Responses to the terrorist attacks of September 11, 2001, and Hurricane Katrina are examples.

The incident command system (ICS) is a component of NIMS. ICS defines the operating characteristics, interactive management components, and structure of incident management engaged throughout the life cycle of an incident. ICS integrates a combination of facilities, equipment, personnel, procedures, and communications operating within a common organizational structure, designed to enable effective and efficient incident management.

The organizational structure necessary to carry out an incident action plan develops from the incident commander down, as the size and complexity of the incident increase and the need for additional resources expands (Figure 1.8.2). ICS's organizational structure includes five major functional areas: command, operations, planning, logistics, and finance/administration. The command function fulfilled by the incident commander is supported by staff, including public information officer, safety officer, and liaison officer.

Within these five functional areas, branches may be established. For example, the operations section can be expanded

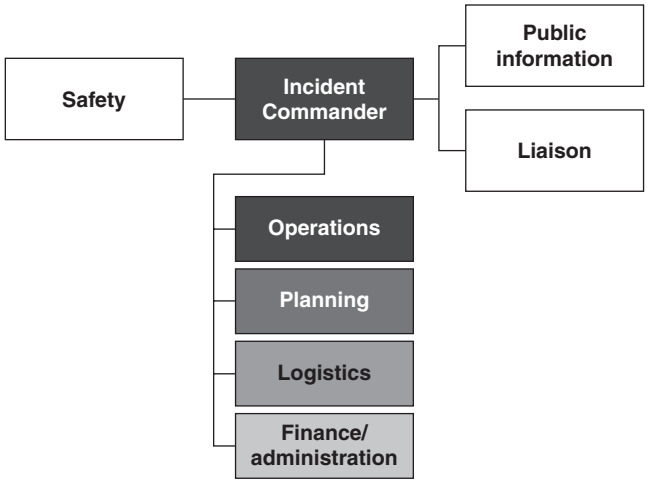

FIGURE 1.8.2 Incident Command Organization

into branches for protective actions for life safety, supervision of building systems and utilities, and site and building security. The expansion of the organization enables a manageable span of control. With the assignment of additional managers, one person is not overwhelmed with more responsibilities than can be effectively managed.

A defined command structure ensures there is an orderly line of authority for decision making. In the private sector, this is especially important since the traditional management structure may not work well during an emergency. Authorization to warn occupants to take protective action (e.g., evacuate a building) must be vested in the leader of the emergency response team who also serves as incident commander. Any delay in the order to evacuate a building at risk may endanger building occupants and first responders.

Transfer of command to the first arriving fire department or law enforcement officer and subsequently to the highest-ranking officer in charge continues this process and ensures there is a clear authority in charge who is properly briefed and able to command all resources. As additional resources from multiple departments, functional areas, or jurisdictions arrive on scene, unification of command authority becomes necessary. A unified command structure enables all to identify incident objectives, determine resource objectives, develop a consolidated incident action plan, and work jointly toward stabilization of the incident.

Management of an incident requires facilities where the leader and members of the emergency response, business continuity, and crisis management teams can assemble or confer to assess the situation, develop the incident action plan, and direct resources. Responses to site level emergencies require identification of an incident command post—the location in proximity to the incident where the incident commander will direct operations. Interior and exterior incident command post locations should be identified in advance, based on hazard scenarios and coordinate locations with the lead public agency that will respond to the incident.

Major emergencies, crises, and business continuity efforts are managed from an emergency operations center (EOC) that may be located on site or distant from the incident. "Virtual" EOCs can be created via conference call. Staff can collaborate and share information via the Internet or a private intranet and develop incident objectives and an incident action plan. The ability to communicate with all responders and resources is critical to effective incident management. Interoperable communications capabilities such as common radio frequencies or sharing of equipment to enable interdepartmental and multijurisdictional communications may be necessary for larger incidents.

Coordination with Public Agencies. The services of public agencies will be required for many incidents including medical emergencies, fires, hazardous materials spills, and acts of terrorism. Coordination of planning between the private entity and the public responders helps assure emergency responders arrive at the correct location or entrance, dispatch the appropriate complement of equipment, and seek out the person who has been designated as the facility's incident commander.

Incident management requires unification of command of all responding agencies. Working relationships should be established with internal department heads, emergency response and business continuity team leaders, and the leaders of public emergency response organizations. The leaders of the facility's emergency response and business continuity teams should be introduced to public emergency services. A clear understanding of who is in charge will help avoid delays and confusion and help assure a smoother response.

A cooperative private-public pre-incident planning effort begins with facility management compiling information about the site, facility, building construction, occupancy, hazards, protection systems, and emergency organization. This information should be reviewed by fire, law enforcement, hazardous materials, emergency medical responders, and others who may respond to the facility. Public emergency responders can then develop site- and facility-specific tactical response plans. NFPA 1620, *Recommended Practice for Pre-Incident Planning,* describes the information that should be compiled and provides example report forms to display information that should be immediately available to emergency responders.

Finance and Administration. Besides the financial support for response teams and plans, plans must address administrative and financial procedures for approval and procurement of resources needed during an incident. Procedures must assure that the approval process is compliant with the organization's fiduciary authorization levels and procedures. In addition, accounting procedures must be established to track all costs related to the emergency, business continuity, and recovery efforts. This includes setting up account numbers for time and costs, tracking work hours for nonexempt labor, and documenting claims for property damage, business interruption, liability, and other claims that may or may not be insurable. These procedures should be organized under the finance and administration section of the incident command system.

EMERGENCY MANAGEMENT

Functions and Level of Response

The size of a facility, the nature and severity of hazards, the availability and capability of external emergency services, regulations, and funding factor into the determination of the functions and level of response of the emergency organization. A large campus or facility with many lives at risk requires a more robust capability to protect occupants. A facility that manufactures, treats, or stores large quantities of highly hazardous materials warrants or may legally require a hazardous materials response team. If the facility is distant from public emergency services, response time is excessive, or the knowledge or capabilities of the public emergency responders is limited, then the facility will need to organize and train personnel to provide first aid, administer CPR, deploy an automated external defibrillator, fight incipient fires, or contain a spill of hazardous materials.

Functions of an emergency organization may include administering medical care, fire fighting, hazardous materials containment or cleanup, rescue of entrapped workers, or search and rescue of trapped persons. Minimum-level functions include notification of public emergency services, evacuating and accounting for building occupants, sheltering occupants in place, locking down a building, supervision of building utilities and systems, salvage, and cleanup. Security of a site or building, investigation of suspicious packages, searching a building when a bomb threat has been received, and controlling or dispersing a crowd may be managed by on-site security staff with or without the assistance of sworn law enforcement officers.

Emergency Organization

Leader. The emergency organization should include a leader with authority to take immediate action to protect building occupants and persons capable of notifying public emergency services and warning building occupants to take protective action. The leader should be very familiar with the facility, its occupants, protection systems, utilities, hazards, and emergency response plan. The leader should be well known to members of the emergency organization and agencies that would respond to the facility. Deputies should be assigned to provide coverage whenever the facility is operational.

Teams. Industrial facilities, places of assembly, hospitals, schools, larger retail establishments, and certain structures, including high-rise buildings, underground buildings, and selected buildings with an atrium, are required by fire prevention codes to have fire emergency plans and trained personnel. Many jurisdictions have adopted more stringent requirements for the organization of fire safety teams and emergency action plans.

A team should be organized to ensure swift evacuation of all occupants from all buildings and accountability at evacuation assembly areas. Evacuation teams should also be trained to shelter occupants in place in the event of an exterior hazard. Lockdown procedures should be implemented and persons should be assigned to warn occupants to take cover if there is a suspected or armed intruder or potential or act of violence in progress. Members of the emergency organization should be provided and trained to assist persons with disabilities.

Additional functional teams can be organized for medical (administer first aid, CPR, or AED), fire fighting, technical search and rescue, or hazardous materials. A medical capability is required by OSHA if there is no infirmary, clinic, or hospital in near proximity to the workplace for the treatment of all injured employees.[4]

Industrial Fire Brigade. Fire fighting is not required by OSHA standards or the two model fire prevention codes; however, local laws in major cities may require appointment of a fire safety director and an emergency organization for high-rise buildings.* Duties of these organizations include supervision of a building's fire protection and utility systems. Facilities that choose to organize an industrial fire brigade must comply with OSHA Standard 29 CFR 1910.156, "Industrial Fire Brigades," and should follow NFPA 600, S*tandard on Industrial Fire Brigades,* and referenced documents therein. Options for industrial fire brigades include incipient-level fire fighting using portable fire extinguishers or advanced interior and exterior fire fighting.

Rescue and Emergency Services. OSHA Standard 1910.146, "Permit-Required Confined Spaces," requires employers to "develop and implement procedures for summoning rescue and emergency services, for rescuing entrants from permit spaces, for providing necessary emergency services to rescued employees, and for preventing unauthorized personnel from attempting a rescue." If the facility decides to provide rescue services, then the OSHA standard defines equipment, training, and other requirements for the rescue service. NFPA 1670, *Standard on Operations and Training for Technical Search and Rescue Incidents,* includes requirements not only for confined space rescue but also for structural collapse rescue, vehicle and machinery rescue, water rescue, and trenches and excavations rescue.

Hazardous Materials Response. OSHA 1910.120, "Hazardous Waste Operations and Emergency Response," dictates requirements for response to hazardous materials at hazardous materials cleanup sites, regulated hazardous waste treatment, storage, disposal facilities, or emergency response operations for releases of, or substantial threats of releases of, hazardous substances without regard to the location of the hazard.

NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents,* provides significant guidance on incident planning, response levels, safety, incident mitigation, and decontamination. NFPA 472, *Standard for Professional Competence of Responders to Hazardous Materials Incidents,* defines the competencies for responders at the awareness, operations, technician, incident commander, and specialist levels. It also

*Chicago's Title 13 Municipal Code of Chicago Chapter 13-78, "High Rise Buildings—Emergency Procedure." In New York City, Local Law 26 of 2004 requires "standards, procedures and requirements for the orderly evacuation of occupants from any office building, including evacuation of persons necessitated by explosion, biological, chemical or hazardous material incidents or releases, natural disasters or other emergency, or the threat thereof."

defines the competencies for technicians for differing storage tanks.

Organizational Statement. If a fire brigade or hazardous materials response team is organized, a statement or written policy that establishes the existence of each team should be prepared and maintained. The statement or policy should also define basic organizational structure; the type, amount, and frequency of training; the expected number of members on each team; and the functions that the teams are to perform.

Operational Procedures

Protective Actions. Every facility should have documented procedures for protection of building occupants—protective actions for life safety—as well as procedures for response to credible threat scenarios. Basic protective actions include partial, phased, or full evacuation of occupants from a building, shelter in place of occupants within a building when there is an exterior hazard, and lockdown of occupants when there is an intruder or armed perpetrator within a building.

Scenarios for evacuation planning should include not only fire and explosion but also bomb threats, suspicious packages, chemical hazards, and the release of chemical or biological agents. Evacuation planning should anticipate the obstruction of primary means of egress and plan for use of secondary means of egress. Use of the building's fire alarm, emergency voice communication, and public address systems to warn occupants and direct them to take threat-specific action is critically important. Multistructure campus-style environments may also incorporate pager, cell phone, PDA, and computer email messages that notify the occupants of an emergency requiring evacuation. Supervision of the building's ventilation system under the command of the incident commander should be assigned to competent members of the building staff. Procedures should be established for control of all systems based on potential threat scenarios. Protection of employees whose evacuation will be delayed while they shut down machinery or process systems must also be addressed.

Evacuation, shelter in place, and lockdown protective actions must address the needs of persons with disabilities including those with mobility, sensory, or cognitive impairments. Persons with disabilities should be identified; planning scenarios need to be determined; personnel and equipment resources to move them to safety should be determined; and persons to render assistance should be trained. Systems to warn occupants who may not hear evacuation signals, communications equipment to enable persons awaiting rescue assistance to communicate with emergency responders, special chairs (stair descent devices) to evacuate mobility-impaired occupants down stairwells, and personnel to provide immediate assistance to cognitive-impaired occupants who may become agitated or disturbed when confronted with the urgency of a potential life-threatening situation should be provided.

Procedures should be established for treatment of persons with injuries or illnesses. Procedures may be limited to notification of public emergency medical services (EMS) and directing arriving EMS responders to the location of the victim. However, in larger facilities and those with significant hazards, including chemical hazards, emergency procedures should address immediate lifesaving action required for exposure to on-site chemical hazards, including rescue, isolation, and decontamination procedures, and administration of first aid and CPR, or use of automated external defibrillators.

Private businesses also need to prepare for how they would respond in the event of a public health emergency such as pandemic disease. Pandemic flu is an example of a global disease outbreak that occurs when a new influenza virus emerges for which people have little or no immunity and for which there is no vaccine. The disease spreads easily person to person, causes serious illness, and can sweep across the country and around the world in a very short time. An especially severe influenza pandemic could lead to high levels of illness, death, social disruption, and economic loss. Everyday life would be disrupted because so many people in so many places become seriously ill at the same time. Impacts can range from business closings to the interruption of basic services such as public transportation and food delivery. Businesses should develop a plan incorporating human resource policies and procedures, crisis communications, and alternate operating strategies to maintain critical services caused by lack of personnel, goods, or services.

A search and rescue capability may be warranted for facilities located at a distance from public emergency services or facilities located in a seismically active region. A major earthquake could overtax the resources of the public fire service, and the facility's first responders may need to conduct immediate search and rescue.

Supporting Actions. Besides the immediate and urgent task of protecting life safety, the emergency organization should take action to assess damage in coordination with the business continuity team and initiate mitigation and recovery efforts as soon as it is safe. This includes debris removal and cleanup, repairing damage, and restoring utilities in conjunction with contractors and public utilities.

Emergency Procedures. Every facility should have documented procedures for response to credible hazards identified during the risk assessment process. Procedures should include fire, explosion, medical emergency (injury and illness), power failure or loss of another critical utility, severe weather, bomb threat, suspicious package, intruder or violent perpetrator, and acts of terrorism, including chemical, biological, and radiological weapons. Pipe breaks and water damage can be considerable, so documentation of the location and shutoffs of potable and fire protection water valves is essential.

Most facilities are threatened by one or more natural hazards including earthquake, hurricane, flooding, wildfire, landslide, subsidence, and possibly even volcano or tsunami. Plans should identify potential damage to the area, site, and building. Procedures should address property damage, interruption of business operations, and injuries. Consideration should be given to whether public agencies and emergencies services will be able to reach the facility in a timely manner if a regional disaster occurs. Facilities with significant exposure to earthquake

should plan for structural failure of buildings susceptible to seismic damage.

Procedures should be documented for spill or leakage of hazardous materials, including natural or LP-gas if used. Actions can be limited to evacuation; however, the locations and protection of gas piping should be addressed in the plan and communicated to emergency responders. The location of controls, procedures for shutdown of machinery and process systems, and rescue procedures for confined space entry should be immediately available. Facilities located in proximity to major transportation routes, such as highways, freight railways, and commercial shipping channels, should prepare shelter-in-place procedures to protect building occupants from incidents involving the release of hazardous materials in transit.

Retail establishments, properties with on-site banking services, or facilities containing valuables or precious metals should also develop procedures for robbery. Additional procedures may be warranted if there is a probability of strikes, civil disturbances, kidnap, or other security threats.

Detection, Notification, Alerting, and Warning. Procedures should identify the means for detection of a threat, so signs are not missed and the emergency organization is able to respond quickly. For example, overpressurization of a vessel constitutes an emergency requiring immediate shutdown of the equipment. Procedures for notification of trained personnel, the emergency response team, and public agencies should be documented along with the preferred means of notification. Up-to-date lists should be kept of telephone and pager numbers, radio channels, and the other means of notifying internal and external personnel.

Procedures should be documented for use of fire alarm, emergency voice communication systems, and public address systems for different scenarios. Responsibility should be assigned for competent individuals to use these systems to warn occupants when instructed by the incident commander when a fire detection or suppression system operates or when notified of an emergency. Scripts should be written to ensure life safety instructions are broadcast, the audibility of systems should be evaluated to determine whether broadcast messages can be heard and understood throughout the facility, and operator skills should be honed through periodic drills. During an emergency, important information should be broadcast early and the message repeated often to ensure all occupants hear the broadcast and understand what to do.

BUSINESS CONTINUITY

Companies large and small are developing business continuity plans for many reasons. First, business continuity planning may be required by laws and regulations. Financial services firms that process millions of transactions have little tolerance for downtime, and health care institutions have to protect confidential patient information and ensure its availability for life-saving treatments. Planning may be stipulated in contractual agreements with customers who require assurance that critical suppliers will be able to meet their needs. Homeland security standards for industries owning or operating critical infrastructure have requirements for recovery of operations.

Today's global business environment requires highly efficient, streamlined companies to achieve maximum profitability and growth. Unfortunately, highly efficient companies do not always have the redundancy in operations and excess capacity to deal with unforeseen shutdown of critical facilities or functions. Business continuity planning is now more important than ever.

Business continuity planning identifies the impact of potential losses and maintains viable recovery strategies and plans to ensure continuity of critical services. Business continuity begins with management commitment, appointment of a program coordinator, and organization of an advisory or steering committee. Business continuity planning requires a clear understanding of business objectives and how manufacturing or sales of products and the delivery of services achieve the business objectives.

Organization

The business continuity team should be led by the business continuity manager with functional teams for, and led by, managers of the following departments:

- Facilities
- Operations
- Manufacturing
- Logistics
- Information technology
- Finance
- Communications
- Human resources
- Legal

Each team is responsible for the development of the plan for its functional area and for response in the event of an extended interruption of business functions. In small to medium-sized organizations, the business continuity team would be responsible for and frequently will execute all of the business continuity activities. In a large organization, many additional teams will be required for each of the larger departments.

Business Impact Analysis

The impact of potential losses—referred to as the business impact analysis (BIA)—is derived from the analysis of hazards and their impact on business operations (the risk assessment process.) However, a business impact analysis requires a thorough analysis of the manufacturing or service delivery process to identify and quantify the loss of critical functions or activities that would prohibit the organization from achieving its business objectives.

BIA Goal. The intent of the BIA is to identify the downtime and financial impact resulting from the loss of business functions. The higher the loss potential, the stronger the justification for developing strategies for recovering, and allocating resources to recover, the function. Estimation of the loss potential requires not only an understanding of the financial loss potential (e.g., loss of sales) but also an assessment of indirect losses.

The BIA requires identification of critical business functions and assessment of their underlying processes. The goal is

to identify resource requirements and points of failure. An understanding of the time-sensitive nature of the process is needed to determine recovery time objectives—when the business function and underlying processes must be restored before irreparable harm is done to the business and the ability to achieve business objectives is lost. Most companies have numerous functions and not all are critical. Not all functions deemed critical have to be restored immediately after a loss or disruption. It would be prohibitively expensive to build that level of resiliency into any organization.

BIA Procedure. Begin the BIA by meeting with senior management who understand the direction of the company and the business units, products, and services that are most important to the financial success of the company and its future. Using this information about critical products and services, develop questionnaires specific to the organization, its business functions, and processes. Meet with managers of all functional areas of the company, including finance, customer service, human resources, purchasing, manufacturing, materials management, facilities, payroll, and others. Ask managers to identify major business functions and business processes. Ask them to identify the financial impact that a loss of the function would have on the company if the function were lost for 1 hour, 8 hours, 24 hours, 3 days, 1 week, 1 month, and longer.

The assessment must take into account the timing of any outage or loss. Catalog retailers experiencing shutdown of a call center in the weeks before Christmas may lose a high percentage of their annual sales. Likewise, manufacturers of seasonal equipment or materials would suffer their greatest loss when running at peak capacity to meet the seasonal demand for their product. The financial impact should include an analysis of the loss of revenue and impact on expenses.

The financial impact may result from loss or deferral of sales, loss of income from related goods or services, loss of contracts, loss of discounts, and so on. The impact on expenses could include emergency expediting expenses to procure replacement equipment or materials, overtime or temporary labor working to make up lost production, facility or equipment rentals, fines or penalties, insurance deductibles, and so on. There are also many intangibles that must be factored into the overall equation. These include negative impact on customer goodwill, image, reputation, quality, and the opportunity cost that occurs when the organization is unable to pursue additional business opportunities.

Piecing together the business impact analysis also requires an understanding of interdependencies between departments within a facility and interdependencies with other company-owned facilities, as well as external suppliers. An outage at one company facility could shut down operations at other company-owned facilities. The outage could result from loss of a common resource such as information technology or telecommunications, interruption of the supply chain, or disruption of infrastructure. The potential impact on multiple facilities from natural hazards, such as earthquakes, hurricanes, or flooding, should be analyzed.

Businesses run numerous computer applications, including customer ordering, procurement, inventory management, manufacturing planning, manufacturing control, machinery control, shipping, customer service, and general ledger functions. Businesses depend on electronic mail, intranets, extranets, and websites to communicate internally and externally. All of these applications are not critical and do not need to be restored immediately. The business impact analysis must assess each function, rank its priority, and identify the time frame that it must be recovered before serious harm is done to the company.

The interview process should be used to determine whether departments have identified critical machinery, equipment, suppliers, knowledgeable employees, contractors, vendors, records, and information in all forms that would be necessary to restore or replace a process or function. The analysis should identify whether contact names and telephone numbers have been documented to notify contractors, vendors, and staff to respond 24/7 to an outage. It should also determine whether specifications are available for the types, models, or other requirements necessary to procure replacement equipment and the procedures for the step-by-step restoration of functions and processes.

After critical functions have been identified, the underlying processes should be analyzed to determine the facilities, systems, equipment, staffing, technical knowledge, and information (all forms and media) needed to run the process. All department heads should be interviewed and asked to identify the support they provide to others.

Identification of Vital Information. The business impact analysis must also evaluate the loss of critical information. Electronic information can be lost when hardware fails, system security is breached, a virus or worm deletes or overwrites data, or an operator mistakenly deletes a file. Whatever the cause, information may be lost on primary computer media. The true loss is the gap between the information on the primary media and duplicate information on backup media. If the time between the loss and the last information backup is long, then the loss of information may be considerable. Therefore, the protection of information and the frequency of backups of vital information should be addressed as part of the business impact analysis.

Some paper records, drawings, specifications, and other documentation may also be essential to support critical business functions or to facilitate continuity and recovery efforts. Vital records should be identified and backup strategies employed to ensure vital information is available. This includes documentation of the off-site storage location, box numbers, and retrieval instructions.

Recovery Time Objectives

A recovery time objective (RTO) is the maximum allowable time to restore a critical function before irreparable harm is done to the business and the ability to achieve business objectives is lost. There is an inverse relationship between recovery time and recovery strategy cost. Reducing the time to recover a critical function requires more money. For example, if information technology is essential and no downtime is acceptable, then fully redundant facilities and equipment with sophisticated data mirroring are required. The cost for this high level of redundancy may be prohibitive.

Full recovery of a critical function is not always necessary in the initial hours following an interruption. For example, immediately upon activation of the business continuity plan, incoming calls can be rerouted to voice messaging systems for later callback. After 2 hours, calls can be redirected to another facility that has been equipped with phone lines and order entry terminals. After 24 hours, the number of incoming lines can be expanded as needed.

Alternate Operating Strategies

Alternate operating strategies are the means for an organization to run its business in the hours and days following a loss but before facilities, systems, and equipment are restored to their preloss condition and operational status. These strategies do not necessarily duplicate the function they are replacing; rather they are a creative means to bridge the gap.

Manual Workarounds. Manual workarounds are one example of an alternate operating strategy. Time and costs can be tracked manually, and checks can be issued manually or payroll services can be instructed to issue checks in the same amount as the prior period.

Hot Site Contracting. Strategies for data centers can include contracting with a commercial "hot site" (a fully equipped and operational data center ready for installation of client application software and backup data). Testing is required to ensure applications and data can be successfully run on the hot site's hardware, electronic data must be accessible, and connectivity with the company's data network must be established. Hot site contracts can be expensive and they may not be available in the event of a widespread disaster when numerous companies compete for the same data processing space.

Cold Site Configuration. Other alternatives include configuring a "cold site"—a room with utilities and minimum equipment at the same or a second company facility. If the primary facility were destroyed, computer hardware would have to be procured, but the setup time would be less because the facility would be preconfigured with utilities to support the hardware. This strategy may be less expensive than a hot site and would allow resumption of data processing soon after hardware is delivered.

Other Alternate Strategies. Use of other company-owned or company-controlled facilities that have the capacity to accommodate the production or service needed of the damaged facility is the easiest recovery strategy to employ. However, efforts to boost productivity and minimize expenses have eliminated excess production capacity in most firms. Therefore, this option may only be available if production demands are less than peak and excess capacity is available. Reciprocal agreements with competitors provide another means of maintaining critical functions. Competitors with similar products and manufacturing methods may be able to make up lost production and label products to meet competing brand requirements. Distribution companies may be able to arrange for direct shipment from manufacturer to customer or contract with third-party logistics services to receive and distribute products.

Procedures

Procedures must be established for damage assessment, declaration of a disaster, activation of the plan, mobilization of resources, execution of alternate operating strategies, resumption of "normal" operations, and demobilization of resources.

Damage Assessment. When normal operations are interrupted or disrupted, damage assessment should commence immediately. A determination should be made whether critical functions have been damaged, interrupted, or disrupted. If so, the leader of the business continuity team should be notified. The leader should be vested with the authority to declare a disaster and initiate business continuity and recovery efforts.

Plan Activation. The plan should include the names, telephone numbers, and functional responsibilities for the business continuity team. Procedures should be established for alerting members of the business continuity team along with procedures for alerting members of the emergency response and facility management teams. Members of the business continuity team should check in with the command post and report to the business continuity team's work site.

The business continuity plan is activated based on predefined criteria outlined in the plan. Activation may be ordered by the crisis management team when the emergency response team reports significant damage or when interruption of critical functions meets or is expected to meet predefined criteria. Upon activation, the business continuity team should convene at a predetermined location and assess the scope and expected duration of any interruption. If the expected duration exceeds the recovery time objective for any critical function, then the prescribed alternate operating strategies should be initiated. Members of the business continuity team may need to relocate to a predefined alternate location, and logistical support must be provided for transportation, food and shelter, and other needs. Coordination of the business continuity efforts should be managed through the organization's incident command system. Team members should also be mindful of their personal situations and should make sure they have made provisions to take care of the needs of their immediate family members.

When the facilities, systems, and or equipment have been restored to normal operating status, emergency operations are terminated. Facilities, systems, equipment, and members of the business continuity team are demobilized.

CRISIS MANAGEMENT

Defining a Crisis

A crisis is an event or a series of events that threatens an entity's brand, image, or reputation, or significantly and negatively impacts employees, customers, critical suppliers, or investors. Crises can result from natural or man-made disasters, accidental or intentional events, as well as improprieties that may have occurred at the company. The crisis may be apparent immediately, or it may develop over time. Unlike emergencies, however, crises take many days, if not weeks or months, to overcome.

The handling of an event or series of events and the actual or perceived impact will often determine whether the series of events becomes a crisis. The death of the well-known leader of a firm would be a crisis for a small business. However, it would probably not become a crisis for a large company—unless the company mishandles media inquiries into its succession plans and investors get jittery and dump their stock. If fire destroys a manufacturing facility, the result may not be material to earnings or shareholder value—if the facility is fully insured, a business continuity plan enables shifting of production to alternate sites, and a communication strategy quickly informs stakeholders the loss will not affect growth and earnings. If that facility employs a measurable percentage of a community's population and makes a sizeable contribution to the tax base, the loss would be considered a crisis for the community, however.

Early Warning Signs

Many signals and indicators may precede a crisis. Prompt detection and proper interpretation of these signals, understanding their potential implications, and notification of management in a position to remedy the underlying situation may avoid the crisis. A spike in calls to customer service after a new product has been launched may be dismissed as "to be expected." Days later, the news media report a fatality allegedly resulting from the defective product. Analysis of the initial series of calls may have identified a product defect and enabled warning of customers. A limited product recall may be required, but prompt action may limit the damage to a manageable level.

Complaints of harassment or discrimination or rumors of impropriety are often suppressed. When the pattern of activity becomes publicly known and widely publicized, the implications and consequences are magnified. Mandatory reporting and investigation of any allegation of harassment, discrimination, or impropriety may uncover problems before they become newsworthy and the subject of class action.

Close communication with suppliers will enable early warning of potential supply chain interruptions, allowing time to resource critical supplies from alternate vendors. Nokia and Ericsson were two leading manufacturers of mobile phones. A fire at Philips Electronics NV's Albuquerque, New Mexico, facility in March 2000 shut down production of computer chips. Nokia became aware of the impact on its supply of chips before Philips informed Nokia of the fire. Within two weeks, Nokia was able to redesign the chips it needed and restore its supply from available vendors. Unlike Nokia, Ericsson did not have backup suppliers for the chips and was millions short of its manufacturing needs. Ericsson subsequently reported a loss of at least $400 million in potential revenue prior to any insurance recovery.[5]

Organization

Crisis Management Team. Crises may jeopardize the future viability of an organization, so the highest level of management must manage the crisis. A crisis management team, composed of executive management and senior staff representing operations, finance, legal, human resources, and corporate communications, should be organized. Operations staff should include representatives from operating business units or divisions of the company.

Support Team. An incident support team should be organized to provide the logistical and technical support for the senior management crisis management team. Members of the support team should include staff from communications, legal, finance, human resources, operations (e.g., manufacturing, services, etc.), risk management, security, environmental health and safety, engineering, medical, and ad hoc members with expertise or experience as needed. A leader for the support team should be appointed and clerical and logistical support should be provided.

The support team's role is to gather information, conduct research, verify and assemble facts, communicate with affected sites, and prepare briefing papers for the crisis management team. Advance preparation by the incident support team will enable the crisis management team to quickly assess the situation, evaluate current and potential future impact, and determine a course of action.

Procedures

Notification and Escalation. Prompt alerting of management to events that involve fatalities, multiple injuries, significant property damage, business interruption, or contamination of the environment will enable management to react as quickly as possible to inquiries from the news media, stakeholders, regulators, customers, suppliers, or others. Objective criteria for events that require senior management notification should be established and communicated to all facilities. Communication channels, such as telephone, fax, and electronic mail, should be established for reporting events. Procedures should be established so that receipt of messages will be immediate, and management can be alerted 24 hours per day. Call lists with office, home, and cellular telephone numbers should be compiled, kept up-to-date, and made available to authorized persons.

Information Collection and Distribution. Information is critical for effective decision making. Unfortunately, in the early stages of a crisis, only limited information is available. Further compounding the problem, the available information may be conflicting or later prove to be false. Forms and instructions for prompt reporting of incidents should be prepared and distributed to all facilities and managers. Forms and procedures should be integrated with emergency response and business continuity plans and procedures. Use of forms and instructions will help ensure minimum and accurate information is gathered at the site and communicated up the organization's hierarchy.

The executive-level crisis management team must evaluate available information; determine the current and potential future impact of the events on the organization, its employees, shareholders, and business strategies; and then determine action to ameliorate the situation.

Crisis Communications

Understanding Your Audiences. Communication with stakeholders during a crisis is critically important. The message that reaches stakeholders will influence their perception of damage caused by the crisis and the organization's ability to meet their needs. An authoritative response that is clearly commu-

nicated can assuage stakeholders and calm their fears. If no statement is issued, stakeholders will listen to media reports and form their opinion based on information that will probably be limited at best and false at worst. Statements to the media that are poorly articulated, argumentative, or perceived as deceitful or covering up the facts can be injurious to the firm's reputation and fuel speculation about the firm and its ability to survive the crisis. The ability of the news media to broadcast a story to a worldwide audience in minutes requires a rapid capability to respond to the news media and provide responsible information.

Effective crisis communications requires understanding the stakeholders and other potential audiences. Identify who you must reach during a crisis, the message that you must communicate, and the most appropriate group to speak on behalf of the company. Create a list of your stakeholders and audiences and prioritize the order you will reach out to them. Identify the information that you must convey to each audience and the best method of communicating the information. Assign human resources, public affairs, legal, regulatory affairs, labor relations, and investor relations responsibility for defining their respective audience and preparing scripts for communication.

Your audiences include the community that may be directly or indirectly affected by an incident at your facility. The community's interest in the event could vary greatly depending on whether community members' health and safety are potentially at risk or whether their economic well-being is at risk. A chemical release that could be injurious to health or contaminate the groundwater surrounding a manufacturing facility would evoke a serious outcry from the community. A fire that destroys a major employer in the community would evoke serious concern but not necessarily an outcry unless there was some element of impropriety by the company whose facility was destroyed.

Other audiences include employees and their families. Crises resulting from events with fatalities or numerous injuries require communication with family members and special protocols for notification of next of kin. Employees need reassurance that their safety is not jeopardized, and they want to be reassured that steps have been taken to prevent a similar accident.

When an accident occurs, regulators may need to be notified. A release or spill of hazardous chemicals exceeding threshold quantities requires notification of environmental authorities. A workplace fatality or multiple workplace injuries require notification of OSHA. Reporting requirements for each facility should be identified and protocols and procedures for prompt reporting should be documented.

Another audience that is the lifeblood of most companies is its customers. If a business suffers a loss, customers may assume the worst and defect to competitors. Timely information should be broadcast to customers informing them if and when products or services will be delivered and the location and means to access alternate or temporary sites. Sales and marketing staff should develop a plan to reach out to customers if products or services could be or have been interrupted.

Communicate promptly with critical suppliers. Inform them to suspend shipments or where to redirect shipments so goods are not shipped to a facility that cannot receive them. Communicate with critical suppliers to protect your supply chain. Inform financial investors and analysts that the firm's finances are secure and insurance coverage is in place to cover the loss.

Communications and Briefing Center. Communications and media briefing centers should be established for receipt of inquiries from the news media, stakeholders, employees, customers, suppliers, regulators, employees, and other interested parties. Information gathering, preparation of scripts and statements, research, monitoring of news reports, and disseminating information are all done within the communications center. A media briefing center should be located in an easily accessible location away from the scene of emergency operations and away from the emergency operations center.

A protocol should be defined for coordinating the flow of information between all levels of the organization, including the affected sites, division or business units, and corporate. Identify who is authorized to speak to various audiences and how information is approved for release.

Script bulletins to provide information necessary to protect health and safety. This information may include security precautions for company employees traveling in an area that has experienced a disaster or is subject to acts of violence. Instruct employees how to communicate with management. Direct employees to sources of official information such as the company website, call centers, or radio stations. Establish a capability to communicate with the special needs population and procure equipment to communicate with stakeholders who are visually or hearing impaired.

Company officials should coordinate with public officials on site as part of a joint information center (JIC) established under the incident command system. Do not speculate on issues pertaining to law enforcement, cause and origin of a fire, or casualties. Private officials should express concern and sympathy for any victims, their families, and those affected directly or indirectly by the incident. Communicate that the company is working closely with and providing full support to public officials.

TRAINING, DRILLS, AND EXERCISES

Overview

The ability of the emergency response, business continuity, and crisis management teams to respond effectively depends on their knowledge of the program, its plans, procedures, and resources. Managers of the teams must be aware of hazards and the impact of hazards so they can develop an incident plan to protect people, property, operations, and the environment. Their collective ability depends on the effective use of all resources under the direction of a knowledgeable incident commander.

A pyramid of training, drills, and exercises is needed to educate all about the program and their roles and responsibilities as defined therein. Everyone should receive basic training in protective actions. Drills are required to hone skills, and exercises are needed to familiarize persons with the plan and to identify gaps in the ability to execute plans.

Program Goals and Objectives. The scope of training, drills, and exercises should be commensurate with the goals and objectives of the overall program explained at the beginning of this chapter. A training program should be designed to develop the level of knowledge required of all employees as well as members of emergency response, business continuity, and crisis management teams. Drills should be designed to hone specific skills or reinforce knowledge of basic protective actions, and exercises should be conducted to evaluate the firm's ability to carry out the overall program and individual plans and standard operating procedures.

Training and Education Curriculum. A training and education curriculum should be established to support the program (Figure 1.8.3). It should include three tiers or levels, beginning with a basic level of training for all employees. A second and higher level of training should be developed for members of emergency response, business continuity, and crisis management teams. Leaders of emergency response, business continuity, and crisis management teams require the highest level of training.

The training and education curriculum should include learning objectives specific to the audience (e.g., all employees, team members, and team leaders). Learning objectives should be determined after careful assessment of the knowledge base and skills required to achieve the stated program goals and objectives and the levels of knowledge, experience, and skill sets that currently exist. The curriculum must also comply with regulations that specify the scope and frequency of training. Adults learn from doing; thus, training should be interactive and as hands on as possible. Respect the knowledge and experience of team members and allow them to contribute without digressing off subject.

Incident Management System. Effective management of an incident requires use of a management system. All members of emergency response, business continuity, and crisis management teams should receive basic training in the incident command system (ICS). Training should include the ICS structure, assuming incident command, establishing an incident command post, operation of the emergency operations center, and appointment of leaders for operations, planning, logistics, and finance sections.

FIGURE 1.8.3 Emergency Response Training (Source: Donald L. Schmidt, Preparedness, LLC)

Frequency of Training. The frequency of training should be sufficient to develop and maintain the desired level of capability and comply with regulatory and certification requirements. Initial training is required for members of emergency response, business continuity, and crisis management teams. Follow-up training is required when hazards, plans, and procedures are changed. Annual evacuation drills may be required in many occupancies for all employees—more frequently in some jurisdictions and for occupancies like health care. More frequent training is required for members of fire brigades, hazardous materials response teams, and technical search and rescue teams.

Record Keeping. Records should be kept of all training. The date, duration, and subject matter of all training sessions should be documented in a master file. All participants should sign an attendance log, and the log should be filed with the master training file. Individual training records may be kept with human resource records. A system should be developed to identify persons who have not completed required training or whose certifications will soon expire. Records should be made available to authorized persons.

Regulatory Requirements. Numerous regulations dictate the scope and frequency of training, particularly for members of emergency response teams. However, the applicability of regulations vary depending on the functions and level of response of the emergency response team. For example, members of an industrial fire brigade that is organized and equipped for interior structural fire fighting must be medically fit to participate, receive considerable training, and participate in periodic drills and exercises, whereas persons trained to use fire extinguishers within their assigned work area need only receive annual training in the use of fire extinguishers along with basic emergency procedures. OSHA standards should be reviewed for fire fighting, medical response, hazardous waste operations and emergency response (HAZWOPER), and emergency action plans and fire prevention plans for employer training requirements. Fire prevention codes also specify training, drill, and exercise requirements for emergency response, including evacuation. Local laws and regulations should also be reviewed for additional requirements that may be more stringent than state and federal laws.

Drills

A drill is a coordinated, supervised activity employed to test a single task, procedure, or operation. Drills are commonly used to provide training on new equipment, develop or test new policies or procedures, or practice and maintain current skills.

Drills and exercises are an important element of the emergency management and business continuity program. Adults

learn from doing, and drills are one of the best means to hone specific skills. Can occupants of a building find a secondary exit if the primary exit is blocked? Do occupants know where to assemble after they have exited the building? Are members of the evacuation team able to account for all persons who have evacuated? Evacuation drills teach people what to do and allow them to practice their skills.

Drills are needed to hone the skills of all members of the emergency organization. Members who have to operate or supervise systems or equipment should participate in a drill that requires them to reach their assigned location and manipulate (or simulate operation of) controls under the supervision of someone who is knowledgeable and can instruct if necessary. For example, drills should include operation of a building's emergency voice communication system, shutting down a building's ventilation system, and using a portable fire extinguisher to suppress an incipient fire.

Exercises

There are different types of exercises that can be used to familiarize team members with the plan, their role, and how to manage different types of incidents.[6] These include orientation, tabletop, functional, and full-scale exercises. The orientation is simply a review of the organization, plans, and standard operating procedures.

Tabletop Exercises. Tabletop exercises (TTX) are typically held in a meeting or conference room (Figure 1.8.4). Discussion centers around a hypothetical incident or series of events that has been customized to the entity and its organization, operations, or facilities. A TTX is intended to enhance the understanding of concepts, identify strengths and weaknesses in a plan or the organization's ability to execute the plan, and to get team members to work together to assess the unfolding series of events and develop an incident action plan.

Participants should be encouraged to discuss issues in depth and develop plans through slow-paced problem solving rather than the rapid, spontaneous decision making that occurs under actual or simulated emergency conditions. Tabletop exercises require less planning, take less time, and, therefore, can be cost-effective when compared with functional or full-scale exercises. The effectiveness of a TTX is derived from the energetic involvement of participants and their recommended revisions to current policies, procedures, and plans.

FIGURE 1.8.4 Tabletop Exercise Training (Source: FEMA)

There are two types of tabletop exercises: basic and advanced. In a basic TTX, the scene set by the scenario materials remains constant. It describes an event or emergency incident and brings discussion participants up to the simulated present time. Players apply their knowledge and skills to a list of questions presented by the facilitator, problems are discussed as a group; and resolution is generally agreed on and summarized by the facilitator. In an advanced TTX, play revolves around delivery of pre-scripted messages to players that alter the original scenario. The exercise controller (moderator) usually introduces problems one at a time in the form of a written message, simulated telephone call, videotape, or other means. Participants discuss the issues raised by the problem, using appropriate plans and procedures.

Functional Exercises. Functional exercises, also known as command post exercises, are designed to test and evaluate individual capabilities, multiple functions or activities within a function, or interdependent groups of functions. Functional exercises are generally focused on exercising the plans, policies, procedures, and staffs of the direction and control nodes of incident command (IC). Generally, events are projected through an exercise scenario with event updates that drive activity at the management level. Movement of personnel and equipment is simulated.

The objective of a functional exercise is to execute specific plans and procedures and apply established policies, plans, and procedures under crisis conditions within or by particular functional teams. A functional exercise simulates the reality of operations in a functional area by presenting complex and realistic problems that require rapid and effective responses by trained personnel in a highly stressful environment.

Full-Scale Exercise. A full-scale exercise is the most complex type of exercise and typically involves multiple agencies and tests many facets of emergency response and recovery. They include many first responders operating under the incident command system (ICS) or unified command system (UCS) to effectively and efficiently respond to, and recover from, an incident. A full-scale exercise focuses on implementing and analyzing the plans, policies, and procedures developed in discussion-based exercises and honed in previous, smaller, operations-based exercises. The events are projected through a scripted exercise scenario with built-in flexibility to allow updates to drive activity. A full-scale exercise is conducted in a real-time, stressful environment that closely mirrors a real event. First responders and resources are mobilized and deployed to the scene where operations are conducted as if a real incident had occurred (with minor exceptions). A full-scale exercise simulates the reality of operations in multiple functional areas by presenting complex and realistic problems requiring critical thinking, rapid problem solving, and effective responses by trained personnel in a highly stressful environment.

PROGRAM EVALUATION AND MAINTENANCE

The emergency management and business continuity program requires continual maintenance to keep pace with changes in facilities, operations, hazards, regulations, staffing, funding, and resources. When a building is renovated, travel paths to exits may change or evacuation assembly areas may change. As processes are added or changed, new hazards may be introduced or the scope of a hazard may increase. Regulations change over time, reflecting our collective knowledge of hazards and how best to mitigate their impacts. Staffing changes over time. Many persons must contribute to the program, and, as they leave, others must be appointed and trained to continue the program. Changes in funding or the commitment of management to the program will also require changes to the program. The level of response may have to be reduced if funding is not available for personnel, equipment, training, or supplies. Changes in the availability and capability of external resources must also be assessed and the program changed as necessary.

Goals and Objectives

Goals and objectives established when the program was created should be periodically reviewed and validated to ensure they are acceptable to management and can be supported and funded over time. Goals and objectives should also be compared to regulatory requirements and resource constraints to determine whether they are realistic and attainable now and for the foreseeable future. These goals and objectives then become the overarching standard for evaluating elements of the program.

Reviews, Testing, Audits, and Evaluations

The emergency management and business continuity program should be reviewed whenever there is a change that could impact the program. The review should encompass the nature of the change and the impact on the program. If the change has a material impact on the program, then the program element should be revised as necessary.

Elements of the program that are regulated by the government should be reviewed on a schedule that is compliant with the regulation. Fire prevention codes require periodic drills and review of evacuation plans annually.

Most elements of the program are not tested but are rather evaluated to determine whether they meet current needs. Testing is limited to elements of the program that either pass or fail. For example, a fire alarm system is tested to ensure all occupants of the building can hear the evacuation signal. Occupants may or may not hear the signal. Elements of the business continuity plan are also tested to determine whether they work or not. For example, restoration of data and application software is tested on replacement computers to determine whether or not aspects of the information technology business continuity plan work.

Companies with multiple facilities may dictate standards for emergency management and business continuity programs. Facility management sets goals and standards for the program and must hold persons accountable for the development and implementation of program elements. Compliance with statutes and regulations is a requirement for some elements of the program. In all cases, audits enable management to learn whether the program meets standards, goals, objectives, or regulatory requirements. The criteria used by auditors should be carefully developed so auditors can objectively evaluate program elements. Auditors should assess both the availability and the capability of the resource—person, system, or equipment—to fulfill its function when an emergency occurs.

Evaluations are necessary whenever conditions that can have a material impact on the program change. For example, if a new chemical is introduced, a hazard analysis should evaluate whether additional mitigation efforts are needed to prevent a fire, explosion, or hazardous material spill or release. Emergency procedures should be evaluated to determine whether they address any hazard posed by the chemical. Resource needs should be evaluated to determine if additional fire-fighting equipment or supplies are needed.

Critiques of Drills and Exercises

Using objectives established in advance, critique drills and exercises. Utilize forms and checklists and assign sufficient observers to evaluate drills or exercises. Evaluate the ability of the emergency management and business continuity teams to execute established procedures within acceptable time frames. Identify gaps in procedures or knowledge of documented procedures. Also identify problems or limitations with the facility, equipment, and supplies. Discuss observations with team leaders and prepare recommendations for improvement. Address all recommendations through a defined corrective action process.

Post-Incident Critiques

After an incident has been stabilized, there is an excellent opportunity to review the response to the incident and identify ways to improve the response capability. A formal post-incident critique should be conducted for all incidents where there is personal injury, property damage, interruption to operations, or contamination of the environment. Informal critiques are encouraged for minor incidents that do not require a formal post-incident critique. The incident commander, or whoever was in charge of the response, should initiate the critique and prepare a summary report with any recommendations for improvement.

An informal critique involves an informal discussion of the events, facilitated by the incident commander. Members of the emergency organization informally discuss the various aspects of the incident. Discussion should continue with any outside agencies, internal departments, or others who were involved in the incident to describe their involvement in the incident. After the discussion of operations has been completed, everyone involved in the critique should be encouraged to ask questions and offer recommendations for improved response.

The discussion should follow the chronology of events and address the following:

- The initiating event
- Detection of the incident
- Notification, alerting, and warning procedures

- Implementation of incident command
- Interaction with public emergency services
- Adequacy of systems and equipment
- Effectiveness of protective actions (e.g., evacuation, sheltering, or lockdown)
- Effectiveness of threat-specific actions taken by the emergency response team to stabilize the incident

When the post-incident critique has been completed, management should be briefed and corrective action initiated as necessary. The incident commander or other designated and responsible individual should follow the corrective action process to ensure identified issues are resolved. A copy of the post-incident critique form should be filed for future review.

Corrective Action Process

The corrective action process is designed to address improvements to or shortfalls in the program including organization, standard operating procedures, training, and additions to or modification of facilities, systems, or equipment. Appropriate staff should be identified to review recommended improvements or to assess identified deficiencies. They should identify the root cause of any problem and identify the potential impact on the emergency management and business continuity program. Any historical problems that may relate to the issue should be identified. The most appropriate action should be selected to resolve the problem. The work that is needed should be described, the most appropriate means of addressing the work should be suggested, and the time and expense for budgeting or expenditure approval should be estimated. Recommendations should be submitted in order of priority to management at a high enough level to obtain necessary approval.

Some corrective actions might not be taken immediately due to constraints, such as budgets, staffing, or contracts, and might be deferred as a part of the long-range project. However, temporary actions should be taken to implement the desired option.

The progress of each recommendation should be monitored to ensure that priority issues are addressed and to ensure that action taken will satisfy the problem or address the issue. After work has been completed, the program coordinator or responsible person should verify that work has been satisfactorily completed. Future training, drills, exercises, or after-action reports should be evaluated to determine whether additional corrective action is needed.

SUMMARY

An effective emergency management and business continuity program is needed to protect people, property, operations, and the environment as well as the organization's finances, brand, image, and reputation. Basic emergency response procedures are also mandated by regulations in most jurisdictions. Business continuity plans have become a business necessity for most companies and a regulatory requirement for those operating critical infrastructure. A successful program begins with management commitment, direction, and support. Identification of hazards, probabilities of occurrence, and assessment of the vulnerability of buildings, operations, and the environment will determine potential impact. The magnitude of impact, the availability of resources, regulatory requirements, and management's aversion to risk all factor into management's decisions to invest in mitigation. In addition, the impact analysis provides the criteria for determining business continuity and recovery strategies.

Teams must be organized for immediate response to emergencies to protect building occupants. Businesses can opt to provide a higher level of emergency response including fire fighting, medical, hazardous materials response, and technical search and rescue. All plans and procedures should be coordinated with responding public agencies, and an incident management system should be implemented for effective command of all resources during an incident. Business continuity plans should include strategies for restoring critical functions before irreparable harm is done to the organization. Executive management should be organized into a crisis management team to provide strategic direction and to communicate with important stakeholders within and outside the organization. Training, drills, and exercises are essential to implement the program, maintain skill levels, and keep the program current.

America Burning, fire detection and alarm, fire prevention, Fire Safety Concepts Tree, fire suppression, performance-based design, systems approach

Building design and construction practices have changed significantly during the past century. A little over 100 years ago, structural steel was unknown, reinforced concrete had not been used in structural framing applications, and the first "high-rise" building had just been built in the United States.

The design professions have also advanced significantly during the past century. The practice of architecture has changed markedly, and techniques of analysis and design that were unknown a century or even a generation ago are available to engineers today. Building design has become a very complex process, with many skills, products, and technologies integrated into its system.

Fire protection has made developmental strides in the building industry similar to those of other professional design disciplines. At the turn of the century, conflagrations were a common occurrence in cities. In later years, increased knowledge of fire behavior and building design enabled buildings to be constructed in such a manner that a hostile fire could be confined to the building of origin rather than to one or more city blocks. Progress has continued in the field of fire protection so that, at the present time, knowledge is available that enables a hostile fire to be confined to the room of origin or even to smaller spatial subdivisions in a structure.

See also Section 1, Chapter 3, "Codes and Standards for the Built Environment"; Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection"; Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety"; Section 3, Chapter 11, "Overview of Performance-Based Fire Protection Design"; and Section 20, Chapter 1, "Assessing Life Safety in Buildings."

DESIGN AND FIRE SAFETY

Much activity is taking place today regarding fire safe building design. The general thrust is directed toward quantification procedures and identification of a rational design methodology to parallel or supplement the traditional "go or no go" specifications approach. Knowledge in the field of fire protection is undergoing development and reorganization that will enable buildings to be designed for fire safety more rationally and efficiently. Figure 1.9.1 provides an overview of the steps of performance-based design. The *SFPE Engineering Guide to Performance-Based Fire Protection Analysis and Design of Buildings*[1] describes this process in more detail. This chapter of the *Fire Protection Handbook* deals with a field that is changing dynamically in its analysis and design capabilities.

Role of *America Burning*

America Burning, the report of the National Commission on Fire Prevention and Control[2] identifies several hazards that building designers create unnecessarily, often unwittingly, for the building occupants. In some cases, these unnecessary hazards are the result of oversight or insufficient

John M. Watts, Jr., Ph.D., is director of the Fire Safety Institute, a not-for-profit information, research, and educational corporation located in Middlebury, Vermont. He also serves as editor of NFPA's quarterly technical journal, *Fire Technology.*

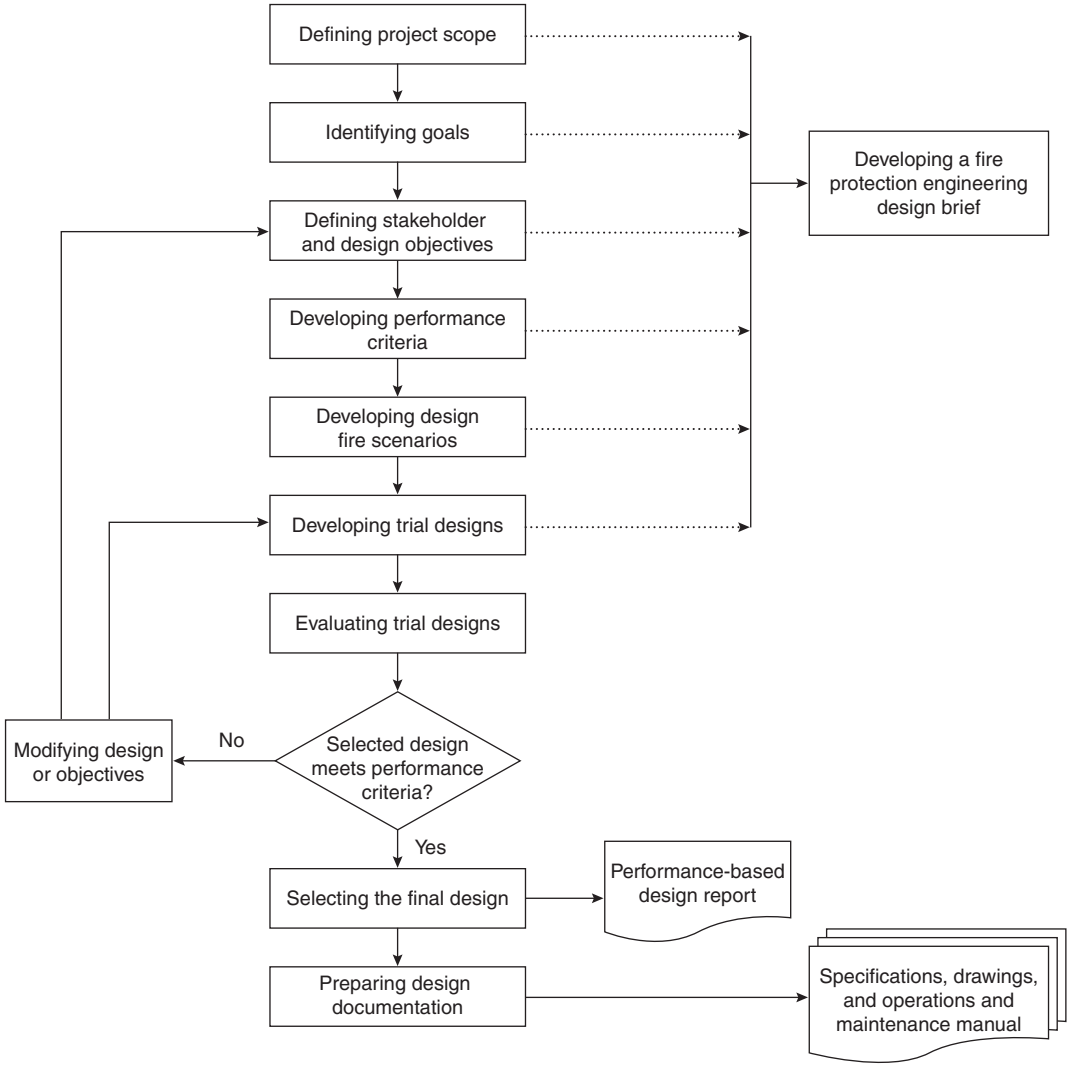

FIGURE 1.9.1 Steps in the Performance-Based Analysis and Design Procedure (Source: *SFPE Engineering Guide to Performance-Based Fire Protection,* 2007)

understanding of the interpretations of test results. In other cases, they are due to lack of knowledge of fire safety standards or failure to synthesize an integrated fire safety program.

The Commission's report cites the minimal attention designers often give to conscious incorporation of fire safety into buildings. Further, building designers and their clients are often content only to meet the minimum safety standards of the local building code. They both may assume incorrectly that the code provides completely adequate measures rather than minimal ones, as is actually the case. Building owners and occupants may also see fire as something that will never happen to them, as a risk that they will tolerate because fire safety measures can be costly, or as a risk adequately balanced by the provisions of fire insurance or availability of public fire protection.

Conditions arising from these attitudes need not continue. Information is available for design professionals to incorporate better fire protection into their designs. Use of this information requires that the various members of the building design team recognize that fire conditions are a legitimate element of their responsibilities. This in turn demands a greater understanding of the special loadings that fire causes on building elements and of countermeasures that can be incorporated into fire-safe designs.

Systems Approach

Fire safety in buildings encompasses an overwhelming number of variables, with only a limited understanding of the relationships of the variables; moreover, obtaining detailed data is often very difficult. The established approach of rigid specification codes and standards has limitations for many modern structures and for older buildings of historic significance. An alternative approach to dealing with fire safety is systems analysis. In the broadest sense, systems analysis is simply the methodical study of an entity as a whole. The objective is to define a credible process for making the best decision from among alternatives.

Interrelation, interaction, and relationships between numerous built-in features, systems, and operational criteria are carefully evaluated to establish the appropriate performance level.

Fire safety can be incorporated into building design by the following three methods:

1. Mandate that design and construction conform to prescriptive requirements in specification-oriented building codes and standards. Such requirements are based on fire experiences and are generally strict.

2. Use performance-based codes to overcome the inflexibility of specification codes. A present limitation of performance-based fire safety is that it is an evaluation procedure, not a design procedure. Once a design has been formulated, performance measures can be used to evaluate fire safety but the approach does not provide direct guidance on how to develop design concepts.

3. Use a systems approach that shows how various protection strategies meet fire safety objectives. Buildings can be designed with a systemic approach and then evaluated using either prescriptive or performance criteria or an appropriate combination of both. This approach to fire safety can require a high level of professional expertise; however, it allows greater flexibility and can achieve a greater level of cost-effectiveness.

The most widely accepted systems approach to fire safety is the NFPA Fire Safety Concepts Tree, a logic diagram that covers all known and conceived means of providing fire safety. This approach was developed by the NFPA Committee on Systems Concepts in the 1970s and continues to be applicable to both traditional and innovative building design. A brief introduction to the "Tree" is published as a technical document, NFPA 550, *Guide to the Fire Safety Concepts Tree.*

Objectives of Fire Safe Design

The conscious, integrated process of design for building fire safety, if it is to be effective and economical, must be integrated into the complete architectural process. All members of the building design team should account for emergency fire conditions in their design effort. The earlier in the design process that fire safety objectives are established, alternative methods of accomplishing those objectives are identified, and engineering design decisions are made, the more effective and economical the final results.

The first step in the process is clearly identifying the specific needs of the client regarding the function of the building. After building functions and client needs are understood, the designer must consciously ascertain both the general and the unique conditions that influence the level of fire safety acceptable for the building. The acceptable levels of safety and the focus of the fire safety analysis and design process objectives are concentrated in the following five areas:

1. Life safety
2. Property protection
3. Continuity of operations
4. Environmental protection
5. Heritage conservation

It is difficult to ascertain the level of risk that will be tolerated by the owner, occupants, and community. Often it is necessary to put a conscious effort into recognizing the sensitivity of the occupants, contents, and mission of the building as to the products of combustion. The levels of sensitivity can vary markedly depending on the focus of interest. Consequently, fire safety criteria often are not identified in a clear, concise manner that enables the designer to provide appropriate protection for the realization of the design objectives. Unfortunately, it is impossible to provide more than general guidelines to consider in building design for achieving the fire safety objectives in this handbook. Specific objectives must be developed for each individual building.

Life Safety. Adequate life safety design for a building is often related only to compliance with the requirements of local building regulations. This may or may not provide sufficient occupant protection, depending on the particular building function and occupant activities.

The first step in life safety design is to identify the occupant characteristics of the building. What are the physical and mental capabilities of the occupants? What range of activities and locations occur during the seven 24-hour periods each week? Are special considerations needed for certain times of the day or week? In short, the designer must anticipate the special life safety needs of occupants during the entire period in which they inhabit the building.

The identification of life safety objectives is usually not difficult, but it does require a conscious effort. In addition, it requires an appreciation of the time and extent to which the products of combustion can move through the building. The interaction of the building response to the fire and the actions of its occupants during a fire emergency determines the level of risk that the building design poses. Also, consideration for the safety of fire-fighting personnel responding to a building fire should be taken into account.

Property Protection. Specific items of property that have a high monetary or other value must be identified in order to protect them adequately in case of fire. In some cases, specially protected areas are needed. The establishment of fire safety objectives should ascertain whether the user of the building has property that requires special fire protection.

In some buildings, the value of the contents of a single room may be extremely high. This value may be due to the cost of highly technical equipment or unique artifacts such as art or rare books. The sensitivity of equipment and artifacts to the effects of heat, smoke, gases, or water must be addressed. In any event, the designer should protect the especially sensitive contents from products of a fire originating either inside or outside of the space.

Continuity of Operations. The maintenance of operational continuity after a fire is the third major design concern. The amount of downtime that can be tolerated before revenues are seriously affected must be identified. Frequently, certain functions or locations are more essential to the continued operation of the building than others. It is important to recognize those

areas particularly sensitive to building operations, so that adequate protection is provided for them. Often, these areas need special attention not required throughout the building. Availability of redundant or backup sites, duplicate records, and the ability to switch over to other locations can be considered in this part of the process.

Environmental Protection. Another important objective considers the impact of a fire on the environment. Problems such as runoff of chemicals housed in the building that may dissolve in fire department water need to be addressed. Waterborne or airborne products of combustion produced in buildings that house certain chemicals can affect the environment significantly.

Heritage Conservation. The preservation of heritage sites from destruction by fire is gaining worldwide importance. This involves providing a reasonable level of fire protection against damage to and loss of historic structures, their unique characteristics, and their contents. Objectives are similar to those of the preservation architect and require a design to minimize damage to historic structures or materials from fire and fire suppression while maintaining and preserving original space configurations and minimizing alteration, destruction, or loss of historic fabric or design.

Substantial renovation or modification to an historic building will often be a difficult challenge. Historic buildings, and spaces within such buildings, have a hierarchy of significance. Particularly for those historic buildings of higher significance, extraordinary attempts should be made to minimize alteration to the original space configurations and the historic design. Fire safety and fire protection features should be designed, implemented, and maintained so as to preserve the original qualities or character of the building, structure, or site.

INTRODUCTION TO THE FIRE SAFETY CONCEPTS TREE

The NFPA Fire Safety Concepts Tree, as described in NFPA 550 and illustrated in Figure 1.9.2, uses a branching diagram to show relationships of fire prevention and fire damage control strategies.

Fire safety features such as construction type, combustibility of contents, protection devices, and characteristics of occupants traditionally have been considered independently of one another. This can lead to unnecessary duplication of protection. On the other hand, gaps in protection can exist when these pieces do not come together adequately, usually as a result of lack of maintenance, modifications to construction features, or fire protection systems that take them out of compliance limits, or other circumstances that cause nonconformance, as evidenced by fire losses that continue to occur. The distinct advantage of the Fire Safety Concepts Tree is its systems approach to fire safety. The Fire Safety Concepts Tree provides an overall structure with which to analyze the potential impact of fire safety strategies. It can identify gaps and areas of redundancy in fire protection strategies as an aid in making fire safety design decisions.

The Fire Safety Concepts Tree shows the elements that must be considered in building fire safety and the interrelationship among those elements. It enables a building to be analyzed or designed by progressively moving through the various concepts in a logical manner. Its degree of success depends on how completely each level is satisfied. Lower levels on the tree, however, do not represent a lower level of importance or performance; they represent a means for achieving the next higher level. Rather than considering each feature of fire safety separately, the Fire Safety Concepts Tree examines all of them and demonstrates how they influence the achievement of fire safety objectives.

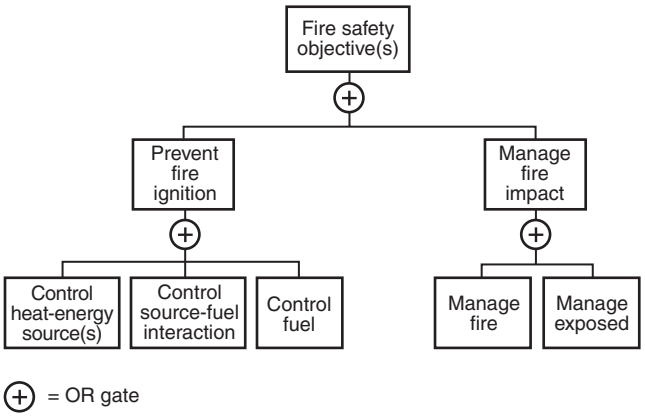

FIGURE 1.9.2 Principal Branches of the Fire Safety Concepts Tree

FIRE SAFETY CONCEPTS TREE AND FIRE SAFETY DESIGN STRATEGIES

The Fire Safety Concepts Tree provides the logic required to achieve fire safety; that is, it provides conditions whereby the fire safety objectives can be satisfied, but it does not provide the minimum condition required to achieve those objectives. Thus, according to the tree, the fire safety objectives can be met if fire ignition can be prevented or if, given ignition, the fire can be managed. This logical "OR" function is represented by the symbol (+) under fire safety objectives in Figure 1.9.2.

Evaluating a design for building fire safety represents a systematic approach to the principal fire safety strategies identified in Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection." These strategies can be identified as follows:

1. Prevent fire ignition
2. Control combustion process
3. Control fire by construction
4. Detect fire early and provide notification
5. Automatically suppress fire
6. Manually suppress fire
7. Manage exposed (people or physical objects)

In general terms, each step represents an increase in the fire size, the areas affected, and the sophistication of the intervention or mitigation strategies necessary to control or extinguish the fire.

FIRE PREVENTION STRATEGIES

The first opportunity to achieve fire safety in a building is through fire (ignition) prevention, which involves separating potential heat sources from potential fuels. Table 1.9.1 lists common factors in fire prevention and identifies major candidate heat sources and ignitable materials, common factors that bring them together, and practices that can affect the success of prevention.

Most building fires are started by heat sources and ignitable materials that are brought into the building, not built into it. This means the design of the building, from the architect's and builder's standpoint, provides limited potential leverage on the building's future fire experience. The building's owners, managers, and occupants, however, will have numerous opportunities to reduce fire risks through prevention, and they should be urged to do so.

For design purposes, fire prevention will be enhanced by careful observance of codes and standards in the design and installation of the electrical and lighting system, the heating system, and any other major built-in equipment, such as cooking, refrigeration, air conditioning, and clothes washing and drying. Venting systems need to be designed carefully to carry carbon monoxide and potential fuels along specially designed and protected paths. These venting systems will need to be inspected and cleaned regularly.

TABLE 1.9.1 Fire Prevention Factors

1. Heat Sources
   a. Fixed equipment (including electrical energy sources)
   b. Portable equipment
   c. Torches and other tools
   d. Smoking materials and associated lighting implements
   e. Explosives
   f. Natural causes
   g. Exposure to other fires
2. Forms and Types of Ignitable Materials
   a. Building materials
   b. Interior and exterior finishes
   c. Contents and furnishings
   d. Stored materials and supplies
   e. Trash, lint, and dust
   f. Combustible or flammable gases or liquids
   g. Volatile solids
3. Factors That Bring Heat and Ignitable Material Together
   a. Arson
   b. Misuse of heat source
   c. Misuse of ignitable material
   d. Mechanical or electrical failure
   e. Design, construction, or installation deficiency
   f. Error in operating equipment
   g. Natural causes
   h. Exposure
4. Practices That Can Affect Prevention Success
   a. Housekeeping
   b. Security
   c. Education of occupants
   d. Control of fuel type, quantity, and distribution
   e. Control of heat energy sources
   f. Maintenance of electrical systems

Protection from lightning and exposure fires will affect the external design of the building, particularly in certain parts of the country, such as areas near urban/wildland interface zones. A fire in one building creates an external fire hazard to neighboring structures by exposing them to heat by radiation, and possibly by convective currents, as well as to the danger of flying brands of the fire. Any or all of these sources of heat transfer may be sufficient to ignite the exposed structure or its contents.

When considering protection from exposure fires, there are two basic conditions: (1) exposure to horizontal radiation and (2) exposure to flames issuing from the roof or top of a burning building when the exposed building is higher than the burning building. Radiation exposure can result from an interior fire where the radiation passes through windows and other openings of the exterior wall. It can also result from the flames issuing from the windows of the burning building or from flames of the burning facade itself. NFPA 80A, *Recommended Practice for Protection of Buildings from Exterior Fire Exposures,* provides guidelines and data on exposure protection.

Inside the building, design features may make incendiarism, arson, or other human-caused fires more or less likely by making security and housekeeping easier or harder to perform. The interaction of the design with these critical support activities should be thought through and planned into the design from the outset.

In the fire safety concepts tree, the "prevent fire ignition" branch shown as Figure 1.9.3 essentially represents a fire prevention code. Most of the concepts described in this branch require continuous monitoring for success. Consequently, the responsibility for satisfactorily achieving the goal of fire prevention is essentially an owner/occupant responsibility. The designer, however, may be able to incorporate certain features into the building that may assist the owner/occupant in preventing fires.

It is impossible to prevent completely the ignition of fires in a building. Therefore, to reach the overall fire safety objective, a high degree of success in the "manage fire impact" branch assumes a significant role. Essentially, this branch of the fire safety concepts tree may be considered as a building code by the design team. After ignition occurs, all considerations shift to the "manage fire impact" branch to achieve the fire safety objectives.

According to the logic of the tree, the impact of the fire can be managed either through the "manage fire" or "manage exposed" branches (see Figure 1.9.2). The "OR" (+) gate indicates that the objectives may be reached through either or both design branches, as long as the avenue selected completely satisfies the fire safety objective. Naturally, it is acceptable to do both, which will increase the likelihood of success over using one branch only.

Through the "manage fire" branch, the fire safety objectives can be achieved by managing the fire itself. Figure 1.9.4 shows

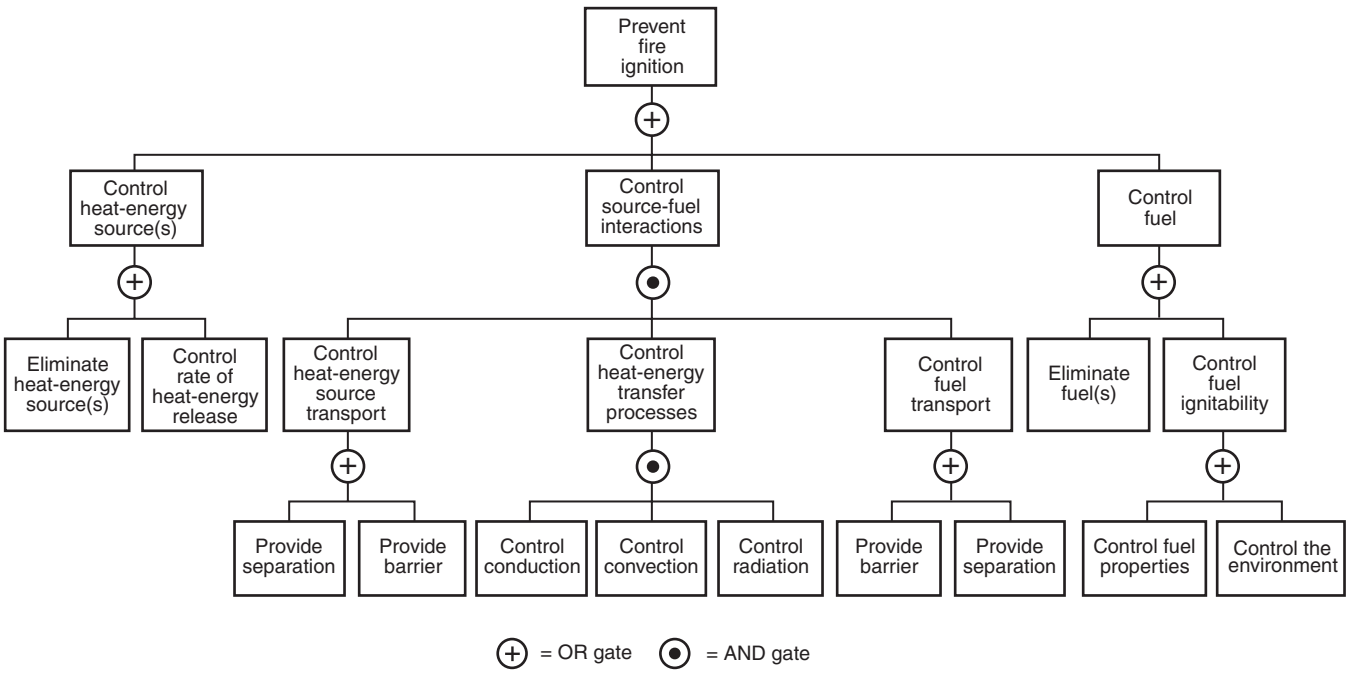

FIGURE 1.9.3 Prevent Fire Ignition Branch of the Fire Safety Concepts Tree

that this can be accomplished by: (1) controlling the combustion process, (2) suppressing the fire, or (3) controlling the fire by construction. Here, again, any one of these branches of the tree will satisfy the "manage fire" concept. In other words, sometimes success is achieved by the building construction controlling the fire, whereas other times success is from controlling the combustion process—through control of the fuel, the environment, or both.

CONTROL STRATEGIES

Combustion Process Control

The concern here is to slow the fire and provide other fire safety measures sufficient time to be effective. A systematic design for this purpose should address the possible ways that a specific quantitative hazard can grow rapidly—for example, flame spread rate, rapid growth in rate of heat release or rate of mass release, unusually toxic gases, unusual corrosivity, quantity of fuel available to feed the fire, and so forth. Each of these can be evaluated separately in terms of the threat to exposed people, property, and mission of the building.

In a building fire, the most common hazard to humans is from smoke and toxic gases. Most building-related fire deaths are directly related to these products of combustion. Death often results from oxygen deprivation in the bloodstream, caused by the replacement of oxygen in the blood hemoglobin by carbon monoxide. In addition to the danger of carbon monoxide, many other toxic gases present in building fires cause a wide range of symptoms, such as headaches, nausea, fatigue, difficult respiration, confusion, and impaired mental functioning.

Smoke, in addition to incorporating toxic and irritant gases, contributes indirectly to a number of deaths. Dense smoke obscures visibility and irritates the eyes and can cause anxiety and emotional shock to building occupants. Consequently, the occupant may not be able to identify escape routes and utilize them. Although heat injuries do not compare in quantity to those caused by inhalation of smoke and toxic gases, they are painful, serious, and cause shock to victims. In addition to deaths from thermal products of combustion, the pain and disfigurement caused by nonfatal burns can result in serious long-term physical and psychological complications.

Property also is affected by the thermal and nonthermal products of combustion, as well as by extinguishing agents. Smoke may damage goods located long distances from the effects of the heat and flames. Fires that are not extinguished quickly often result in considerable water damage to the contents and the structure, unless special measures are incorporated to prevent that damage. It should be noted, however, that the water damage caused in extinguishing a fire rarely exceeds the fire damage resulting from a fire that is not suppressed.

Fast flame spread over interior finish materials or building contents and vertical propagation of fire are serious concerns. The ability of the fire service to contain or extinguish a fire is diminished significantly if the fire spreads vertically to two or more floors. With a given potential for fire growth, the prevention of vertical fire spread is influenced principally by architectural and structural decisions involving details of compartmentation, which are discussed later.

Designing Countermeasures to Fire Growth

The building fire safety system can be organized around fire growth and its resulting products of combustion. The ease of generation and movement of these products is influenced

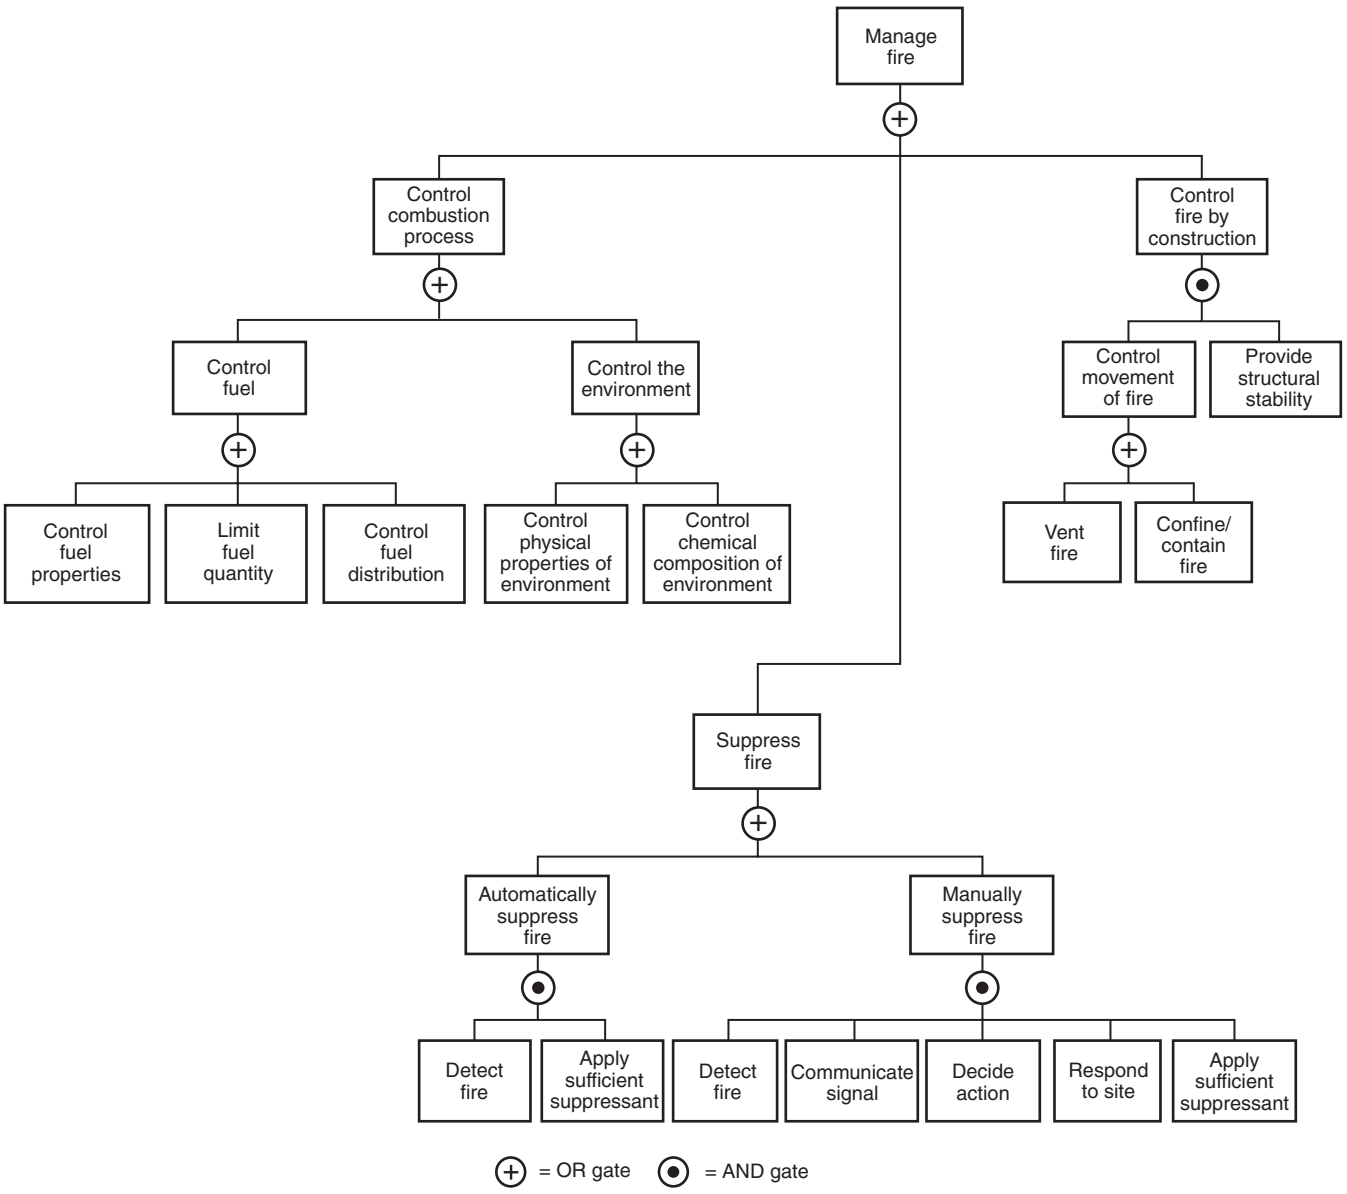

FIGURE 1.9.4 Manage Fire Branch of the Fire Safety Concepts Tree

by the countermeasures provided by the building. The effectiveness of the building fire safety systems determines the rate, quantity, and paths of movement of these products of combustion.

The speed and certainty of fire growth and development in rooms can vary greatly. The contents and interior finish in some rooms are quite safe, and, for this type of situation, it is unlikely that, once ignited, a fire can grow to full involvement of the room. On the other hand, the interior design of other rooms poses a high hazard which, if an ignition were to occur, could lead to an almost certain full room involvement when fixed fire suppression systems are not present.

The traditional method of describing the fire growth hazard has been through fire loads reflected in use and occupancy classifications. Building types, rather than rooms within buildings, have been grouped with regard to their relative hazard. A warehouse containing products that are essentially noncombustible would be considered low-hazard. Residential and educational occupancies are considered ordinary-hazard because they normally contain relatively small amounts of combustibles in the rooms. Mercantile buildings are also ordinary-hazard, even though they typically contain more fuel than other occupancies. Certain industrial and storage buildings may be considered high-hazard because they contain a high fuel load that includes materials that are flammable or even explosive.

Hazard classification is a basis for building and fire code requirements, and, historically, it has been quite useful. However, a more detailed look at the fire growth potential within the rooms of a building can be a valuable part of a detailed fire safety design. The fire growth hazard potential, which identifies

the speed and relative likelihood of a fire reaching full room involvement, is a useful base from which to design suppression interventions and to evaluate life safety problems. For example, situations in which fast moving, severe fires will occur may call for automatic sprinkler protection, even though it may not be required by a building or fire code.

The basis for a fire growth hazard analysis is the combustion potential in a room. Four main factors influence the likelihood and speed with which full room involvement occurs: (1) fuel load (i.e., the quantity and type of materials and their distribution); (2) interior finish of the room; (3) air supply; and (4) size, shape, and construction of the room.

Fire development in a room is neither uniform nor a guaranteed progression from ignition to full room involvement. Fires develop through several stages, sometimes called realms. Table 1.9.2 provides guidance on descriptions of the realms. Within any realm a fire may continue to grow or it may be unable to sustain continued development and die down. Table 1.9.2 includes a rough guide to the approximate flame sizes that may be used to describe the fire size of the realms. It also describes the major factors that influence growth within a realm. Absence of a significant number of the factors would indicate that the fire would self-terminate, rather than continue to develop.

Different rooms pose different levels of risk regarding the likelihood of reaching full room involvement and the time in which fire development takes place. Table 1.9.2 provides a general guide to the important factors.

If one were to focus on a single event that might be used to represent the relative level of hazard posed by the contents and interior finish in a room, it would be the ability of flames to reach the ceiling. The arrangement of contents and types of fuels where it would be difficult for a fire to grow to touch the ceiling pose a relatively low fire growth hazard potential. On the other hand, where furniture combustibility and density will allow a fire to develop to ceiling height, or when combustible interior finish is present, the fire growth hazard potential usually is comparatively high.

Controlling Fire by Construction

One of the most important aspects of fire-safe building design is basic construction. The structural framing and assemblies will typically endure for the life of the building whereas utilities, finishes, and contents may change over time. The aspects of building construction that influence fire safety are the inherent barriers to fire spread and the ability to avoid collapse in a fire.

Barriers. Walls, partitions, and floors separate building spaces. These barriers also delay or prevent fire (and sometimes products of combustion) from propagating from one space to another. In addition, barriers are important features in any fire-fighting operation.

The effectiveness of a fire barrier is dependent on its inherent fire resistance, the details of construction, and any penetrations, such as doors, windows, ducts, pipe chases, electrical raceways, and grilles. Although the hourly ratings of fire endurance do not always represent the actual time that the barrier can withstand a building fire, unpenetrated rated barriers seem to perform rather well. This may be due to the rather large factor of safety inherent in the codes. On the other hand, it is quite common for rated barriers to fail because of inattention to penetrations. For example, the fire resistance of a rated floor-ceiling assembly can be voided because of large or numerous pokethroughs. The fire resistance of a rated partition is lost when a door is left open.

Fire resistance requirements imposed by the regulatory system often have comparatively little meaning because of inattention to the functional and construction details. The myriad of tested and fire-rated assemblies provide extensive detail on not only construction of the assembly, but also on the process by which to manage and deal with most types of penetration in the assembly. To predict field performance of barriers, the penetrations and details of construction must be considered in addition to the fire endurance of the base construction.

TABLE 1.9.2 Major Factors Influencing Fire Growth

Realm	*Approximate Ranges of Fire Sizes*	*Major Factors that Influence Growth*
1. Preburning	Overheat to ignition	Amount and duration of heat flux, surface area receiving heat, material ignitability
2. Initial burning	Ignition to radiation point (10 in. [254 mm] high flame)	Fuel continuity, material ignitability, thickness, surface roughness, thermal inertia of the fuel
3. Vigorous burning	Radiation point to enclosure point (10 in. to 5 ft [254 mm to 1.5 m] high flame)	Interior finish, fuel continuity, heat feedback, material ignitability, thermal inertia of the fuel, proximity of flames to walls
4. Interactive burning	Enclosure point to ceiling point (5 ft [1.5 m]) high flame to flame touching ceiling	Interior finish, fuel arrangement, heat feedback, height of fuels, proximity of flames to walls, ceiling height, room insulation, size and location of openings, HVAC operation
5. Remote burning	Ceiling point to full room involvement.	Fuel arrangement, ceiling height, length/width ratio, room insulation, size and location of openings, HVAC operations

The major function of fire barriers is to prevent heat and flame spread from causing an ignition in an adjacent room or floor. It is useful to classify barrier failure in two categories. One is a massive barrier failure, which would occur when a part of the barrier collapses or when a large penetration, such as a door or a large window, is open. When a massive failure occurs, the adjacent space can become fully involved in a short period of time. The second type of failure is a localized penetration failure. This occurs when flames or heat penetrates small poke-throughs or small windows. A localized penetration failure causes a hot spot to occur which can lead to ignition of combustibles on the other side of the barrier. This was a common mode of fire propagation between floors in the February 1991 Meridian Plaza fire in Philadelphia, Pennsylvania.

Smoke and gases move through a building much faster and more easily than flames and heat. The time duration from ignition until a building space is untenable is an important aspect of fire safety, and the loss of tenability may be due to smoke and gases more often than flames and heat. Therefore, smoke barriers are also important components for controlling the effects of fire. In addition to its value as a means of containing the fire, compartmenting the interior building space also addresses specific needs for protection, such as structural integrity of the building and escape routes.

Structural Collapse. Failure of structural building elements can be a serious life safety hazard. Although prior to the World Trade Center it had not resulted in many deaths or injuries to building occupants, structural collapse has long been a hazard to fire fighters. A number of deaths and serious injuries to fire fighters occur each year because of structural failure. Although some of these failures result from inherent structural weaknesses, many are the result of renovations to existing buildings that materially, though not obviously, affect the structural integrity of the support elements. A building should not contain surprises of this type for fire fighters.

The potential for structural collapse must be determined. Building codes address this through construction classification requirements. The relationship between fire severity and fire resistance to collapse are the principal factors. Collapse can occur when the fire severity exceeds the fire endurance of the structural frame. However, this is comparatively rare. Structural collapse is more commonly associated with deficiencies in construction. These deficiencies are not evident under normal everyday use of the building. They become a problem when the fire weakens supporting members, triggering a local or global collapse.

The National Institute of Standards and Technology (NIST), working with industry experts, has prepared a comprehensive document that provides guidelines for owners and design professionals to help prevent progressive collapse of buildings in the event of certain abnormal loading conditions.[3] The document includes such topics as acceptable risk approach to progressive collapse mitigation and practical means for reducing the risk for new and existing buildings.

In the Fire Safety Concepts Tree, when considering the "control fire by construction" concept, structural integrity must be provided, and the movement of the fire itself must be controlled. As shown in Figure 1.9.4, this can be accomplished either by venting, confining, or containing the fire.

FIRE DETECTION AND ALARM STRATEGIES

Fire Detection Provisions

Fire detection provisions are needed so that automatic or manual fire suppression will be initiated, any other active fire protection systems will be activated (e.g., automatic fire doors for compartmentation and protection of escape routes), and occupants will have time to move to safe locations, typically outside the building.

One reason for concern over any rapid initial fire growth is that it can shrink the time available after detection for these life- and property-saving responses. Therefore, detection provisions must be designed systematically to reflect the building's other features, its occupants, and its other fire safety features.

For example, smoke is often the first indicator of fire, so a system of automatic detection based on smoke detectors often makes sense. In certain properties or areas, however, detectors based on heat or rate of increase in heat may be more appropriate based on the types of fires likely to occur in those areas or the potential for nonfire activations from environmental conditions. Whatever type of detection system is chosen, it is important that, for each area of the building, a realistic assessment be made of the implications for response time after the fire is detected and before a lethal or other high-hazard condition develops.

Alarm Provisions

Alarm provisions need not be linked to the detection sensor locations, but should be designed systematically to tell occupants what they need to do, based on where they are and their ability to respond. This would include the possible use of central annunciator panels and monitors to inform responsible staff, voice messages to provide instructions on occupant movements, and direct remote alarms to supervised stations or fire departments. All of these options will have an impact on the time available for some type of response and, possibly, on the efficiency of that response. A timeline can be constructed to provide a quantitative base for analysis and design of this and related building fire safety features.

SUPPRESSION STRATEGIES

Automatic Suppression

From the Fire Safety Concepts Tree, the "suppress fire" event and its branches are shown in Figure 1.9.4. In this figure, the symbol (•) represents a logical "AND" gate, and signifies that all of the elements in the level immediately below the gate are necessary to achieve the concept above the gate. To accomplish automatic suppression, for example, both concepts, that is, detecting the fire and applying sufficient suppressant, are

necessary. Similarly, to manually suppress the fire, five requirements must occur. The omission of any single concept is sufficient to break the chain and cause the failure of suppression to manage the fire.

For nearly a century and a half, automatic sprinklers have been the most important single system for automatic control of hostile fires in buildings. Many desirable aesthetic and functional features of buildings that might offer concern for fire safety because of the fire growth hazard can be protected by the installation of a properly designed sprinkler system. Among the advantages of automatic sprinklers is the fact that they operate directly over a fire and are not affected by smoke, toxic gases, and reduced visibility. In addition, much less water is used because only those sprinklers fused by the heat of the fire operate, particularly if the building is compartmented. Other automatic extinguishing systems, such as water mist, carbon dioxide, dry chemical, clean (halon replacement) agents, and high-expansion foam, may be used to provide protection for certain portions of buildings, specific hazards, or types of occupancies for which they are particularly suited.

An automatic sprinkler system has been the most widely used method of automatically controlling a fire. The major elements for determining the effectiveness of an automatic sprinkler system are (1) its presence or absence; (2) if present, its reliability; and (3) if reliable, its design and extinguishing effectiveness. Although automatic sprinkler systems have a remarkable record of success, it is possible for the system to fail. Often failure is due to a feature that could have been avoided if appropriate attention had been given at the time of the system's design, installation, or maintenance. Table 1.9.3 describes common failure modes and their causes. During the design stages, these factors should be addressed to increase the probability of successful extinguishment by the sprinkler system.

Manual Suppression

The protection offered by a community fire department has an important influence on building fire design. Some buildings are designed in a manner that helps the fire department extinguish fires while they are small; others are designed in a manner that hinders a fire department. Rarely does the designer consciously design the building for fire department emergency operations. The following discussion provides some guidelines for building design to enhance the building's ability to allow the fire department to extinguish a fire with minimal threat to life (including the lives of the first responders) and property.

Ideally, a building is designed so that should a fire occur, it can be attacked before it extends beyond the room of origin. If

TABLE 1.9.3 Common Automatic Sprinkler Failure Modes

Failure Mode	*Potential Causes*
Water supply valves are closed when sprinkler operates.	Valve supervision is inadequate. Owner's attitude is lackadaisical. Maintenance policies are not effective.
Water does not reach sprinkler.	Dry pipe accelerator or exhauster malfunctions. Pre-action system malfunctions. Maintenance and inspection are inadequate.
Sprinkler fails to open when expected.	Fire rate of growth is too fast. Response time and/or temperature of thermal element are inappropriate for the area protected. Sprinkler thermal element is protected from heat. Sprinkler thermal element is painted, taped, bagged, or corroded. Sprinkler skips.
Water cannot contact fuel. (Note: The intent of this failure mode is to ensure that discharge is not interrupted in a manner that will prevent fire control by a sprinkler.)	Fuel is protected. High-piled storage is present. New construction (walls, ductwork, ceilings) obstructs water spray.
Water discharge density is not sufficient.	Discharge needs are insufficient for the type of fire and the rate of heat release. Change in combustible contents occurs. Number of sprinklers open is too great for the water supply. Water pressure is too low. Water droplet size is inappropriate for the fire size.
Enough water does not continue to flow.	Water supply is inadequate because of original deficiencies, changes in water supply, or changes in the combustible contents. Pumps are inadequate or unreliable. Power supply malfunctions. System is disrupted.

that is not possible, the building design and construction features should retard fire spread so that the fire department will encounter a relatively small, easily controllable fire. The major aspects of this part of building design include (1) fire department notification, (2) initial agent application, (3) fire extinguishment, (4) ventilation, (5) water supply, and (6) barriers. These aspects are discussed briefly to provide guidance for incorporating features into the building that enable departments to be more effective and less harmful to the building. The importance of fire barriers was discussed in a previous section.

Fire Department Notification. The complete chain of events—that is, (1) detection of the fire, (2) decision to inform the fire department, (3) sending of the message, and (4) correct receipt of the information by the fire department—should be a part of every building fire safety design. It should be consciously designed, rather than left to chance. The time available from detection until agent application is very dependent on the speed of fire spread. Buildings have been lost from insufficient attention to the method of notifying the local fire department.

Agent Application. The next critical event is fire department application of agent to the fire. This involves three distinct events for its success: (1) arrival at the site, (2) nozzle entrance into the room, and (3) water discharge from the nozzle. Each of these events can be affected by site or building access considerations in the design, as well as training and resource levels on the fire ground.

Ideal exterior accessibility occurs where a building can be approached from all sides by fire department apparatus. This is not always possible. In congested areas, only the sides of buildings facing streets may be accessible. In other areas, topography or constructed obstacles can prevent effective use of apparatus in combating the fire. Buildings located some distance from the street can make the approach of apparatus difficult. If obstructions or topography prevent apparatus from being located close enough to the building for effective use, fire-fighting equipment—for example, aerial ladders, elevating platforms, and water tower apparatus—are rendered useless. Valuable time and labor must be expended to hand carry hose lines or ground ladders long distances.

The matter of access to buildings has become far more complicated in recent years, especially in light of the movement to secure buildings against possible terrorist attacks by establishing vehicle standoff distance criteria that precludes proximate vehicle access. The building designer must consider this important aspect in the planning stage. Inadequate attention to site details can place the building in an unnecessarily vulnerable position. If preventing adequate fire department access compromises its fire defenses, the building must compensate with more complete internal building protection. The arrival at the site is only a part of the agent application evaluation. The fire fighters then must be able to enter the building, reach the floor of the fire, and find the involved room or rooms. This is often a time-consuming, difficult task, especially in a high-rise environment. Considerable attention must be given to the problem of finding the fire and getting fire fighters and equipment to the fire.

Access to the interior of a building can be greatly hampered where large areas exist and where buildings have blank walls, false facades, solar screens, or signs covering a high percentage of exterior walls. Obstacles that prevent ventilation allow smoke to accumulate and obscure fire fighters' vision. Lack of adequate interior access also can delay or prevent fire department rescue of trapped occupants.

Windowless buildings and basement areas present unique fire-fighting problems. The lack of natural ventilation features such as windows contributes to the buildup of dense smoke and intense heat, which hamper fire-fighting operations. Fire fighters must attack fires in these spaces despite heat and smoke. This can result in lengthy times for fire extinguishment and greater damage by the products of combustion.

Fire Extinguishment. After the time-consuming and sequential events of notification and initial agent application have transpired, the fire department is ready to fight the fire. The size of fire present at the time of initial agent application determines the fire-fighting strategy and likelihood of success of the operation.

Broadly speaking, there are three types of fires. Comparatively small fires may be extinguished by direct application of water. When the fire is larger than can be directly extinguished, the building is opened (ventilated), and the hose streams drive the fire, heat, and smoke out of the building. Third, fires that are too large for this operation must be surrounded. In this last case, all available techniques of ventilation and heat absorption by water evaporation are used; however, the fire area is lost, and the main purpose of this strategy is to protect exposures, both external and internal.

Ventilation. Ventilation is an important fire-fighting operation. It involves the removal of smoke, gases, and heat from building spaces. Ventilation of building spaces performs the following important functions:

1. Protection of life by removing or diverting toxic gases and smoke from locations where building occupants must find temporary refuge.
2. Improvement of the environment in the vicinity of the fire by removal of smoke and heat. This enables fire fighters to advance close to the fire to extinguish it.
3. Control of the spread or direction of fire by setting up air currents that cause the fire to move in a desired direction. In this way, occupants or valuable property can be more readily protected.
4. Provision of release for unburned, combustible gases before they develop a flammable mixture, thus avoiding a backdraft or smoke explosion.

The building designer should be conscious of these important functions of fire ventilation and provide effective means of facilitating venting practices whenever possible. This may involve access panels, movable windows, skylights, or other means of readily opened spaces in case of a fire emergency. Emergency controls on the mechanical equipment or inclusion of an engineered smoke-control system may also be an effective means of accomplishing the functions of fire ventilation. Each building

has unique features, and, consequently, a unique solution should be incorporated into the design.

Water Supply. Water is the principal agent used to extinguish building fires. Although other agents may be employed occasionally (e.g., carbon dioxide, dry chemical, foams and surfactants, and clean Halon agent replacements), water remains the primary extinguishing agent of the fire service. Consequently, the building designer should anticipate the needs of both the fire department and automatic extinguishing systems and provide an adequate supply of water at adequate residual pressure.

Water normally is supplied to the building site by mains that are part of the water distribution system. Few cities can supply a sufficient amount of water at required pressures to every part of the city. Buildings that do not have an adequate, reliable water source for fire fighting must either provide supplemental water or incorporate other fire defense measures to compensate for this deficiency. Careful attention must be given to water supply, distribution, and pressure for fire emergencies. High-rise buildings are particularly sensitive in this respect because the water pressures required depend on building height. The water supply needs of large buildings must also be given careful attention.

Fire conditions that require operation of a large number of sprinklers or use of a large number of hose streams can reduce pressure in standpipe and sprinkler systems to the point where residual pressures in the distribution system are adversely affected. Fire department connections for sprinkler and standpipe systems are important components of building fire defenses. The building designer must carefully consider installation details of fire department connections to make sure they will be easily located, readily accessible, and properly marked. Locations should be approved by the local fire department.

MANAGING THE EXPOSED

As shown in Figure 1.9.5 from the Fire Safety Concepts Tree, fire impact can be lessened by managing the "exposed," that is, people, property, operations, environment, or heritage, depending on the design aspects being considered. In considering the "manage exposed" branch, success can be achieved either by limiting how much is exposed or by safeguarding the exposed. For example, the number of people as well as the amount or type of property in a space may be restricted. Often, this is impractical. If such is the case, the objectives can still be met by incorporating design features to safeguard the exposed.

The exposed people or property may be safeguarded either by moving them to a safe area of refuge or by defending them in place. For example, people in institutional occupancies, such as hospitals, nursing homes, or prisons, must generally be defended in place. To do this, the "defend exposed in place" branch shown in Figure 1.9.4 would be considered. On the other hand, alert, mobile individuals, such as in offices or schools, could be moved to safeguard them from fire exposure on either a short-term or long-term basis, depending on other key design

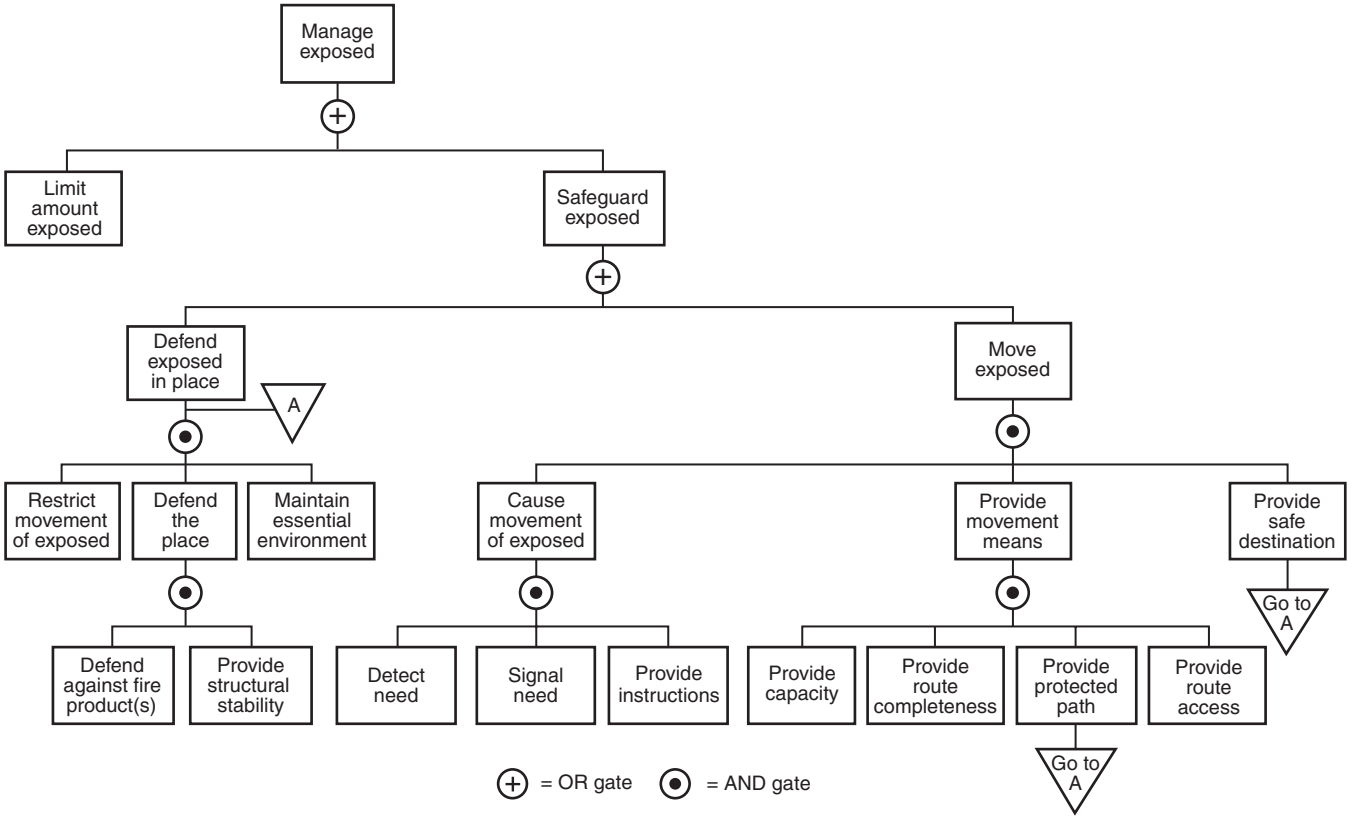

FIGURE 1.9.5 Manage Exposed Branch of the Fire Safety Concepts Tree (∇ = transfer/entry point)

elements. Strategies in high-rise buildings fall in between these two concepts. Occupants from the fire floor, the floor above, and the floor below are normally instructed to relocate to a lower floor and wait for the emergency to pass. Figure 1.9.5 illustrates the concepts that must be satisfied to meet fire safety objectives for exposed property and people.

The design for life safety may involve one or a combination of the following three alternatives: (1) evacuation of the occupants, (2) defending the occupants in place, or (3) providing an effective area of refuge or temporary shelter in place location. These alternatives can be evaluated by the likelihood that the building spaces will be tenable for the period of time necessary to achieve the expected level of safety. The criteria for tenability, therefore, become an important part of the design.

Evacuation

The design for building evacuation involves two major components: (1) availability of an acceptable path or paths for escape, and (2) effective alerting of the occupants in sufficient time to allow egress before segments of the path of egress become untenable.

Alerting occupants to the existence of a fire is a vital part of the life safety design. A useful performance objective could be to ascertain that occupants have adequate time to escape from fire before the escape route becomes blocked. To accomplish this, the designer either must ensure that the fire and the movement of its products of combustion will be slow enough to provide that time or incorporate special provisions into the building to achieve that objective.

Defending in Place

The second life safety design alternative is to defend the individual in place. This may be appropriate for occupancies such as hospitals, nursing homes, prisons, and other institutions. It may be an appropriate alternative for other buildings when the size or design may show that evacuation has an unacceptably low likelihood of success. Defend-in-place design also uses performance criteria of time and tenability levels. The performance criteria relating to time might state that the building space should be tenable for a sufficient period of time after the start of the fire. This duration could be longer than the duration of any expected fire. The definition of tenability may be quite different from that acceptable for evacuation because of the influence of both time and the products of combustion.

Refuge

The third alternative is to design for an area of refuge. In this context, the area of refuge under consideration is different from the area of refuge that is associated with accessible means of egress. This alternative involves occupant movement through the building to specially designed refuge spaces. This type of design is more difficult than either of the other two alternatives because it involves major design aspects of each. In certain types of buildings this may be a reasonable alternative. However, an evaluation of the effectiveness of the area of refuge design and its likelihood of success are extremely important.

The effectiveness of defending in place and areas of refuge may depend on the rescue capabilities of the local fire department or other emergency response service. Although traditional building codes do not address this issue, it is an important consideration in design of fire safe spaces.

Life safety design for a building is difficult. It involves more than a provision for emergency egress. It must also address the population who will be using the building and what they will be doing most of the time. Likewise, it is important to keep in mind that these same egress routes must also be robust enough to be used for "other than fire" events. Bomb threats, power failures, and release of chemical or biological agents can all initiate a phased or total building evacuation. Consideration must then be given to communication, the protection of escape routes, and temporary or permanent areas of refuge for a reasonable period of time for the building occupants to achieve safety.

Even occupants familiar with their surroundings often experience difficulty in locating means of egress. The problem is compounded for transients and occasional visitors to the building. Architectural layout and normal circulation patterns are important elements in emergency evacuation. For example, many large office buildings are a maze of offices, storage areas, and meeting rooms. Clearly marked emergency travel routes can enhance life safety features in all buildings.

Special attention to the needs of the disabled community must also be considered. Operational strategies and protocols, plus use of new technologies such as directional exit sounders should be considered.

SUMMARY

The Fire Safety Concepts Tree can be employed effectively in building design. If the architect incorporates the tree during the preliminary planning phase of design, many important decisions and alternatives can be defined more effectively. For example, decisions can be made regarding evacuation versus temporary refuge, including implications on the functions of the building. Specific needs with regard to design decisions are then recognized.

The tree also provides for the separation of the functions of fire prevention and building design. In this way, the responsibilities of the owner/occupant can be differentiated from those of the building design team. Those concepts that are eventually incorporated into the design can be identified with a specific member of the building design team.

This chapter describes in general terms the processes required to create such a design. More specific guidance requires joining the general processes described here with the more detailed guidance in later chapters on specific fire safety strategies. Building codes and NFPA standards are important factors in building design, and the Fire Safety Concepts Tree should not supersede them. Rather, the tree enables those documents to be interrelated and, consequently, used more effectively.

2

Basics of Fire and Fire Science

Ronald L. Alpert

2.1 Physics and Chemistry of Fire
2.2 Physics of Fire Configuration
2.3 Flammability Hazard of Materials
2.4 Dynamics of Compartment Fire Growth
2.5 Basics of Fire Containment
2.6 Fundamentals of Fire Detection
2.7 Theory of Fire Extinguishment
2.8 Explosions

Effective fire protection relies not just on applying rules, but on understanding the physical science of fires and explosions. Section 2, in covering the basics of fire science, provides a snapshot of this technical foundation for fire protection systems and practice. Although it is the most technical of the 21 sections of the *Fire Protection Handbook®*, this section is nonetheless only a beginning of the physical science of fire protection. Readers needing more in-depth treatment are encouraged to consult the *SFPE Handbook of Fire Protection Engineering.*

In addition to discussing the various mechanisms of heat transfer, Chapter 1, "Physics and Chemistry of Fire," deals with the physical structure of the flame, the chemistry of flame reactions, and how these influence the composition of the combustion effluents. Changes in fire characteristics, such as flame orientation, flame heat transfer, and flame spread propensity, are discussed in a new Chapter 2, "Physics of Fire Configuration." The importance of configuration lies in the fact that, for a wide range of synthetic and natural polymer fuels and for combustible surface critical dimensions greater than the order of 1 m, the configuration of the combustible surface(s) determines a fire's characteristics.

Chapter 3, "Flammability Hazard of Materials," is also new to this edition. This chapter provides the physical basis for and a description of test methods by which the ignitability, heat release rate, flame spread propensity, smoke yield, and extinguishability components of flammability hazard are measured or characterized for solid combustibles.

The purpose of Chapter 4, "Dynamics of Compartment Fire Growth," is to provide a basic understanding of fire growth in enclosed spaces, from the time when burning is first established to the time when the fire involves the entire compartment and the burning rate is controlled by airflow into and out of the compartment's ventilation openings.

Chapters 5 through 7 provide the science that underlies fire protection strategies. Chapter 5, "Basics of Fire Containment," discusses the engineering basis for code provisions pertaining to structural fire resistance and related furnace test methodology and includes some fundamental concepts related to exterior fire spread and how this can be prevented by providing a safe separation distance. Chapter 6, "Fundamentals of Fire Detection," offers a simplified review of fire development in the context of detection and also covers fire signatures and detectable phenomena, thus setting the scene for Section 14, "Detection and Alarm." Chapter 7, "Theory of Fire Extinguishment," covers various physical mechanisms for affecting the combustion process with water and other agents. (Those mechanisms are treated in much more detail in Section 16, "Water-Based Fire Suppression Equipment," and Section 17, "Fire Suppression Systems and Portable Fire Extinguishers.")

The section closes with Chapter 8, "Explosions," which covers that specialized topic through a discussion of various types of explosions, energies released, peak pressures produced, and resulting blast waves.

Ronald L. Alpert, Sc.D., is former manager of the flammability technology research program at FM Global. He heads the U.S. delegation to the International Standards Organization Technical Subcommittee on Fire Safety Engineering and is editor of the *Journal of Fire Protection Engineering.*

Chapter 1

Physics and Chemistry of Fire

Revised by
Dougal Drysdale

Chapter Contents

Heat Transfer
Flame Structure
Fire Chemistry
Chemical Reactions in Flames
Burning of Solids and Liquids

Key Terms

endothermic reaction, exothermic reaction, flame (diffusion), flame (premixed), gasification, heat (units of), heat flux, heat transfer, latent heat, mass flux, specific heat, Stefan-Boltzman constant, stoichiometric combustion, temperature (units of)

Fire is a complex process that involves many interactions between chemical and physical processes. The fundamentals are discussed in this chapter and interactions are identified when relevant. Some of these interactions are illustrated in Figure 2.1.1.

This simplified model of a burning surface shows how the flow of fuel vapors is maintained by heat transfer from the flames to the surface. The maximum rate of burning (as a mass flux, $\dot{m}''$) will be achieved when a steady-state condition is reached, as expressed by the following formula:

$$\dot{m}'' = \frac{\dot{Q}''_{\text{flame}} - \dot{Q}''_{\text{loss}}}{L_g} \text{ kg/sec} \quad (1)$$

where $\dot{Q}''_{\text{flame}}$ is the heat flux from the flame to the surface (kW/m^2), $\dot{Q}''_{\text{loss}}$ is the heat loss from the surface (kW/m^2) expressed as a flux through the surface, and L_g is the heat of gasification (kJ/kg). This formula and Figure 2.1.1 contain the essence of our understanding of fire and fire behavior—specifically, the role of heat transfer in determining the burning process.

In addition to discussing the various mechanisms of heat transfer, this chapter will deal with the physical structure of the flame, the chemistry of flame reactions, and how these reactions influence the composition of the combustion effluents. The physics of ignition and their relationship to the combustibility of materials are dealt with in Section 2, Chapter 2, "Physics of Fire Configuration." The processes that take place within flames are the source of smoke and hot fire products that flow from the seat of the fire, perhaps forming a ceiling layer that will contain smoke and toxic species and act as a source of radiant heat, which will promote the spread of fire beyond the items first involved (Section 2, Chapter 4, "Dynamics of Compartment Fire Growth"). The composition of the layer will determine the toxicity of the smoke that may spread throughout a building, and the reactions will promote the formation of particulate soot, which is the precursor of smoke. Predicting the amount of smoke that may be produced in a fire is almost impossible. Nevertheless, we can identify features of material properties, which will influence the yield of smoke, and indeed influence the rate at which fire will develop. These issues will be discussed in the following sections.

See also the following chapters in Section 2: Chapter 2, "Physics of Fire Configuration"; Chapter 3, "Flammability Hazard of Materials"; Chapter 4, "Dynamics of Compartment Fire Growth"; Chapter 7, "Theory of Fire Extinguishment"; and Chapter 8, "Explosions"; and various chapters in Section 6, "Characteristics of Materials and Products," including Section 6, Chapter 15, "Explosives and Blasting Agents."

HEAT TRANSFER

In considering many fire problems, it is common to think in terms of temperatures, such as the ignition temperature of a combustible solid, the softening points of thermoplastics, and the temperature

Dr. Dougal Drysdale is professor emeritus of fire safety engineering at the University of Edinburgh, author of *An Introduction to Fire Dynamics,* and a section editor of the *SFPE Handbook of Fire Protection Engineering.*

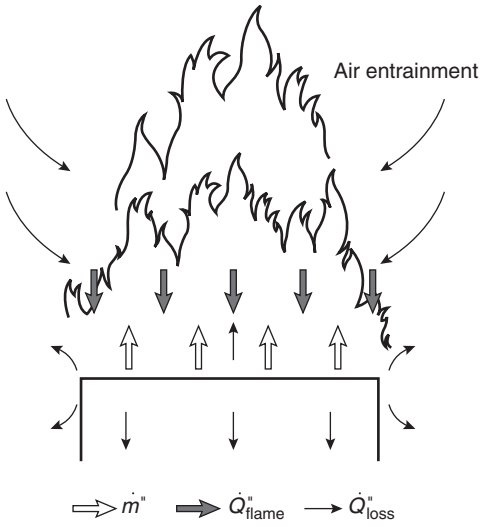

FIGURE 2.1.1 Diagram of a Burning Surface

of structural steel at which there has been sufficient weakening to cause concern. However, this view is too simplistic—it is much more important to consider how these temperatures are achieved as a result of heat transfer. Indeed, it is no exaggeration to say that heat transfer governs all aspects of fire, from ignition through to the fully developed fire and beyond to the failure of structural elements.

Heat transfer is driven by temperature difference: heat always flows from higher to lower temperatures. Before considering the various mechanisms of heat transfer, it is important to review the basic terms used, including the concept of temperature itself.

Temperature Units

Celsius. A Celsius (or centigrade) degree (°C) is 1/100th of the difference between the temperature of melting ice and boiling water at standard atmospheric pressure (101.3 kPa). On the Celsius scale, zero (0°C) is defined as the melting point of ice, and 100°C as the boiling point of water. The Celsius unit is approved by the International System (SI) of units.

Kelvin. A Kelvin degree or Kelvin (K) is the same size as the Celsius degree but the zero on the Kelvin scale is –273.15°C. Zero on the Kelvin scale is the lowest achievable temperature, known as "absolute zero"; thus, the Kelvin scale provides us with so-called *absolute temperatures*. The Kelvin is an approved SI unit. When expressing the units of a property such as specific heat, K is commonly used to indicate "degree" whether the Kelvin or Celsius scale is being referred to in the text. For example, the units of heat capacity are kJ/kg·K.

Fahrenheit. A Fahrenheit degree (°F) is 1/180 of the difference between the temperature of melting ice and boiling water at standard atmospheric pressure (101.3 kPa). On the Fahrenheit scale, the melting point of ice (0°C) is taken as 32°F; thus, 212°F is the boiling point of water (100°C).

Rankine. A Rankine degree (°R) is the same size as the Fahrenheit degree, but on the Rankine scale, zero is –459.67°F (–273.15°C). The Rankine scale provides us with absolute temperatures.

Fahrenheit and Rankine degrees are not approved SI units, and their use is greatly discouraged.

Temperature Measurement

Devices that measure temperature depend on physical change (expansion of a solid, liquid, or gas), change of state (solid to liquid), energy change (changes in electrical potential energy, i.e., voltage), or changes in thermal radiant emission and/or spectral distribution. The principles of operation of the more common temperature-measuring devices are discussed next.

Liquid Expansion Thermometers. These thermometers consist of a tube partially filled with a liquid. The tube measures expansion and contraction of the liquid by changes in temperature. The tube is calibrated to permit reading the level of the liquid in degrees of a temperature scale. The most common example is the mercury-in-glass thermometer.

Bimetallic Thermometers. Bimetallic thermometers are made from strips of two metals that have different coefficients of expansion. They are laminated together so that, as the temperature changes, the strip deflects because the metals expand or contract to different extents. The amount of deflection is measured on a scale that is calibrated in degrees of temperature.

Thermocouples. Thermocouples consist of a pair of wires of different metals or alloys welded together at a point to form a junction. A voltage is generated across this junction, the magnitude of which depends on the nature of the metals and the temperature. The magnitude is compared with a compensating junction at 0°C and the voltage difference is calibrated to give the temperature in degrees.

Pyrometers. Pyrometers measure the intensity of radiation from a hot object. Because intensity of radiation depends on temperature, pyrometers can be calibrated to give readings in degrees of temperature. Optical pyrometers measure the intensity of a particular wavelength of radiation.

Heat Units

Joule (J). Conventionally, the joule is defined as the energy (or work) expended when unit force (1 newton) moves a body through unit distance (1 m). The joule is the most convenient unit of energy to use and can be related to the calorie (*q.v.*), which is defined in terms of the heat energy required to raise the temperature of unit mass of water by 1°. The joule (J) is an approved SI unit, as are kJ (kilojoule) and MJ (megajoule) where 1 kJ = 1000 J and 1 MJ = 1000 kJ.

Watt (W). The watt is a measure of power or the rate of energy release (or consumption). One watt is equal to 1 joule per second (1 W = 1 J/sec). The rate of heat release from a fire can be expressed in kilowatt (kW) or megawatt (MW), units that

are familiar to the electrical engineer. The watt, kilowatt, and megawatt are approved SI units.

Calorie. One calorie is the amount of heat required to increase the temperature of 1 g of water by 1°C (measured at 59°F [15°C]). One calorie is equivalent to 4.183 J.

British Thermal Unit (Btu). The amount of heat required to raise the temperature of 1 lb of water by 1°F (measured at 60°F [15.5°C]) is called the British thermal unit. One Btu equals 1054 J (252 calories) or 1.054 kJ. Btu and calories are *not* approved SI units.

Heat energy has quantity as well as potential (intensity). For example, consider the following analogy. Two water tanks stand side by side. If the first tank holds twice as many liters as the second, then the first tank can hold twice the quantity of water as the second. However, if the level of water in the two tanks is equal, then their pressures or potentials are equal. If the two tanks are joined by a pipe at low level, water will not flow from one to the other because both tanks have the same equilibrium pressure. In a similar manner, one body may hold twice the quantity of heat energy (measured in joules) as a second body. However, if the potentials or temperatures of the bodies are equal, no heat energy will flow from one body to the other when they are brought into contact because the bodies are at equilibrium. If a third body at a lower temperature were brought into contact with the first body, heat would flow from the first to the third until both body temperatures became equal. The amount or quantity of heat flowing until this equilibrium is reached depends on the heat retention capacities of each body involved. (Note that, essentially, ignition involves the addition of sufficient heat [by heat transfer, *q.v.*] to raise the temperature to the appropriate value. On the other hand, extinction may be accomplished by the removal of heat. "Chemical" extinguishment works by another mechanism, i.e., by interrupting chemical reactions that are important in the combustion process.)[1]

Specific Heat

The specific heat of a substance defines the amount of heat it absorbs as its temperature increases. It is expressed as the amount of thermal energy required to raise unit mass of a substance by 1 degree, and its units are J/kg·K. Water has a specific heat of 4200 J/kg·K.

Specific heats vary over a considerable range from 460 J/kg·K for steel to 2400 J/kg·K for oak. Values of specific heat are relevant to fire protection because they define the amount of heat required to raise the temperature of a material to a point of danger or the quantity of heat that must be removed to cool a burning solid to below its firepoint. One reason for the effectiveness of water as an extinguishing agent is that its specific heat is higher than that of most other substances (4200 J/kg·K).

Latent Heat and Heat of Gasification

A substance absorbs heat when it is converted from a solid to a liquid or from a liquid to a gas. This thermal energy is called latent heat. Conversely, heat is released during conversion of a gas to a liquid or a liquid to a solid.

Latent heat is the quantity of heat absorbed by a substance passing between liquid and gaseous phases (latent heat of vaporization) or between solid and liquid phases (latent heat of fusion). A small number of compounds (e.g., naphthalene) go directly from the solid phase to the vapor phase without any chemical change, a transition known as sublimation. This is associated with a latent heat of sublimation. Latent heats are measured in joules per unit mass (J/kg). The latent heat of fusion of water (normal atmospheric pressure) at the freezing or melting point of ice (0°C) is 333.4 kJ/kg; the latent heat of vaporization of water at its boiling point (100°C) is 2257 kJ/kg. The large heat of vaporization of water is another reason for the effectiveness of water as an extinguishing agent. It requires 3 MJ to convert 1 kg of ice at 0°C to steam at 100°C. The latent heats of most other common substances are substantially less than that of water. Thus, the heat absorbed by water evaporating from the surface of a burning solid is a major factor in reducing its temperature and thus reducing the rate of pyrolysis and preventing flame spread to adjacent hot surfaces.

The term *heat of gasification* (L_g in Equation 1) is used to describe the amount of energy that is required to produce unit mass of flammable vapor from a combustible solid that is initially at ambient temperature. Unlike sublimation, chemical decomposition (pyrolysis) of the parent molecules occurs during the process. Heat of gasification is very important because it determines the amount of flammable vapor supplied to a fire in response to a given supply of heat to the pyrolyzing surface. (The fire hazard of some plastics can be reduced by adding inert fillers, such as alumina trihydrate, which increase the effective heat of gasification.)

Density. The density of a substance is the ratio of its mass to volume (expressed as g/cm^3 or kg/m^3).

Specific Gravity. Specific gravity is the ratio of the mass of a solid or liquid substance to the mass of an equal volume of water. (At 15°C, the mass of 1 cm^3 of water is 1 g.)

Gas Specific Gravity. Gas specific gravity is the ratio of the mass of a gas to the mass of an equal volume of dry air at the same temperature and pressure. It is equal to its molecular weight divided by 29, where 29 is the effective molecular weight of dry air (approximately 21% oxygen + 79% nitrogen), and can be derived by applying the ideal gas law (see below).

Buoyancy. Buoyancy is the upward force exerted on a body or volume of fluid by the ambient fluid surrounding it. If the volume of a gas has positive buoyancy, then it is lighter than the surrounding gas and will tend to rise. If it has negative buoyancy, it is heavier and will tend to sink. The buoyancy of a gas depends on both its molecular weight (see *gas specific gravity*) and its temperature.

If a flammable gas with a gas specific gravity greater than 1 leaks relatively slowly from its container, it will tend to sink to a low level. If the conditions are right, it can travel considerable distances and may be ignited by a remote source of ignition. If propane (C_3H_8, molecular weight 44) leaks from a cylinder, it will accumulate and spread at ground level with little dilution.

In a confined space, such as a basement or a boat with poor ventilation, this situation presents a serious hazard.

The density of a gas decreases as its temperature is increased. Thus, hot products of combustion rise. On the other hand, immediately following a spillage of liquefied natural gas (LNG, mainly methane, which has a molecular weight of 16), the vapor is heavier than air because it is at a very low temperature (the boiling point of methane is –161.5°C). As with propane at ambient temperature, LNG spills can be very dangerous because the vapor can spread over a wide area. However, the gas specific gravity of methane is only 0.55 (16/29) so that at ambient temperature the gas rises and disperses. In an enclosed area, it can create an explosion hazard very rapidly (see Section 2, Chapter 8, "Explosions").

Heat Transfer Mechanisms[2,3]

The three basic mechanisms of heat transfer, namely, conduction, convection, and radiation, must be considered together in any fire-related situation, although it is not uncommon for one to dominate the others. Each mechanism will be discussed in detail later, but it is appropriate first to summarize the basic equations. Conduction and convection are similar in that the rate of heat transfer is determined by a simple temperature difference $T = (T_1 - T_2)$, where temperatures can be expressed in °C or degrees Kelvin (K).

The equation for conductive heat transfer is given by

$$\dot{q}'' = \frac{k}{L}\Delta T \text{ kW/m}^2 \qquad (2)$$

This equation applies to heat transfer through solids, where k and L are the thermal conductivity (kW/m·K) and the thickness (m) of the material, respectively. (Caveat: rate of heat transfer may also be expressed in the unit W/m^2. Always check for consistency of units.)

For convective heat transfer between a solid (or a liquid) surface and a fluid (such as air) in contact with that surface, the equation is

$$\dot{q}'' = h\Delta T \text{ kW/m}^2 \qquad (3)$$

where h is the convective heat transfer coefficient (kW/m^2·K). This is not a material property, as will be discussed later.

Radiative heat transfer is quite different. Whereas heat transfer by conduction and convection requires an intervening medium, radiation can occur across a vacuum. The relevant equation for heat loss from a surface is given by

$$\dot{q}'' = \varepsilon\sigma T^4 \text{ kW/m}^2 \qquad (4)$$

where the temperature is in degrees Kelvin, σ is the Stefan-Boltzman constant (56.7×10^{-12} kW/m^2·K^4), and ε is the emissivity, or the efficiency with which the surface can radiate. The most efficient emitters are called *black bodies* and have an emissivity of 1.0.

Conduction[4]

Heat transfer through a solid (e.g., from a heated surface to the interior of the solid) is the process called *conduction.* The rate at which heat (energy) is transferred through a body under steady-state conditions is a function of the temperature difference and the conductance of the path involved. Conductance depends on the *thermal conductivity,* the *cross-sectional area* normal to the flow path, and the *length* of the flow path. The rate of heat transfer is simply the quantity of heat transferred per unit time, but it is convenient to normalize it to unit cross-sectional area and express heat transfer in terms of the heat "flux" (i.e., per unit surface area, normally given the symbol $\dot{q}''$ in which the dot over the q specifies per unit time and the double prime indicates per unit surface area).

Transient heat conduction problems can be extremely complex, despite the simplicity of Equation 2,[4] but simple steady-state problems can be used to illustrate a number of important concepts. For example, it is straightforward to calculate the steady-state heat flux ($\dot{q}''$) through a pane of glass (thickness 5×10^{-3} m and thermal conductivity 0.76×10^{-3} kW/m·K) if the temperatures of the "inside" and "outside" surfaces are known. Using Equation 2 and assuming that $T_{wi} = 25$°C and $T_{wo} = 5$°C (i.e., $\Delta T = 20$ K) [Figure 2.1.2(a)], the heat flux through the glass is

$$\dot{q}'' = \frac{k}{L}\Delta T = \frac{0.76 \times 10^{-3}}{5 \times 10^{-3}}(25 - 5) = 3.04 \text{ kW/m}^2 \qquad (2a)$$

However, this problem is not the one we normally wish to solve. If we want to calculate the rate of heat loss through a window, we normally know the inside and outside air temperatures (T_1 and T_2, respectively). Heat is transferred to the inside surface of the glass by convection. Under steady-state conditions, according to Equation 3, this rate will be given by

$$\dot{q}'' = h(T_1 - T_{wi}) \qquad (5)$$

where T_{wi} is the inner surface temperature of the glass (unknown). If the temperature of the outside surface of the glass is T_{wo} (also unknown), we use Equation 2 to calculate the rate of heat transfer by conduction through the glass, as follows:

$$\dot{q}'' = \frac{k}{L}(T_{wi} - T_{wo}) \qquad (6)$$

and the rate of heat loss to the outside air (by convection) will be

$$\dot{q}'' = h(T_{wo} - T_2) \qquad (7)$$

where T_2 is the external air temperature.

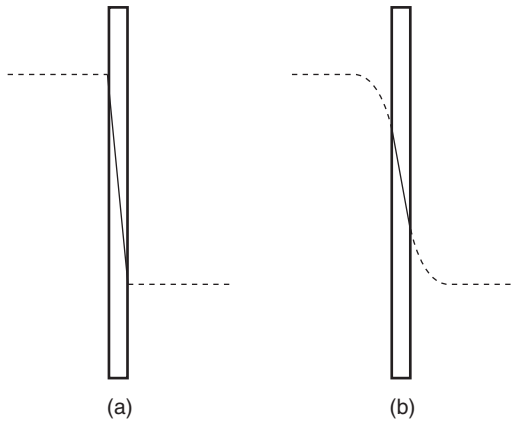

FIGURE 2.1.2 Heat Loss Through a Window

Under steady-state conditions, these three heat fluxes must be equal. If Equations 5, 6, and 7 are rearranged as follows

$$\frac{\dot{q}''}{h} = (T_1 - T_{wi})$$

$$\frac{\dot{q}''L}{k} = (T_{wi} - T_{wo})$$

$$\frac{\dot{q}''}{h} = (T_{wo} - T_2)$$

and added together, we get (after rearrangement)

$$\dot{q}'' = \frac{T_1 - T_2}{\frac{1}{h} + \frac{L}{k} + \frac{1}{h}} \tag{8}$$

This equation has the same form as the equation that describes the flow of an electrical current (I) induced by a voltage V along a wire of resistance R:

$$I = \frac{V}{R} \tag{9}$$

In Equation 8, the heat flux and the temperature difference are analogous to the current and the voltage, respectively, and the denominator is, effectively, a thermal resistance. Protection of structural steel by thermal cladding is an example of providing thermal resistance to the flow of heat into the steel.

Applying appropriate values for the quantities in Equation 7 for the rate of heat loss through the pane of glass (taking h = 0.01 kW/m^2·K), we get

$$\dot{q}'' = \frac{T_1 - T_2}{\frac{1}{h} + \frac{L}{k} + \frac{1}{h}} = \frac{25 - 5}{\frac{1}{0.01} + \frac{5 \times 10^{-3}}{0.76 \times 10^{-3}} + \frac{1}{0.01}} =$$

$$\frac{20}{206.58} = 0.0968 \text{ kW/m}^2$$

which is significantly less than that calculated previously when the surfaces of the glass were assumed equal to the air temperatures (Equation 2a). The actual surface temperatures can be backed out of Equations 5 and 7, substituting $\dot{q}''$ for, h, T_1, and T_2, giving T_{wi} = 15.3°C and T_{wo} = 14.7°C (each to one decimal place) [see Figure 2.1.2(b)]. Clearly, convective heat transfer at the two surfaces throttles the rate of heat loss from the room. This concept is very clearly illustrated if the sheet of glass is replaced by a sheet of mild steel of the same thickness but of high thermal conductivity, that is, 45.8 × 10^{-3} kW/m·K. According to Equation 8, the heat loss would be

$$\dot{q}'' = \frac{T_1 - T_2}{\frac{1}{h} + \frac{L}{k} + \frac{1}{h}} = \frac{25 - 5}{\frac{1}{0.01} + \frac{5 \times 10^{-3}}{45.8 \times 10^{-3}} + \frac{1}{0.01}} =$$

$$\frac{20}{200.11} = 0.09994 \text{ kW/m}^2$$

which is only 3 percent more than through the pane of glass.

The thermal conductivity of steel is so high that the temperature of the steel is virtually uniform. This can be shown by carrying out the same calculation as previously for the temperatures of the "inside" and "outside" surfaces of the steel. Thus, T_{wi} = 15.006ºC and T_{wo} = 14.994ºC, a difference of only 0.012 K between the faces, yet large enough to allow a heat flux of 0.0999 kW/m^2 to pass through. It is said to behave as a *thermally thin* solid under these specific conditions. The test for whether a sample will behave as thermally thin is to examine the dimensionless Biot number, $Bi = hL/k$, which is effectively the ratio of the rate of convective transfer to the surface to the rate of conductive transfer from the surface (into the solid). If the Biot number is less than 0.1, then any temperature gradient within the solid can be ignored and the material can be treated by the "lumped thermal capacity" approximation. The two examples (glass and steel) have Biot numbers of 0.65 and 0.011, respectively; that is, only the steel behaves as thermally thin in this case. Perhaps surprisingly, a 50-mm-thick slab of steel also behaves as (just) thermally thin (Bi = 0.11). It is for this reason that the "lumped thermal capacity" model can be used in calculations of the temperature response of steel elements and of fusible links in sprinkler heads when exposed to heat. This model makes transient heat transfer calculations much easier.

For example, consider a thermally thin combustible solid, which can be ignited when its temperature reaches T_{ig}ºC (the "firepoint"). Then we can estimate how long it would take for it to ignite if exposed to a defined heat flux. Taking a sheet of paper, for which L = 0.5 × 10^{-3} m and k = 0.1 × 10^{-3} kW/m·K, then if h = 0.015 kW/m^2·K, we can treat it as "thermally thin" because Bi = 0.07. If it is heated convectively by exposing it to air at T_∞ on both sides, then the rate of temperature rise will be

$$\frac{dT}{dt} = \frac{Ah}{V\rho c}(T_\infty - T) \tag{10}$$

where T is the temperature of the solid, which will be uniform across the full thickness (Bi < 0.1), A is the area through which the heat is transferred, and V is the associated volume of material to which the heat is transferred. This equation is a statement that the rate of temperature rise of the material is equal to the rate of heat transfer by convection $Ah(T_\infty - T)$ divided by the thermal capacity of the volume of material associated with surface area A.

Rearrangement and integration gives

$$\frac{T_\infty - T}{T_\infty - T_o} = \exp\left(-\frac{2ht}{x\rho c}\right) \tag{11}$$

where T_o is the initial temperature of the paper and $x = V/2A$. The factor of 2 appears because heat is being transferred to both faces, halving the effective thickness.

If the "firepoint temperature" is T_{ig}, through rearrangement a value for the time to ignition can be given by

$$t_{ig} = \frac{x\rho c}{2h} \ln\left(\frac{T_\infty - T_o}{T_\infty - T_{ig}}\right) \tag{12}$$

This equation shows that the time to ignition is proportional to the thickness x (or, more correctly, the thermal capacity per unit surface area). Moreover, T_∞ must be greater than T_{ig} for ignition to be possible. (The same equation provides the basis for the "response time index" of sprinkler heads.)

However, most materials of interest do not behave as thermally thin and temperatures cannot be assumed to be uniform—a

temperature gradient will exist. In the steady state, this gradient will be linear, but if one face of a slab, initially at a temperature T_o, is suddenly exposed to a convective (or a radiative) heat flux, then heat will be conducted into the slab as the surface temperature rises, developing a transient temperature profile through the slab thickness, as illustrated schematically in Figure 2.1.3. In that figure, profiles (a) through (c) (at 1, 5, and 10 minutes, respectively) are behaving as semi-infinite solids, but heat is being lost through the rear face in (d) and (e) (30 and 120 minutes, respectively). The dotted line identifies the initial temperature of the slab.

The ability of the slab to conduct heat from the surface will influence how rapidly the surface temperature can rise. Materials of high thermal conductivity (such as steel) feel cold to the touch because they draw the heat away from the surface. Alternatively, if you place your hand on the surface of a block of polyurethane foam, it feels warm because heat is not conducted away from the surface and heat losses from your hand are reduced.

The mathematics of transient heat transfer in thermally thick solids are not straightforward and it is easier to consider the semi-infinite solid for which a mathematical solution exists. A semi-infinite solid is one for which thermal loss from the rear face is not an issue because the "heat wave" never reaches the rear surface [see Figures 2.1.3(a), 2.1.3(b), and 2.1.3(c)]. The expression for the temperature rise of the surface of the semi-infinite solid is given by the following equation:

$$\frac{T - T_o}{T_\infty - T_o} = 1 - \exp\left(\frac{h^2 t}{k\rho c}\right) \cdot erfc\left(\frac{h\sqrt{t}}{\sqrt{k\rho c}}\right) \qquad (13)$$

in which t is time (sec) and the product k (thermal conductivity, kW/m·K) × ρ (density, kg/m^3) × c (heat capacity, kJ/kg·K) is known as the thermal inertia ($k\rho c$). A high value, associated particularly with a high value of k, means that the surface temperature will increase very slowly indeed, whereas the surface temperature of insulating materials (low value of k and, hence, low $k\rho c$) will show a very rapid temperature response. This is illustrated in Figure 2.1.4 for a range of materials.

Although the concept of the semi-infinite solid is an abstraction, the equation is valid for real solids when one face is exposed to a heat flux for a short period of time. This is shown in Figure 2.1.3(a) to (c). The surface temperature has increased, but the rear face is still at the initial temperature T_o. To all intents and purposes, a slab of finite thickness will behave as a semi-infinite solid until the rear face temperature starts to rise, that is, before there are significant heat losses from the rear face. This period of time (t) is defined for a thickness x by the expression $x = 4\sqrt{\alpha t}$, where $\alpha = k/\rho c$ (m^2/sec) is known as the thermal diffusivity, although $x = 2\sqrt{\alpha t}$ is a good approximation. Consequently, thick materials that ignite quickly when exposed to a high heat flux may still be behaving as semi-infinite solids. (This assumption can be made when analyzing the times to ignition for samples exposed to high heat fluxes in test equipment such as the cone calorimeter.)

Samples of material that behave in this way may be said to behave as thermally thick solids, the semi-infinite solid being the ultimate example for which the steady state can never be achieved. Real thicknesses, in principle, can reach the steady state, although in fires this is rare and probably of little relevance. It is the transient behavior that is important: How quickly can a combustible solid be ignited under a given heat flux? How rapidly will flames spread over surfaces? How quickly will an insulated steel column reach a critical temperature? and so on.

Convection

Convection involves the transfer of heat by a circulating fluid—either a gas or a liquid. Thus, heat generated in a stove is distributed throughout a room by heating the air in contact with the stove (by conduction across the stationary boundary layer in contact with the hot surface). The hot, buoyant air then rises, setting up convection currents that transfer heat to distant objects in the room. Heat is transferred from the air to these distant objects again by conduction across the boundary layer. Air currents can be made to carry heat by convection in any direction by use of a fan or blower (forced convection).

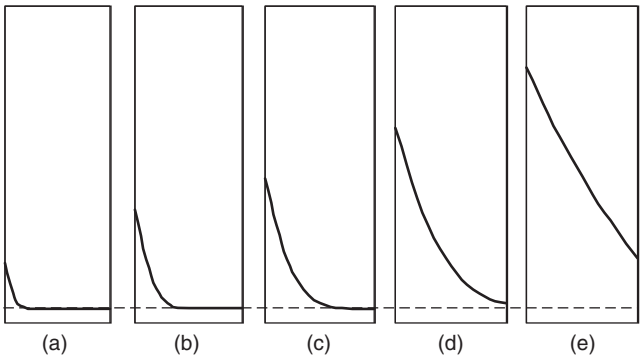

FIGURE 2.1.3 Temperature Profiles at Increasing Time Intervals Inside a Thick Solid as Heat Is Transferred Through the Left Face

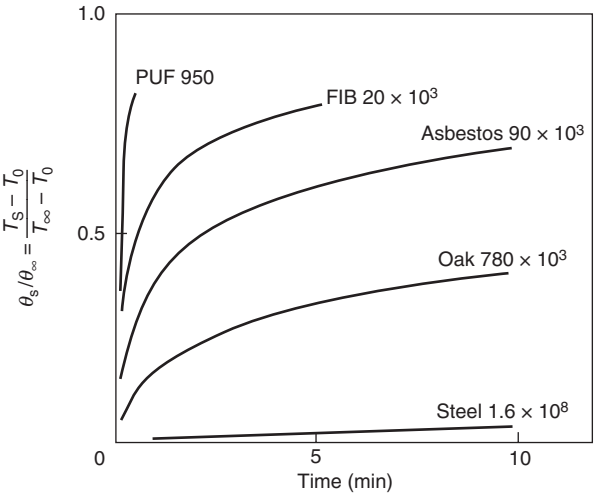

FIGURE 2.1.4 Effect of Thermal Insulation ($k\rho c$) on the Rate of Temperature Rise at the Surface of a "Semi-Infinite" Solid. The figures are values of $k\rho c$ in units W^{2}sec/m^{4}K^2. FIB = fiber insulation board; PUF = polyurethane foam.

In the present context, the term *convective heat transfer* is commonly used to describe the mode of heat transfer between a fluid and a solid surface. The corresponding convective heat transfer coefficient (h) is defined by Equation 3:

$$\dot{q}'' = h\Delta T \text{ kW/m}^2$$

where $\dot{q}''$ is the rate of heat transfer per unit surface area (kW/m^2), and ΔT is the temperature difference (K) between the fluid and the surface. The convective heat transfer coefficient h (kW/m^2·K) is defined by this expression, but it is not a simple material property. It depends on a number of factors, including the geometry of the system, the characteristics of the flow (laminar or turbulent), the properties of the fluid, and the temperature difference between the surface and the fluid.

The movement of the fluid may occur naturally, driven by density differences (buoyancy-driven flow) or it may be a result of an imposed flow (forced convection). In the former case, if a surface is at a higher temperature than the surrounding fluid (e.g., air), then the air adjacent to the surface will be heated and become less dense than the surrounding air and so rise. Density of air can be calculated using the ideal gas law, which describes the relationship between pressure, temperature, and volume for a gas:

$$PV = nRT \tag{14}$$

where P is pressure (Pa, or bar), V is volume (m^3), T is the temperature (K), R is the ideal gas constant (8.314 J/K·mol or 8.2×10^{-5} m^3·atm/K·mol), and n is the number of moles of gas involved.

This shows that for a given quantity of gas (i.e., n is constant), pressure is inversely proportional to volume at constant temperature (this is known as Boyle's law), whereas for a sealed container (constant n and V), pressure is directly proportional to temperature (Charles' law). Air, its constituent gases, and the "permanent gases" (H_2, He) obey this law closely, although higher molecular weight species tend to deviate from "ideal behavior." The easiest way of distinguishing between a gas that is likely to behave "ideally" and one that does not is to consider its boiling point. Gases that are close to their condensation temperature (i.e., just above the boiling point of the liquid) are likely to deviate strongly from ideal behavior: such gases are more properly described as "vapors."

Nevertheless, this equation is widely used in fire safety engineering calculations. In most cases, the extent of dilution of fire gases is so great that they consist mainly of air. The preceding equation is a satisfactory approximation to real behavior.

The density of air can be calculated using the ideal gas law (Equation 13); density (mass/unit volume) is given by the ratio $n \times MW/V$, where MW is the molecular weight of air (28.95 g). Thus

$$\text{Density of air} = \frac{n \times MW}{V} = \frac{P \times MW}{RT} \tag{15}$$

At ambient temperature (T = 293 K [20ºC]) and pressure (P = 1 bar), with $R = 8.2 \times 10^{-5}$ m^3·atm/K·mol:

$$\text{Density of air } (\rho_{air}) = 1204.9 \text{ g/m}^3$$

It is inversely proportional to the *absolute* temperature (degrees Kelvin), so that at 100ºC (373 K), ρ_{air} = 898.3 g/m^3. Air heated to this temperature will have significant buoyancy with respect to the surrounding air at 20ºC.

Experiments have shown that the convective heat transfer coefficient (h in Equation 2) can be expressed as a function of dimensionless groups, the Reynolds number, the Prandtl number, and the Grashof number. These are as follows:

$$\text{Reynolds:} \quad Re = \frac{v\rho L}{\mu} \qquad \left(\frac{\text{Inertial stress}}{\text{Viscous stress}}\right)$$

$$\text{Prandtl:} \quad Pr = \frac{C_p\mu}{k} \qquad \left(\frac{\text{Kinematic viscosity}}{\text{Thermal diffusity}}\right)$$

$$\text{Grashof:} \quad Gr = \frac{\beta g \Delta T L^3 \rho^2}{\mu^2} \qquad \left(\frac{\text{Buoyancy force}}{\text{Viscous drag}}\right)$$

where

L = Linear dimension (m)

v = Velocity (m/sec)

ρ = Density (kg/m^3)

μ = Viscosity (N.sec/m^2)

C_p = Specific heat (constant pressure) (kJ/kg·K)

β = Coefficient of thermal expansion

g = Gravitational acceleration (m^2/sec)

The heat transfer coefficient is normally expressed as the dimensionless Nusselt number, $Nu = hL/k$, in which k is the thermal conductivity of the fluid (in this case, air) and L is a characteristic length. Theoretically, it has been shown that for natural convection when buoyancy is important

$$Nu = f(Pr, Gr)$$

whereas for forced convection

$$Nu = f(Re, Pr)$$

Experimental values of convective heat transfer coefficients for different geometries are available in the literature. Generally, they are expressed in terms of the Nusselt number; typical expressions for forced convection and laminar convection are given in Table 2.1.1.

For example, for natural convection, laminar flow, at a vertical flat plate of length L

$$Nu = 0.59(Gr \cdot Pr)^{1/4}$$

whereas for forced convection,

$$Nu = 0.66 Re^{1/2} Pr^{1/3}$$

Further information on convective heat transfer coefficients can be found in any text on heat transfer, for example, Incropera and de Witt,[2] Welty et al.,[3] and many others.

Radiation

Thermal radiation is a form of energy that travels across a space without the need for an intervening medium, such as a solid or a fluid. It travels as electromagnetic waves in straight lines, behaving similarly to light, radio waves, and X-rays (Figure 2.1.5). In a vacuum, all electromagnetic waves travel at the speed of

TABLE 2.1.1 Some Recommended Convective Heat Transfer Correlations

Nature of the Flow and Configuration of the Surface	$Nu = \frac{hL}{k}$
Forced Convection	
Laminar flow parallel to a flat plate of length L ($20 < Re < 3 \times 10^5$)	$0.66Re^{1/2}Pr^{1/3}$
Turbulent flow, parallel to a flat plate of length L ($Re > 3 \times 10^5$)	$0.037Re^{4/5}Pr^{1/3}$
Flow round a sphere of diameter L (general equation)	$2 + 0.6Re^{1/2}Pr^{1/3}$
Natural Convection	
Laminar: natural convection at a vertical plate of length L ($10^4 < Gr{\cdot}Pr < 10^9$)	$0.59(Gr{\cdot}Pr)^{1/4}$
Turbulent: natural convection at a vertical plate of length L ($Gr{\cdot}Pr > 10^9$)	$0.13(Gr{\cdot}Pr)^{1/3}$
Laminar: natural convection at a hot horizontal length L (face up) ($10^5 < Gr{\cdot}Pr < 2 \times 10^7$)	$0.54(Gr{\cdot}Pr)^{1/4}$
Turbulent: natural convection at a hot horizontal length L (face up) ($2 \times 10^7 < Gr{\cdot}Pr < 3 \times 10^{10}$)	$0.14(Gr{\cdot}Pr)^{1/3}$

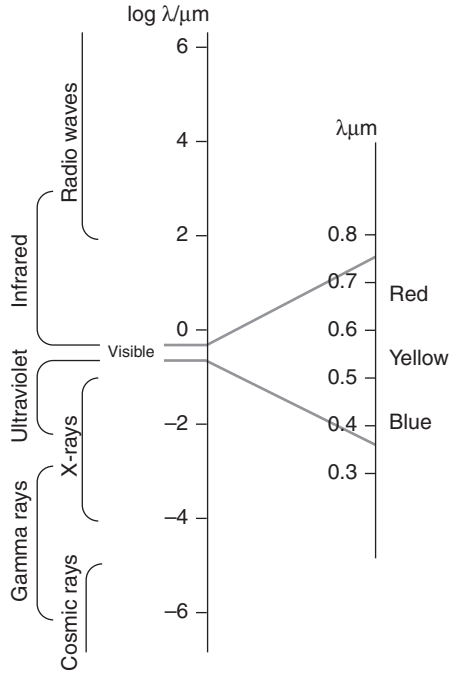

FIGURE 2.1.5 Electromagnetic Spectrum (Source: D. D. Drysdale, *An Introduction to Fire Dynamics,* 2nd ed., John Wiley & Sons, Chichester, UK, 1999, Figure 2.16. Copyright 1999. Copyright John Wiley & Sons Limited. Reproduced by permission.)

light (3×10^{10} m/sec). If these waves are directed onto the surface of a body, they can be absorbed, reflected, and/or transmitted. Visible light consists of wavelengths between 0.4×10^{-6} to 0.7×10^{-6} m, which correspond to the blue and red ends of the visible spectrum, respectively, whereas thermal radiation occurs principally in the infrared (and far-infrared) region (wavelengths greater than 0.7×10^{-6} m). Figure 2.1.5 shows that the range of wavelengths visible to the naked eye is tiny. A small fraction of radiation in the visible region is emitted by hot objects when the temperature is high enough. The visible radiation increases in intensity and changes in color as the temperature is raised, as indicated in Table 2.1.2.

The distinction between thermal radiation and convection can be illustrated by reference to a candle flame. The air that is required for combustion of the fuel vapors is drawn into the flame from the surrounding atmosphere by a process known as entrainment. The hot gases rise vertically upward as a plume that carries with it most of the heat (70%–90%) released by combustion (depending on the nature of the fuel). The rest of the heat is lost from the flame by radiation, which can be detected if a hand is held near the side of the flame. The sensation of warmth is caused by radiant heat transfer (i.e., thermal radiation), which is emitted from the flame in all directions. Up to 30 percent of the heat released in the flame is lost in this way, but the hand intercepts only a small proportion. If instead the hand is held over the top of the flame, in the plume of hot combustion products, it will intercept all of the "convected" heat and experience a much higher rate of heat transfer.

Most of the heat radiated from a diffusion flame arises from minute particles of soot (solid carbonaceous particles) formed in the complex series of reactions that occurs within the flame.[5] The mechanism of formation is described in the section on fire chemistry. The particles are the source of the characteristic yellow luminosity. They radiate over a wide range of wavelengths, mainly in the infrared: we see only that part of the emission that lies in the visible region. The gaseous combustion products H_2O and CO_2 also emit radiation but only within narrow wavelength bands in the infrared.[6] Fuels that do not produce soot (such as hydrogen, methyl alcohol, and polyoxymethylene) have nonluminous flames. As a rough guide, ≤ 10 percent of the heat of combustion is lost from the flame by radiation in these cases.

Larger fires (diameters > 0.3 m) involving "ordinary" fuels may release 30 percent to 50 percent of the total amount of energy as radiation, exposing nearby surfaces to high levels of radiant heat transfer. Radiation travels in straight lines. We would expect intuitively that the heat received from a small area source

TABLE 2.1.2 Color Variation with the Temperatures of Hot Objects (indicative only)

Temperature (°C)	*Appearance*
550	First visible red glow

900	Cherry red
1100	Orange/yellow
1400	White

would be less than that received from a large radiating surface, provided the sources were at comparable distances and were emitting comparable energies per unit area (Figure 2.1.6).

Thermal radiation passes freely through gases that consist of symmetrical diatomic molecules, such as oxygen (O_2), and nitrogen (N_2) (the principal constituents of air), but is absorbed in narrow wavelength bands by water vapor (H_2O), carbon dioxide (CO_2) and other asymmetrical molecules such as carbon monoxide (CO) and sulfur dioxide (SO_2). Although their concentrations are low, the presence of carbon dioxide and water vapor in the normal atmosphere prevents solar radiation that lies in narrow bands around 2.8 μm (microns) and 4.4 μm (in particular) from reaching the surface of the earth.

Advantage is taken of this fact in the development of infrared flame detectors, which can be designed to be blind to solar radiation by responding only to 2.8 μm or 4.4 μm (see Section 14, Chapter 2, "Automatic Fire Detectors"). These wavelengths are emitted strongly by molecules of water and carbon dioxide in flames. On the same principle, water vapor and carbon dioxide in the atmosphere are responsible for the absorption of appreciable amounts of thermal radiation emitted from large fires: the effect is significant only at large distances from such fires. This absorption helps to explain why forest fires or large LNG fires are (relatively) less hazardous on days when humidity is high. Also, because water droplets absorb almost all the incident infrared radiation, mists or water sprays are effective attenuators of radiation.[7] This property is used by fire fighters for their protection. (It should be noted that suspended smoke particles absorb thermal radiation selectively but transmit a sufficient proportion to allow infrared cameras to "see" hot objects through smoke.)

When two bodies face each other and one body is hotter than the other, a net flow of radiant energy from the hotter body to the cooler body will ensue until thermal equilibrium is achieved. The ability of the cooler body to absorb radiant heat depends on the nature of the surface. If the receiving surface is shiny or polished, it will reflect most of the radiant heat away, whereas if it is black or dark in color, it is likely to absorb most of the heat.

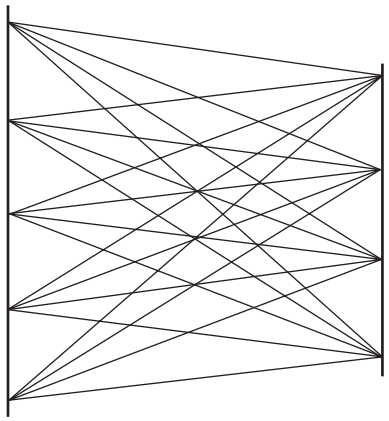

FIGURE 2.1.6 Radiation Exchange Between Two Surfaces

The *absorptivity* of the surface is simply the fraction of the incident radiant heat that is absorbed by the surface. A surface with an absorptivity of 1.0 (the maximum value) is called a *black surface.* Most nonmetallic materials are effectively "black" to infrared radiation, despite the fact that they may appear light or colored to the naked eye (i.e., visible radiation). Some substances, such as pure water and glass, are transparent to visible radiation and allow it to pass through them with minimal absorption; however, both liquid water and glass are opaque to most infrared wavelengths. Glass greenhouses and solar panels operate on the principle of being transparent to the sun's visible radiation while at the same time being opaque to the infrared radiation attempting to escape from the greenhouse or solar panel.

Shiny metallic materials are excellent reflectors of radiant energy and have low absorptivities (perhaps less than 0.1).[3] For example, aluminum foil often is used together with fiberglass in building insulation. Sheet metal is often used beneath stoves or on heat-exposed walls.

The Stefan-Boltzmann law states that the radiation emitted per unit area from a hot surface is proportional to the fourth power of its *absolute temperature.* The law is expressed in the formula:

$$\dot{q}'' = \varepsilon\sigma T^4 \text{ kW/m}^2 \tag{4}$$

where

$\dot{q}''$ = The radiant emission per unit surface area (also known as the emissive power)

ε = The surface emissivity (which is 1.0 for a black body or black surface)

σ = The Stefan-Boltzmann constant (equal to 56.7×10^{-12} kW/m^2·K^4)

T = The absolute temperature expressed in Kelvin (K)

It should be noted that the numerical values of emissivity and the absorptivity of a surface are equal (Kirkhoff's law).

To appreciate the importance of the fourth-power dependence, consider the following situation.

EXAMPLE: A heater is designed to operate safely with an external surface temperature of 260°C. What is the increase in radiation if the external surface temperature is allowed to increase by 100°C to 360°C and by 240°C to a maximum of 500°C?

SOLUTION: First, it is necessary to convert the temperatures from degrees Celsius to degrees Kelvin by adding 273: thus, 260°C becomes 533 K, 360°C becomes 633 K, and 500°C becomes 773 K. Next, if we assume that the surface is "black" (ε = 1.0), the radiant emission per unit area of the external surface (its "emissive power") for safe operation at 260°C is

$$\dot{q}'' = \varepsilon\sigma T^4 = 1.0 \times 56.7 \times 10^{-12} \times (533)^4 = 4.6 \text{ kW/m}^2$$

The corresponding emissive powers at the higher temperatures are

$$\dot{q}'' = \varepsilon\sigma T^4 = 1.0 \times 56.7 \times 10^{-12} \times (633)^4 = 9.1 \text{ kW/m}^2$$

$$\dot{q}'' = \varepsilon\sigma T^4 = 1.0 \times 56.7 \times 10^{-12} \times (773)^4 = 20.2 \text{ kW/m}^2$$

Thus, it can be seen that, by increasing the stove temperature by 100°C, the emissive power is approximately doubled from 4.6 to 9.1 kW/m^2. If the amount of heat radiated was only a function of the first power of the absolute temperature, then it would increase by only about 20 percent if the absolute temperature was increased from 533 to 633 K. Finally, if one were so careless as to allow the stove to reach 500°C, it would emit 20 kW/m^2, which is sufficiently high to lead to ignition of many typical home furnishings that might be in close proximity to the stove.

Because residential coal or wood stoves can sometimes undergo a temperature "runaway" if given too much air, it is important to keep all nearby furnishings well away from the stove to ensure that the maximum received radiant heat transfer is kept to safe levels. The radiant energy transmitted from a point-like source to a receiving surface will vary inversely as the square of their separation distance (Figure 2.1.7). If a stove is small relative to its distance from nearby objects, then it behaves like a point source; doubling its separation distance will decrease the incident radiant heat (per unit area) by a factor of 4. However, if the nearby object is close to the stove, the stove appears as a large surface and small changes in separation will have a lesser effect on the intensity of radiation falling on the receiving surface (e.g., a large stove located within a few centimeters of a combustible wall). In this case, one must protect the wall by some means such as a noncombustible board faced with a reflecting material (low absorptivity). The transfer of radiant heat between the two surfaces shown in Figure 2.1.6 can be calculated by using configuration factors that describe the geometrical relationship of the two surfaces, one to the other. It takes into account the heat radiated back to the hot surface as the temperature of the receiving surface increases.[2]

Generally, we have a good understanding of radiant heat transfer between solid surfaces.[2,6] If the emissive power of a surface is known (Equation 4), then it is possible to calculate the intensity of radiation falling at a point at a known distance from the surface. This is given by the equation

$$\dot{q}'' = \phi\varepsilon\sigma T^4 \text{ kW/m}^2$$

where ϕ is known as the "area to point" configuration (or "view") factor, defining the geometrical configuration between the area of the radiating surface and the distance between the radiator and the receiver (see Figure 2.1.7).[3,8] This configuration factor may be used to calculate the radiant intensity at a point on a surface that is exposed to radiant heat. For some applications, it may be necessary to calculate the radiation exchange between two surfaces as shown in Figure 2.1.6. A practical example would be the radiation exchange between a heated ceiling and the wall of a compartment. For this, the "area to area" configuration factor is required. Both types of configuration factor may be calculated from tables or nomograms that are available in most heat transfer texts.[2]

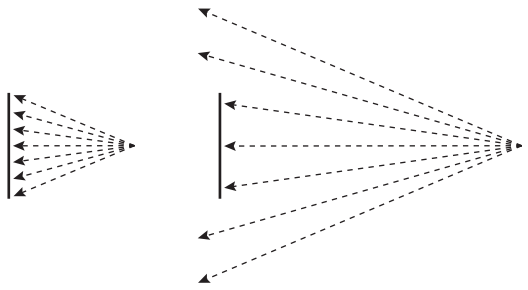

FIGURE 2.1.7 Schematic Diagram of Decreasing Intensity of Radiation from a Point Source as the Square of the Distance Between the Source and the Receiver

It is also possible to carry out reliable estimates of radiant heat absorbed or emitted by gases of a known composition and temperature, for example, from the gases in a combustion chamber, where the principal species present are carbon dioxide and water vapor. Detailed studies carried out by Hottel and his coworkers[9] provided an empirical method for calculating the amount of radiation emitted from these combustion products as a function of partial pressure of the vapor and the path length through which the radiation is being emitted. However, it is more difficult to estimate the amount of heat radiated from diffusion flames because of the presence of soot particles that act as individual black body emitters. The concentration of these particles must be known as well as the path length, which is effectively the thickness of the flame. There is, however, one useful rule of thumb: the total radiant output from flames from fires burning on a fuel bed of diameters more than approximately 0.3 to 0.5 m is usually about 30 percent of the total heat output. Most of the remaining energy (60%–70%) is carried away by convection, with the remaining fraction accounted for by incomplete combustion (carbon monoxide, soot, etc.). These figures are indicative only as the chemical nature of the fuel can make a significant difference (e.g., methanol produces no soot particles and the fraction radiated can be < 10%, as mentioned previously).

The emissivity of flames is strongly linked to the quantity of soot particles present, which in turn will depend on the nature of the fuel and on the structure and behavior of the flame. The potential of a fuel to produce soot and smoke can be assessed by measuring the smoke point.[10,11] For a given fuel, this is the minimum height of a laminar diffusion flame for which there is a release of soot particles at the flame tip (i.e., the tip becomes luminous). Fuels that contain the aromatic ring, such as polystyrene, have a very small smoke point and, consequently, yield a large amount of smoke. Polymethylmethacrylate and polyoxymethylene, on the other hand, produce relatively small amounts of smoke and have large smoke points. Alcohol fires, particularly those of methyl alcohol, burn with blue flames containing no soot particles. The radiating species in such flames are the gaseous molecules of water and carbon dioxide. They radiate very weakly, in comparison to soot particles, and for this reason, the temperatures of flames of alcohol fires are much higher than those of fires involving hydrocarbons. This was shown clearly by Rasbash and coworkers in the 1950s.[12]

FLAME STRUCTURE

The following are the two types of flame that we have to consider:

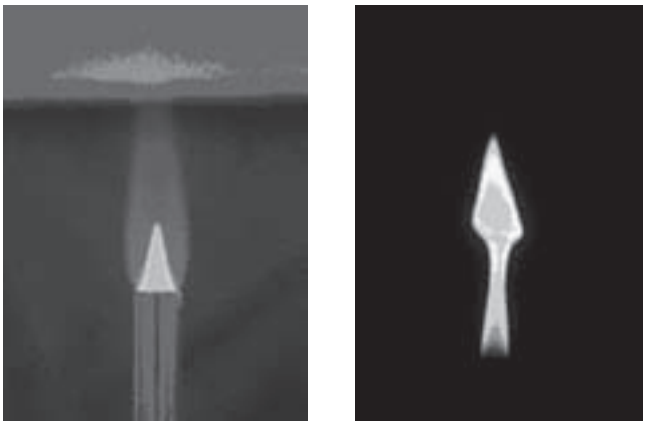
1. The premixed flame in which fuel and air are intimately mixed before ignition
2. The diffusion flame in which fuel and air are initially separate and burn in the region in which they mix

Although premixed burning is associated with the internal combustion engine and with gas explosions, it is important to distinguish between these modes of burning. It may not seem to be relevant to understanding uncontrolled fires, but it is relevant to our understanding of the ignition process and flame stabilization.

If a mixture of flammable gas in air is within the limits of flammability, introduction of an ignition source will initiate a flame that will then propagate throughout the mixture, wherever it is within the limits of flammability.[13] The thickness of the flame is of the order of 1 mm and it propagates at a rate of the order of 0.5 m/sec (for hydrocarbon fuels in a quiescent mixture). This means that the reaction is complete in approximately 2 milliseconds (2×10^{-3} sec).[14,15] Such rapid conversion of fuel and air to combustion products (with the release of the heat of combustion) is possible only because the fuel and air are intimately mixed. In the case of diffusion flames, the process of diffusion is very slow and becomes the rate-determining process, reducing the rate of combustion by two orders of magnitude. This difference may be illustrated by comparing the power densities of premixed flames (100 to 200 MW/m^3) and diffusion flames (0.5 to 1 MW/m^3).[16] This is reflected in the average temperatures of these flames. Because a diffusion flame is effectively diluted by excess air, the apparent (average) temperature is much lower than that of a premixed flame in which the flammable gas-air mixture is stoichiometric or near-stoichiometric. It is accepted that a premixed flame is unable to propagate unless it can produce a flame temperature greater than approximately 1300ºC (approx. 1600 K). Much lower (average) temperatures are measured in diffusion flames, although they will contain pockets of burning fuel/air mixture at much higher temperatures.

The topics associated with flammability limits and gas explosions are covered in Section 2, Chapter 8, "Explosions," and will not be discussed further in this chapter. However, it is important to understand the structure of the premixed flame and how it differs from the diffusion flame. They are compared in Figure 2.1.8: Figure 2.1.8(a) shows a premixed flame (propane + air) stabilized on a Bunsen burner, whereas Figure 2.1.8(b) shows a flame burning when pure propane is flowing from the same Bunsen burner. The premixed flame does not need to seek any additional air to burn, whereas the air for combustion of the propane has to be entrained from the surrounding atmosphere. The entrainment process is driven by the shear forces between the jet of propane and the surrounding air: the flame exists where propane and air have mixed by diffusion—laminar for small flames, turbulent for large flames (fire diameter > 0.3 m).

Early work on the structure of the diffusion flame was based on the hypothesis that the flame height was determined by the entrainment rate (see Drysdale[17]). It was assumed that the flame tip corresponded to the height at which the ratio of the fuel to entrained air was equal to the stoichiometric ratio, which implies that complete combustion will have occurred within the flame. However, this cannot be the case as at least a small amount of smoke (a sure sign of incomplete combustion)



(a) (b)

FIGURE 2.1.8 Bunsen Burner Flames. (a) Premixed flame. (b) Diffusion flame.

is normally seen to be released from the flame tip. In fact, the amount of air entrained is very much greater than that required for stoichiometric burning by a large factor (certainly > 4). This fact is clear evidence that within the diffusion flame the combustion process is not uniform. Mixing by diffusion is not efficient, and within the flame there will be a wide variation in the fuel concentration. A simplistic view is that combustion will take place in those regions where the fuel-air mixture is stoichiometric. However, this view does not account for the fact that the flame entrains excess air, and it is wrong to think of the flame in such idealized terms. A "stoichiometric surface" will not exist: instead, there will be a finite volume within which fuel and air are mixing and where reaction will occur, but is by no means uniform. It would be anticipated that burning would occur wherever the fuel-air mixture was within the relevant flammability limits. That is, combustion will be occurring across the spectrum of concentrations, from near the lower limit (fuel lean) to near the upper limit (fuel rich), remembering that at these elevated temperatures, the limits will be wider than those associated with ambient temperatures.

The following other two factors need to be considered:

- As diffusion continues, the localized combustion process can be quenched (interrupted) if mixed with excess air (or fuel) as a result of continuing mixing.
- Reactions can take place on the fuel-rich side of the reaction zone where there is insufficient oxygen present for premixed burning. These reactions include gas-phase pyrolysis, which is ultimately responsible for the formation of soot particles in the flame. These may be resistant to oxidation and can escape the flame to form smoke particles, which is discussed in the next section.

Studies of diffusion flames from 300-mm-square gas burners have shown that combustion is not uniform throughout the flame and that it is possible to map out the "combustion intensity" as a function of position within the flame.[18] What we see as the boundary of a diffusion flame corresponds to the outside region of the flame where the combustion intensity is very low

("flame" may be present for only 5% of the time). Within this flame envelope, there is a great deal of turbulence and large concentration and temperature gradients exist. The discussion of the "fire plume" in Section 2, Chapter 4, "Dynamics of Compartment Fire Growth," deals with the consequences of these features.

Modeling such behavior is extremely difficult, and in CFD codes it is necessary to make simplifying assumptions. One of the most commonly used is the laminar flamelet model in which combustion is assumed to occur in those small volumes where the mixture is stoichiometric. This topic is covered in detail elsewhere.

FIRE CHEMISTRY

This section presents basic definitions and concepts relevant to fire chemistry. It does not attempt to be comprehensive but is intended to present some of the background material applicable to this and other sections of this handbook.

Atoms and Molecules

Atom. Atoms are the building blocks of chemistry. They form the basis of all matter with which we are familiar. Each atom has a dense, positively charged nucleus, or core, which contains protons (positively charged) and neutrons (no charge), and around which negatively charged electrons swarm in a regularly structured pattern. The number of protons and electrons is equal, ensuring that the atom is electrically neutral. The precise structure of the electron "swarm" (or "cloud") determines the chemical nature and reactivity of the atom.

Atomic Number of an Element. The atomic number is the number of protons in the nucleus of the atom of an element. It determines the position of that element in the periodic table (Table 2.1.3), which reveals the underlying regularity in the properties of the elements.

Atomic Weight of an Element. The atomic weight of an element is proportional to the weight of its atom. The "scale" is based arbitrarily on the carbon-12 isotope (the isotope of carbon containing six protons and six neutrons). The mass of C-12 corresponding to 12 g contains 6.022×10^{23} atoms (known as Avogadro's number). The atomic weights of the elements are given in Table 2.1.4.

Element. Elements are substances that are composed of only one type of atom (e.g., pure carbon, C; nitrogen, N_2; bromine, Br_2).

Note: Based on the assigned relative atomic mass of the carbon-12 isotope equal to 12.00. Most elements consist of isotope mixtures. Elements with atomic weights in parentheses are unstable isotopes.

*In some cases, the symbol bears no relationship to the English name of the element. These symbols are derived from the Latin names, thus: Ag (Silver, or Argentum), Au (Gold, or Aurum), Fe (Iron, or Ferrum), Hg (Mercury, or Hydrargyrum), K (Potassium, or Kalium), Na (Sodium, or Natrium), Pb (Lead, or Plumbum), Sn (Tin, or Stannum), and Sb (Antimony, or Stibium).

Isotope. Atoms that contain the same number of protons but different numbers of neutrons are called *isotopes.* Most elements have more than one isotope (e.g., C-12 and C-13 contain six protons, but they have six and seven neutrons, respectively).

Molecule. Molecules are groups of atoms combined in fixed proportions. Substances composed of molecules that contain two or more different kinds of atoms are called *compounds.* The molecules of a single compound are identical.

Chemical Formula. A chemical formula represents the number of atoms of the various elements in a molecule. For example, water is H_2O (two atoms of hydrogen and one of oxygen) whereas propane is C_3H_8, where C stands for carbon (see Table 2.1.4 for symbols of other elements). A formula may be written to indicate the arrangement of the atoms in the molecule. Thus, propane is $CH_3CH_2CH_3$.

Molecular Weight of a Compound. The molecular weight of a compound is the sum of the atomic weights of all atoms in its molecule. For example, from its chemical formula, the molecular weight of propane (C_3H_8) is $(3 \times 12 + 8 \times 1) = 44$. The *gram molecular weight* of a substance is the mass of the substance equal to its molecular weight in grams.

Mole. A mole of an element or compound is the amount that corresponds to the gram molecular weight. Thus, one mole of propane has a mass of 44 g. One mole of any element or compound contains 6.022×10^{23} molecules (see definition of *atomic weight*).

Chemical Reaction. A chemical reaction is a process by which *reactants* are converted into *products.* More often than not, the equation that is used to describe a chemical reaction hides the details of the mechanism by which the change takes place. Thus, the equation for the oxidation of propane is written conventionally as

$$C_3H_8 + 5O_2 = 3CO_2 + 4H_2O$$

However, the mechanism is very complex and involves highly reactive species called free radicals. Free radicals include atomic hydrogen and oxygen, the hydroxyl radical (OH), and many more. The conversion of propane to carbon dioxide and water involves hundreds of intermediate steps (*elementary reactions*), which create a chain reaction. Typical elementary reactions are

$$C_3H_8 + H = C_3H_7 + H_2$$

$$C_3H_8 + OH = C_3H_7 + H_2O$$

$$C_3H_7 + O_2 = C_3H_6 + HO_2$$

The radicals are highly reactive and very short-lived. The reaction of H atoms with molecular oxygen is particularly important because it leads to chain branching:

$$H + O_2 = OH + O$$

$$C_3H_8 + O = C_3H_7 + OH$$

in which one free radical (the H atom) is replaced by three (two OH and one C_3H_7). At high temperatures, the reaction begins to dominate and the conversion rate (propane to products) increases dramatically. If species that remove hydrogen atoms (e.g., halons) are added to a flame, then the conversion rate (i.e., the rate of burning) falls dramatically as explained in Section 2, Chapter 7, "Theory of Fire Extinguishment."

Stoichiometric/Stoichiometry. A stoichiometric mixture of fuel and air is one in which there is an exact equivalence of fuel and oxygen (in the air) so that after combustion all fuel has been consumed and no oxygen is left. The equation for the oxidation of propane (see above) defines the stoichiometric propane/oxygen mixture as 1:5 (by volume). As oxygen is approximately 21 percent of normal air, the stoichiometric propane/air mixture would be 1:(5/0.21), that is, 1:23.8 (by volume).

$$C_3H_8 + 5O_2 + 18.8N_2 = 3CO_2 + 4H_2O + 18.8N_2$$

This formula corresponds to a ratio of 1:15.7 by mass. Note that the nitrogen does not take part in the reaction, although the energy released by the reaction will be distributed between the reaction products CO_2 and H_2O and the nitrogen, which has the effect of reducing the flame temperature as the nitrogen acts as a "thermal sink." (The expected premixed flame temperature for a stoichiometric propane/oxygen mixture is of the order of 4500ºC whereas that for a stoichiometric propane/air mixture is approximately 2000ºC.)

Heat of Reaction. The heat of a chemical reaction is the energy that is absorbed or released when that reaction takes place. *Exothermic* reactions release energy when they occur whereas energy is absorbed when an *endothermic* reaction takes place. Combustion reactions are exothermic, implying that the products are more stable than the reactants. Endothermic reactions include the pyrolysis of solid fuels, as well as the decomposition processes that occur in concrete when chemically bound water is released at high temperature.

The chemistry of fire processes encompasses not only oxidation reactions in the gas phase but also thermal decomposition, or pyrolysis, reactions that are associated with the release of flammable vapors from combustible solids. Gas phase oxidation is an exothermic, self-sustaining reaction that is usually (but not necessarily) associated with the reaction of fuel vapors with atmospheric oxygen. In flaming combustion of solids and liquid fuels, vaporization is an essential part of the burning process. However, it should be remembered that some solids can undergo glowing combustion or smoldering in which oxygen reacts directly at the surface of the solid (see Ohlemiller[19] and Section 2, Chapter 3, "Flammability Hazard of Materials").

A flame represents a gas phase oxidation process. The premixed flame is much more efficient than a diffusion flame and the conversion of fuel into combustion products is very rapid (see above). As the oxidation process is exothermic, the mixture of combustion products and nitrogen (from the air) is at a high temperature (certainly more than 1600 K) and will occupy a greater volume if allowed to expand or create a high pressure, if confined (see Equation 16) (Section 2, Chapter 8).

Fuels include innumerable materials that, due to their chemistry, can be oxidized to yield more stable species, such as carbon dioxide and water; thus, for example,

$$C_3H_8 + 5O_2 = 3CO_2 + 4H_2O$$

Hydrocarbons, such as propane (C_3H_8), consist entirely of carbon and hydrogen and may be regarded as "prototype fuels." All common fuels, whether solid, liquid, or gaseous, are based on the element carbon, with significant proportions of hydrogen, and may also contain oxygen (e.g., wood, polymethylmethacrylate [PMMA]), nitrogen (e.g., wool, nylon), chlorine (e.g., polyvinyl chloride [PVC]), and so on.

In the present context, the most common oxidizing agent is molecular oxygen (O_2) in the air, which comprises approximately one-fifth oxygen and four-fifths nitrogen. However, certain chemicals are powerful oxidizing agents, such as sodium nitrate ($NaNO_3$) and potassium chlorate ($KClO_3$), which, if intimately mixed with a solid or liquid fuel, produce highly reactive mixtures. Thus, gunpowder is a physical mixture of carbon and sulfur (the fuel) with sodium nitrate as the oxidizer. If reactive groups, such as the nitrate group (NO_3), are incorporated chemically into a fuel, such as in cellulose nitrate or trinitrotoluene (TNT), the resulting species can be highly unstable and will decompose violently under appropriate conditions (see Section 6, Chapter 15, "Explosives and Blasting Agents").

There are circumstances involving reactive species in which combustion may take place without oxygen being involved. Thus, hydrocarbons may "burn" in an atmosphere of chlorine, whereas zirconium dust can be ignited in pure carbon dioxide.

Ignition. Before examining the detailed chemistry of fire, it is appropriate to identify the conditions under which liquid and solid fuels can be ignited. Ignition is the process by which self-sustaining combustion is initiated. Thus, for a flammable vapor/air mixture (i.e., the fuel concentration lies within well-defined flammability limits as discussed in Section 2, Chapter 8, "Explosions"), introduction of the ignition source in the form of a spark or small flame will result in a flame propagating through the mixture. The relevance of this process to condensed fuels (liquids and solids) is best illustrated by considering the concept of flashpoint for liquid fuels. Flashpoint defines the critical condition under which a fuel can be ignited and refers to the minimum temperature at which a flammable vapor-air mixture exists above the surface of the liquid. It can be measured in a closed cup apparatus. The closed cup flashpoint corresponds to the temperature at which the equilibrium vapor pressure is equal to the lower flammability limit. Introduction of a pilot ignition source into the headspace above the liquid surface gives rise to a flash of flame. It can be measured in the Pensky-Martens Closed Cup Apparatus.[20]

The open cup flashpoint is measured under conditions when the fuel vapor can diffuse away from the surface of the liquid. It is the lowest bulk liquid temperature at which a flash of flame is observed when an ignition source is present at the rim of the container that is specified in the standard test. All the fuel vapor within the flammability limits is consumed momentarily, but flaming does not persist. It is measured in the Cleveland Open Cup Apparatus.[21] (The open cup flashpoint is higher than the closed cup flashpoint although the behavior of methanol and ethanol is anomalous.[22])

For ignition to be followed by continuous burning of the liquid, its temperature must be raised to the firepoint, which may also be measured in the Cleveland Open Cup Apparatus. Introduction of an ignition source into the vapor-air mixture above the liquid surface will give a flash of flame, but this will be followed by sustained burning. The firepoint temperature is higher than the open cup flashpoint. To give an example, for *n*-decane (n-$C_{10}H_{22}$), the closed cup and open cup flashpoints, and the firepoint are 46°C, 56°C, and 64°C, respectively.

For both combustible liquids and solids, initiation of flaming occurs in the gas phase. Energy is required to convert sufficient fuel into the vapor phase to create a flammable vapor-air mixture in the vicinity of the surface. For most liquid fuels, this is simply a process of evaporation, but almost all solid fuels must undergo chemical decomposition before vapor is released. The minimum temperature associated with the formation of a flammable mixture at the fuel surface is easily determined for liquid fuels as the bulk temperature of the liquid. However, although exactly the same phenomena of flashpoint and firepoint can be observed for combustible solids, the process involves irreversible chemical changes and they can only be defined in terms of surface temperature. This surface temperature is not normally measured, and it is more common to determine the ignition characteristics of combustible solids as a function of imposed heat flux (see Section 2, Chapter 3, "Flammability Hazard of Materials"). It should be noted that this type of ignition requires the presence of a pilot ignition source. In practice, the piloted ignition temperatures of solids are influenced by air movement, the rate of heating, and the size and shape of the fuel bed. For this reason, measured ignitability characteristics of a solid depend on the specific test method used.

The ease with which a combustible solid may be ignited is determined in part by the chemical composition of the material, although it must be emphasized that the physical form of the material and the environment in which it is located can have a significant, if not an overriding, effect. The clearest examples of this effect are the effects of fuel thickness (wood shavings are easily ignited, whereas wooden planks are not) and of density (polyurethane foam can be ignited very easily because of its low thermal inertia, whereas solid polyurethane of high density will be relatively difficult to ignite; compare with the data presented in Figure 2.1.4).

The effect of chemical composition on "ease of ignition" can be illustrated by referring to two specific properties, the heat of combustion of the vapors and their reactivity. If the heat of combustion is high, then more energy will be available to sustain flaming after ignition. For example, the heat of combustion of the vapors arising from polypropylene is approximately 44 kJ/g whereas that for the vapors released from wood is about 14 kJ/g, and from PMMA c. 23 kJ/g.[11] These differences are partially offset by the fact that the firepoint temperature for polypropylene is 360°C, whereas those for wood and PMMA are approximately 300°C. The reactivity of the vapors will depend in part on the presence of flame-retardant elements such as chlorine and bromine in the formulation of the solid (e.g., PVC).

These species inhibit the reactions in the flame (see below) to an extent that higher temperatures will be necessary for combustion to take place.

CHEMICAL REACTIONS IN FLAMES

Our understanding of the processes that take place within a flame arise from detailed experimental studies of premixed flames. An oxidation reaction can be expressed, quite simply, as the balanced chemical reaction, showing reactants and products in their stoichiometric proportions; thus, for methane

$$CH_4 + 2O_2 = CO_2 + 2H_2O$$

However, this is simply a statement of the proportion of stable final products that results from this combustion process and it hides a complexity of detail as discussed earlier. The conversion takes place by a series of elementary reactions—"elementary" in the sense that they cannot be split into simpler chemical steps. These involve reactions of free radicals, highly reactive molecular fragments produced during the reaction sequence. The principal elementary reactions for the oxidation of methane (CH_4) are shown in Table 2.1.5.

The process can be initiated by an ignition source that introduces free radicals into the system. (Alternatively, at a high enough temperature, free radicals will be formed spontaneously by reactions a and b in Table 2.1.5.) In reaction a, dissociation of a methane molecule (energy being transferred during the collision with a third body [M]), produces two reactive species, the methyl radical (CH_3) and a hydrogen atom (H). The methyl radical will react readily with an oxygen molecule (reaction g) to produce formaldehyde (CH_2O) and the free hydroxyl radical (OH). CH_2O turns out to be the main source of the highly toxic species carbon monoxide (CO) via reactions h to m. CO is oxidized to CO_2 when it reacts with OH (reaction p), but if reaction p is interrupted due to a shortage of OH radicals, for example, then CO will be a product of "incomplete combustion." This will occur if the mixture is fuel rich and there is insufficient oxygen present to burn all the fuel.

TABLE 2.1.5 The Reaction Mechanism for the Oxidation of Methane

$CH_4 + M = CH_3 + H + M$	a
$CH_4 + O_2 = CH_3 + HO_2$	b
$CH_4 + H = CH_3 + OH$	c
$CH_4 + OH = CH_3 + H_2O$	d
$O_2 + H = O + OH$	e
$CH_4 + O = CH_3 + OH$	f
$CH_3 + O_2 = CH_2O + OH$	g
$CH_2O + O = CHO + OH$	h
$CH_2O + OH = CHO + H_2O$	i
$CH_2O + H = CHO + H_2$	j
$CHO + O = CO + OH$	k
$CHO + OH = CO + H_2O$	l
$CHO + H = CO + H_2$	m
$H_2 + O = H + OH$	n
$H_2 + OH = H + H_2O$	o
$CO + OH = CO_2 + H$	p
$H + OH + M = H_2O + M$	q
$H + H + M = H_2 + M$	r
$H + O_2 + M = HO_2 + M$	s

Methane is consumed by reactions c and d and, to a lesser extent, by reaction f. The higher the concentration of free radicals (H and OH, particularly), the more rapidly the methane will be consumed and the faster the overall process. The most important pair of reactions consists of reactions e and f, which lead to chain branching and a rapid acceleration of the overall reaction due to the increase in the number (and hence the concentration) of free radicals. As can be seen in reactions c, d, and h–m, the rate of consumption of methane and the rate of formation of H_2O, CO, and CO_2 are directly linked to their concentration. This link to their concentration is responsible for very high reaction rates and leads to rapid flame propagation through any methane-air mixture within the flammability range. The hydrogen atom is a key participant in this process and, as reaction e occurs during the oxidation of all hydrogen-containing fuels, the mechanism illustrated in the preceding sequence is common to all systems in which we are interested.

Detailed analysis of these oxidation reaction systems is beyond the scope of this chapter, but it is covered in detail elsewhere. Two points need to be emphasized here.

First, any process that reduces the rate of the branching reaction (reaction e) will have a disproportionate effect on the rate of the reaction as it will effectively stop the branching process from occurring. The most efficient flame suppressants, including the halons, work in this way and will render flammable vapor-air mixtures nonflammable at relatively low concentrations (typically 8% or less). Flammable mixtures may also be inerted by the addition of a gas, such as carbon dioxide, but will require much higher concentrations (approximately 30%), because the action is physical and not chemical. (It acts as a "heat sink," reducing the flame temperature to below the critical value of c. 1300°C.) For combustible solids, there is a range of flame-retardant additives, which can improve the fire properties, such as ignitability. These additives commonly contain chlorinated and brominated species, which are released when the material becomes involved in a fire or is exposed to an ignition source. These volatile species will be released at the same time as the fuel vapors. Hydrogen chloride and hydrogen bromide will be formed and will effectively scavenge hydrogen atoms and inhibit the flame. Chlorine and bromine atoms are relatively unreactive and cannot give rise to chain branching.

$$H + HCl = H_2 + Cl$$

$$H + HBr = H_2 + Br$$

Second, if there is any interruption of the reaction sequence, then intermediate species such as formaldehyde (CH_2O) or car-

bon monoxide (CO) in the preceding example will survive and escape the flame unburnt. This reaction can occur during fuel-rich combustion and is the source of toxic and harmful species that are associated with smoke from a fire. With more complex fuels such as propane and gasoline, the variety of intermediate products is very large, and the potential to generate a range of noxious gases is considerable. In a diffusion flame, this process will begin with the pyrolysis of the fuel vapor in the fuel-rich parts of of the flame. This can produce reactive species which can undergo polymerization in the flame, building up large molecules that are resistant to oxidation. These species form the minute soot particles within the flame that grow in size and radiate to produce the characteristic yellow luminosity associated with diffusion flames. If these escape from the flame, they agglomerate to form smoke particles. In general, the larger the fire, the greater the number of soot particles and the greater the yield of smoke.

In the preceding discussion, the emphasis has been on premixed combustion as it is this model that gives us the greatest understanding of the reactions that take place in a flame. However, in real fires, premixed combustion is relatively unimportant, and the flames that we observe are diffusion flames in which the mixing of fuel vapors and air involves laminar or turbulent diffusion and the concentrations of fuel and air are not uniform. As discussed earlier, the amount of air entrained into a diffusion flame greatly exceeds the stoichiometric requirement, yet combustion of the fuel vapor is seldom, if ever, complete for this reason.

The mechanism of soot formation in flames appears to involve the polymerization of small reactive molecules within the fuel-rich regions of the flame.[23,24] These build up to produce structures similar in nature to the aromatic ring that have a degree of resistance to oxidation.[25] Once formed, they can coalesce to produce the minute particles that will eventually escape from the flame as smoke. The yield of smoke from a fire will depend at least in part on the chemical nature of the fuels involved. However, if a fire is burning under poorly ventilated conditions, such as in a compartment with limited ventilation, the yield of smoke will be significantly higher. Under these circumstances, it is expected that the yield of carbon monoxide and other noxious species will also be higher. It is known that soot particles in the flame will compete with carbon monoxide for hydroxyl radicals (OH), thus reducing the rate of conversion of carbon monoxide to carbon dioxide according to reaction p.

During the early stages of fire development in a compartment (Section 2, Chapter 4, "Dynamics of Compartment Fire Growth"), the fire products accumulate under the ceiling and will radiate downward, increasing the rate of burning. As the fire grows in size, many reactions will occur in the hot gas layer, and the yields of partially burnt combustion products will increase. A number of studies have shown that as the equivalence ratio increases, the yield of carbon monoxide increases.[26,27] This increased yield of carbon monoxide is associated with an advanced stage in the preflashover fire when the flames are entering the smoke layer, temperatures are high, and the oxygen concentration is reduced. Smoke escaping from the upper layer into the rest of the building at this stage will be highly toxic.

BURNING OF SOLIDS AND LIQUIDS

In Section 2, Chapter 3, the concept of flammability of materials is discussed in detail. It consolidates much of the information contained in this chapter that is based on the relevant chemistry and physics of the fire process. The burning process itself can be understood in terms of heat and mass transfer associated with the burning surface (see Figure 2.1.1 and Equation 1). It is appropriate to emphasize that Equation 1 can be modified to take into account additional heat transfer provided by nearby heat sources or burning items.

$$\dot{m}'' = \frac{\dot{Q}''_{\text{flame}} + \dot{Q}''_{\text{ext}} + \dot{Q}''_{\text{loss}}}{L_g} \text{ kg/m}^2\cdot\text{sec}$$

where $\dot{Q}''_{\text{ext}}$(kW/m^2) represents the heat flux to the surface from other sources. The actual rate of burning is very sensitive to all three terms in the numerator, which is the reason why reproducibility is a major problem in fire experiments. This is particularly true in the standard tests, which are designed to capture one or more "properties" of a combustible material. Relatively minor changes to the apparatus can have a disproportionate effect on the result. To understand and appreciate why this should be the case, it is necessary to examine the fundamentals of the burning process, recognizing that there are many other factors that should be taken into account, including the geometry of the fuel surface, whether it is vertical or horizontal, whether it will melt and flow when it is heated, and if flame retardants are present.

SUMMARY

Fire is a complex phenomenon. To gain an understanding of fire behavior, it is necessary to have at least a basic knowledge of a range of subjects, including chemistry, physics, heat and mass transfer, and fluid dynamics. In this chapter, some of the chemistry and physics required to explain the most important aspects of fire behavior are presented. The relevant terminology is explained in detail and an attempt has been made to place the individual terms in context. It is important to use terminology that is consistent with scientific and engineering disciplines.

The underlying science of fire protection engineering rests on the following principles:

1. For combustion to take place, an oxidizing agent, a combustible material, and an ignition source are essential. (The exception is spontaneous combustion, which does not require an independent ignition source.)
2. The combustible material must be heated to its piloted ignition temperature before it can be ignited or can support the spread of flame.
3. Subsequent burning of a combustible material is governed by the heat feedback from the flames to the pyrolyzing or vaporizing combustible (Equation 1).
4. The burning will continue until one of the following happens:
   a. The combustible material is consumed.
   b. The concentration of oxidizing agent (normally, oxygen in the air) is lowered to below the concentration necessary to support combustion.

c. Sufficient heat is removed or prevented from reaching the combustible material, thus preventing further fuel pyrolysis.
d. The flames are chemically inhibited or sufficiently cooled to prevent further reaction.

All the material presented in this handbook for the prevention, control, or extinguishment of fire is based on the principles outlined in this chapter.

Chapter 2

Physics of Fire Configuration

Ronald L. Alpert

Chapter Contents

Flammable Gas Jets and Liquid Sprays
Pools or Horizontal, Upward-Facing Surfaces
Walls or Vertical Surfaces
Ceiling or Horizontal, Downward-Facing Surfaces
Inclined Material Surfaces
Parallel Facing Vertical Surfaces
Ceiling-Corner Surface Combinations
Combustible Ducts

Key Terms

ceiling fire, corner fire, duct fire, fire growth, fire plume, flammable jet, flammable spray, flue fire, heat flow, heat release rate, heat transfer, King's Cross Station fire, pool fire, wall fire

The behavior of the flaming combustion zone in an accidental fire is highly scenario dependent, with the configuration, scale, and composition of the burning material being the salient factors. Configuration, however, is the most important of these factors since for a wide range of synthetic and natural polymer fuels and for combustible surface scales greater than the order of 3.3 ft (1 m) in height or width, fire characteristics are mainly determined by the configuration of the combustible surface. These defining characteristics include flame shape and motion, flame heat transfer, and flame spread rates that lead to propagation of the fire to new, uninvolved areas of fuel. The chapter discusses many of the defining characteristics of fires in the following configurations of the combustible surface:

- Fuel jets, sprays, and atomized combustible liquids
- Liquid pools or horizontal, upward-facing combustible surfaces
- Single walls or vertical combustible surfaces
- Ceilings or horizontal, downward-facing combustible surfaces
- Inclined upward-facing or downward-facing combustible surfaces
- Parallel, vertical combustible surfaces
- Ceiling-corner combustible surfaces
- Combustible ducts

The jet/spray configuration is applicable to gaseous and liquid fuels and the pool (or floor) configuration pertains both to liquid fuels and solid combustible surfaces, including those that melt rather than char. The remaining configurations, which relate only to solid combustible surfaces, include both single, isolated flat surfaces and combinations of flat or curved surfaces.

For related topics see also Section 2, Chapter 1, "Physics and Chemistry of Fire"; Section 2, Chapter 4, "Dynamics of Compartment Fire Growth"; and Section 21, Chapter 11, "Road Tunnels and Bridges."

FLAMMABLE GAS JETS AND LIQUID SPRAYS

Accidental leakage of gases and liquids pressurized in pipes or hoses can lead to gas jets or atomized liquid sprays that are easily ignited to form large, turbulent flames.[1] Such an accident scenario is a serious concern in many industries and has even resulted from natural gas leaks with domestic appliances. The mass flow of fuel to the jet or spray in these cases is not determined by flame heat transfer, as with other types of fires, but by the flow rate from the leakage orifice. If the fuel is a liquid, the combination of orifice size and pressure drop across the orifice determines the degree of atomization (i.e., the distribution of droplet sizes) of the liquid based on a critical Weber number.[2] Sufficiently small droplet sizes (e.g., less than 0.004 in. [0.1 mm] diameter) ensure that the fuel is burned completely in the spray, but larger drop sizes (e.g., greater than 0.04 in. [1 mm]) can result

Ronald L. Alpert, Sc.D., now retired, was principal research scientist and assistant vice-president at FM Global Research, where he managed the Flammability Technology Research Program. He received his undergraduate and graduate education at the Massachusetts Institute of Technology, where he majored in mechanical engineering. Dr. Alpert is currently a consultant on fire protection science and participates in the ISO technical subcommittee on fire safety engineering as head of the U.S. delegation. He authored a chapter in the *SFPE Handbook of Fire Protection Engineering,* 3rd edition, and is editor of the *Journal of Fire Protection Engineering,* the official journal of the Society of Fire Protection Engineers.

in some of the fuel "raining" out from the spray to form a liquid pool that may burn in a new configuration (see section below on pool fires).

Although close to the leak orifice the gas jet or spray may be a momentum-dominated, high-velocity flow, further from the orifice the flame behavior is dominated by buoyancy, tending toward a vertical fire plume. This buoyant flow of flame presents a significant thermal radiation hazard to the surroundings since flame lateral dimensions are often large enough to produce an optically thick radiant source of heat flux in the range of 10.6 to 14.1 Btu/ft^2·sec (120 to 160 kW/m^2) toward vulnerable targets near or within the flames.[3] In addition to the radiant flux, there is a significant (but smaller) convective heat flux due to the gas velocity in the jet/spray flame. Whereas the radiant flux is highest in the buoyancy-dominated region of the large-scale plume, the convective flux is highest in the high momentum region near the leak orifice.

Because of the high levels of radiant and/or convective heat flux in fuel-jet and spray flames, it is important to be able to estimate the length or height of these flames, since a structure (e.g., roof beams) engulfed by such flames could fail catastrophically. Flame length correlation formulas for gas jets[4] are similar to those for pool fires as long as the length of flame controlled by buoyancy is much greater than the high momentum region. For liquid spray flames, at least two correlation formulas are available.[1,5]

POOLS OR HORIZONTAL, UPWARD-FACING SURFACES

General Behavior of Flames

Flammable Liquid Fires. Liquid fuels from accidental leaks in tanks or piping generally flow to the lowest accessible surface. Such liquids are often contained by dikes, dams, or other obstructions (e.g., compartment walls) so that a pool is formed. Burning, if not already established in the liquid near the leakage origin, may then be initiated, depending on the presence of an ignition source and the flammability of the liquid. The resulting liquid pool fire has flames that pulsate by shedding roughly symmetrical ring vortices (see "smoke rings" in Figure 2.2.1) moving up from the pool surface to the flame tip at a distinctive, observable frequency, *f*. Vortex shedding is due to complex interactions between the inflowing air, the fire plume, and the pool boundary. The flame pulsation frequency is affected by the actual or equivalent diameter, *D*, of the burning pool such that[6]

$$f\left(\frac{D}{g}\right)^{1/2} \approx 0.5$$

Pool fire flames are strongly affected by the amount of *freeboard,* or the distance between the top edge of the pool boundary and the liquid surface. If the liquid is nearly flush with the top of the container, the flames neck immediately above the pool to form a relatively stable, slender fire plume.[7] As the freeboard increases, however, the base of the flames billows outward beyond the pool boundary and becomes more turbulent. Because of this change in pool fire flame shape, associated changes in heat flow back to the liquid fuel occur, leading to an increased burning rate as the freeboard increases from zero (the liquid at the top of the container) up to a maximum when the freeboard value is comparable to the pool scale.

FIGURE 2.2.1 Flames from 15 m × 15 m Crude Oil Pool Fire, Showing Pulsation Vortices ("Smoke Rings") and Smoke Mantle Covering Upper Portion of Flames (Source: NIST Building and Fire Research)

Another defining characteristic of pool fire flames occurs when the diameter or minimum dimension of the pool becomes greater than a critical value of 10 to 20 ft (3 to 6 m) for virtually all fuels (including even LNG).[8] At this critical pool dimension, a smoke mantle begins to form near the flame tip, covering the outer surface of the flame. The smoke mantle obscures more and more of the flame as the diameter or minimum dimension of the pool increases further above the critical value, as shown in Figure 2.2.1. Due to this flame obscuration, thermal radiant emission from the flame envelope where there is a smoke mantle is very low, less than 1.8 Btu/ft^2·sec (20 kW/m^2).

Fires on Solid Surfaces. Solid, upward-facing combustible surfaces, such as floors or carpeting, can produce pool fire flames similar to those from a liquid, once flaming has been established

on the surface (see below for further discussion on flame spread across solids and liquids). In the case of solid combustible materials, the fuel can be distributed not just on a flat, horizontal surface but also in complex arrays, for example, as a variety of storage arrangements or as the fully involved contents of one or more enclosures on one or more elevations of a structure. When the surface area of fuel involved in flaming combustion becomes sufficiently large (e.g., a stack of three or more wooden pallets), the height of flames in the fire plume may be much greater than the height of the combustible array or dimensions of any of the individual elements in the array. At this point, the flames have the appearance of those in a pool fire, with the pulsation and smoke mantle characteristics discussed earlier. In fact, there have been instances of an entire single-story warehouse fully involved in fire but with flames covered so completely by the smoke mantle, due to the size of the warehouse, that trucks were still able to pull trailers away from the loading docks at the periphery of the building during the fire.

Heat Flow

For small pool fires with equivalent diameters up to about 6 in. (150 mm), heat flow from the flame to the burning fuel is mostly due to convective heat transfer and to conduction heat loss to the container/boundary. For larger pool diameters greater than about 3.3 ft (1 m), however, this heat flow is dominated by flame radiation and radiation blockage near the pool surface. Because the flame thickness is greatest at the center of the pool and becomes much smaller at the edges, the radiation-dominated heat transfer rate to the combustible also attains a peak value near the center of the pool, typically reaching a value of 3.5 to 6.2 Btu/ft^2·sec (40 to 70 kW/m^2) for pools up to several meters across.[9] Note that this heat flux is well below the maximum emissive power (about 14.1 Btu/ft^2·sec [160 kW/m^2]) of pool fire flames[3] because of the absorption of roughly half the incident radiation near the pool surface by cooler, soot-laden fuel vapors.

Fire Growth

After flame spreads across the surface of a flammable liquid pool fire, a steady burning rate is established,[10] leading to heat release rates of 176 to 264 Btu/ft^2·sec (2000 to 3000 kW/m^2) for a wide range of hydrocarbon liquids. The time for flame spread will be very short for fuels with a boiling point near or below normal ambient temperature but will increase as the fuel boiling point increases above ambient. For flammable liquids with the highest boiling points, the rate of flame spread will be very low unless there is a substantial ignition source that raises the bulk temperature of the liquid. This flame spread time will be influenced by effects of surface tension and convective flow in the liquid and hence will be dependent on the depth of the liquid. Burning rate is also dependent on the liquid depth and, in fact, cannot be sustained if the liquid depth becomes less than a few millimeters.

An interesting feature of flammable liquid pool fires occurs when a fixed volume flammable liquid spills on a nearly level surface that is not bounded by dams or dikes. As the spill area increases due to a balance between gravity, liquid inertia, and liquid surface tension (not due to additional liquid added to the spill), the burning rate of the liquid also increases proportionally to the area, meaning that the fire duration will keep decreasing for a fixed amount of liquid. Hence, whereas flame heat flux at a given height above the pool can only increase up to a maximum value—that is, the emissive power of the flames, neglecting convection—the duration of application of this heat flux decreases the larger the pool area becomes.

For combustible solid materials on horizontal surfaces, steady burning may occur after a relatively slow "creeping" flame spread involves the entire material surface, assuming that flame spread is complete before there is significant burn-out or consumption of available fuel. Unlike upward fire propagation, "creeping" flame spread is a very stable, steady process, in which the flame front anchors to the surface at a point where an opposed flow of air, drawn in ahead of the flame, meets fuel vapor to sustain ignition conditions (hence the alternate name, *opposed flow flame spread*). If the flame spread front is roughly circular on the horizontal surface and because the outward "creeping" velocity, v, is nearly constant, then the radius, R, of the flaming region is increasing proportional to time, t ($R = vt$). The area of the active pool fire then increases as t^2 and the total heat release rate (HRR) also increases as t^2. As this same type of slow, constant, radial spread velocity can also occur within a complex array of combustible surfaces (e.g., pallets or box storage) to form an expanding area pool fire at the top surface of the array, it is often assumed that heat release rate increases as t^2 in real fires.

WALLS OR VERTICAL SURFACES

General Behavior of Flames

Fires established on vertical combustible surfaces are especially dangerous because of the potential for rapid upward fire spread, which will be discussed in detail below. Such surfaces are virtually everywhere in the built environment because of the presence of wall linings and decorations, as well as various storage arrangements attached to walls. In commercial establishments and institutions, the practice of storing boxed and open products to very great heights (e.g., from several meters in small stores and libraries up to tens of meters in warehouses) greatly increases the potential for a destructive fire if there is an accidental ignition.

Flames on vertical burning surfaces transition from a steady laminar flow to a turbulent flow near the flame base. With increasing height on the vertical surface, flame thickness increases proportionally, which results in increased thermal radiation both to the material surface and outward to potential targets.[11] This can be seen from the increase in flame brightness with height, as shown in Figure 2.2.2, where a 12 ft (3.66 m) high wall of polymethyl methacrylate (PMMA) polymer slab is burning between water-cooled sidewalls that confine the flames and produce near uniformity from side to side.[12] It can also be observed in Figure 2.2.2 that the flames extend above the burning surface (where the sidewalls are absent) a distance equal to less than half the slab height. When there is no sidewall confinement of flames on the burning wall, as in Figure 2.2.3, the flame extension above the burning region is much less. Figure 2.2.3 is

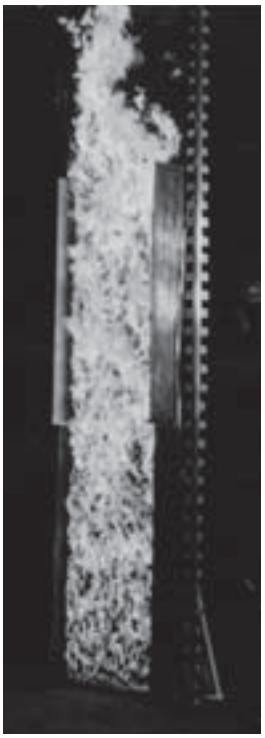

FIGURE 2.2.2 PMMA Wall Fire 12 ft (3.66 m) High with Water-Cooled Sidewalls

a view of flames from the back side of a model (1 ft [300 mm] high) slab of the same transparent polymer, in this case ignited at a single point near the base.

Heat Flow

Heat flow to the lowest 6 to 10 in. (150 to 250 mm) of the surface from the flames is dominated by convective heat transfer, but the remainder of the burning surface above this level is primarily subject to thermal radiation heat transfer. The burning vertical surface receives a roughly constant 0.9 Btu/ft^2·sec (10 kW/m^2) of convective heating, a low level partly due to the cooling effect of the flow of fuel vapors from the surface. Convective heating is somewhat greater above the actively burning region where flames cover the surface because a flow of fuel vapors is not yet established there. In contrast to convection, levels of radiant heat flux incident on the burning material surface increase steadily with height until flames become optically thick. As a result, heat fluxes over 8.8 Btu/ft^2·sec (100 kW/m^2) are possible. This is due to the fact that the layer of cool soot-laden vapor near the material surface is less effective in blocking the incident radiation for a wall fire than for a pool fire.

Fire Growth

Upward flame spread is driven by heat transfer (mainly radiation) in the region between the top of the active burning (fuel gasification) zone and the flame tip. As a result of the heat transfer in this region, as discussed above, ignition occurs after a time period controlled by thermal inertia. For a combustible surface that can support upward flame spread (also known as concurrent flow flame spread, because spread is in the same direction as the induced gas flow), the rate of increase of flame height is proportional to the current flame height, which translates into an exponential increase in flame height with time or a constant time to doubling of flame height. This is why vertical surface burning is so hazardous.

In contrast, lateral and downward flame spread on a vertical surface is opposed by the air flow induced by the flames themselves and thus is very similar to the creeping flow on a horizontal surface. This can be clearly seen in Figure 2.2.3 where the extent of flame spread horizontally and downward from the ignition point near the base of the PMMA wall is much less than the flame spread upward to the top of the wall.

CEILING OR HORIZONTAL, DOWNWARD-FACING SURFACES

Two types of ceiling fire scenarios are considered here, one with flames originating from a fire plume below an unobstructed combustible ceiling and the other with an ignition source at the surface of a combustible ceiling.

Flames from Fire Plume Below Unobstructed Combustible Ceiling

Flames originating from a fire plume below an unobstructed combustible ceiling (for a combustible ceiling obstructed by one

or more walls, see the section "Ceiling-Corner Surface Combination") lead to fire involvement of the ceiling material and the establishment of a flaming ceiling jet layer that moves radially outward from the point of impingement of the plume to form an axisymmetric flow. Heat transfer and flame spread rates in this configuration should be comparable to what occurs during upward flame spread on a vertical surface if the heat release rate associated with the impinging fire plume is at least as great as that associated with the involved ceiling material.

Ignition at Surface of Combustible Ceiling

An ignition source at the surface of a combustible ceiling can lead to active burning of the ceiling material. Heat flow and fire growth for such a configuration is different from that for a fire on a vertical or a horizontal, upward-facing surface. In this second scenario, a set of flame "cells" is produced,[13] with individual cells moving in different directions over the ceiling surface. The resultant cellular burning process is distinctive in appearance. Cellular burning has the potential to produce intense thermal radiation heat transfer because the cells extend a significant distance below the ceiling, resulting in a thick flame layer.

INCLINED MATERIAL SURFACES

Flame Attachment and Heat Flow

Based on a series of experiments[14] with a rectangular gas burner designed to simulate burning surfaces having a channel (or trench) flow confined by sidewalls and a burning surface length greater than 2.1 ft (0.65 m), results summarized in Figure 2.2.4 were obtained. Note that the solid symbols in the figure represent flame separation from the burning surface (as in pool fires). "B" is the solid-fuel mass transfer driving force being simulated by the gas burner setup, with B = 1 approaching a real flammable material. For an ordinate of 1.0 in the figure, the mass transfer flux is 0.002 lb/ft^2·sec (10 g/m^2·sec).

The following conclusions can be drawn from the experimental correlation in Figure 2.2.4 regarding the effect of angle of inclination on fire characteristics:

- Flames attach to upward-facing burning surfaces inclined more than 15° from horizontal, making flame spread and heat flow along the incline much more like that on a vertical surface than on a horizontal one. If the upward-facing burning surface is inclined less than 15°, flames are detached and much thicker, with the appearance and high heat transfer rates typical of pool fire flames.
- Flames attach to downward-facing burning surfaces inclined more than 12° from horizontal, increasing flame spread rates. If the downward-facing burning surface is inclined less than 12° from horizontal, flames detach and thicken to form the characteristic cellular pattern of a ceiling fire. Near this 12° transition, the formation of a cellular ceiling fire leads to increased heat transfer rates.

These results from the gas burner channel/trench experiments of deRis and Orloff,[14] which have yet to be superseded, indicate that as a given length of large-scale burning surface inclines from upward facing horizontal to vertical, then continues to incline 78° further to downward facing, 12° from horizontal, net heat transfer rates to the burning surface steadily decrease by roughly a factor of 2 or more. A further inclination of the downward-facing surface from 12° to 0° from horizontal to form a cellular ceiling fire results in a small increase in heat flow to the burning surface, still well below that in pool and vertical wall fires.

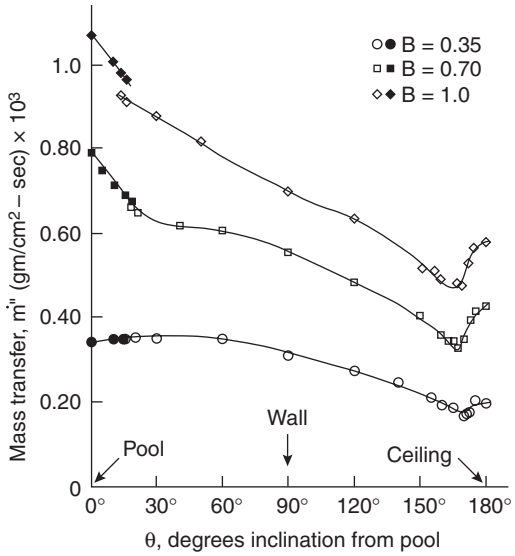

FIGURE 2.2.4 Mass Transfer Rate Versus Burner Inclination for Pool, Wall, and Ceiling Fires (0°, 90°, and 180° Inclination Angles, Respectively). Note: The burning rate of a given material associated with a "driving force" B is simulated here by the mass transfer flux of gaseous fuel from a burner (mass transfer ordinate) inclined at various angles to represent pool, wall, and ceiling fires. (Source: de Ris and Orloff, 15th Symposium on Combustion, 1975, pp. 175–182)

King's Cross Underground Fire Example

Fire in London's King's Cross Underground station on November 18, 1987, propagated much more rapidly than expected up the 30° incline of a wooden escalator (Figure 2.2.5), trapping many people in the ticketing area at the top end of the escalator. It had been assumed that a localized fire at any point along the escalator would grow laterally similar to the creeping flame spread in a pool fire configuration. However, the angle of inclination of the escalator channel was more than double the angle needed to cause flames to become attached to the inclined surface, based on the correlations from de Ris and Orloff.[14] Such attachment resulted in the rapid flame spread characteristic of vertical surface fires. This scenario has been confirmed by scale-model experiments[15] and by extensive field model calculations.[16]

PARALLEL FACING VERTICAL SURFACES

This configuration can occur in a variety of storage arrangements (e.g., rows of piled boxes) or in structural fixtures (e.g., facing rows of vertical cable trays). Because of the reduced area where

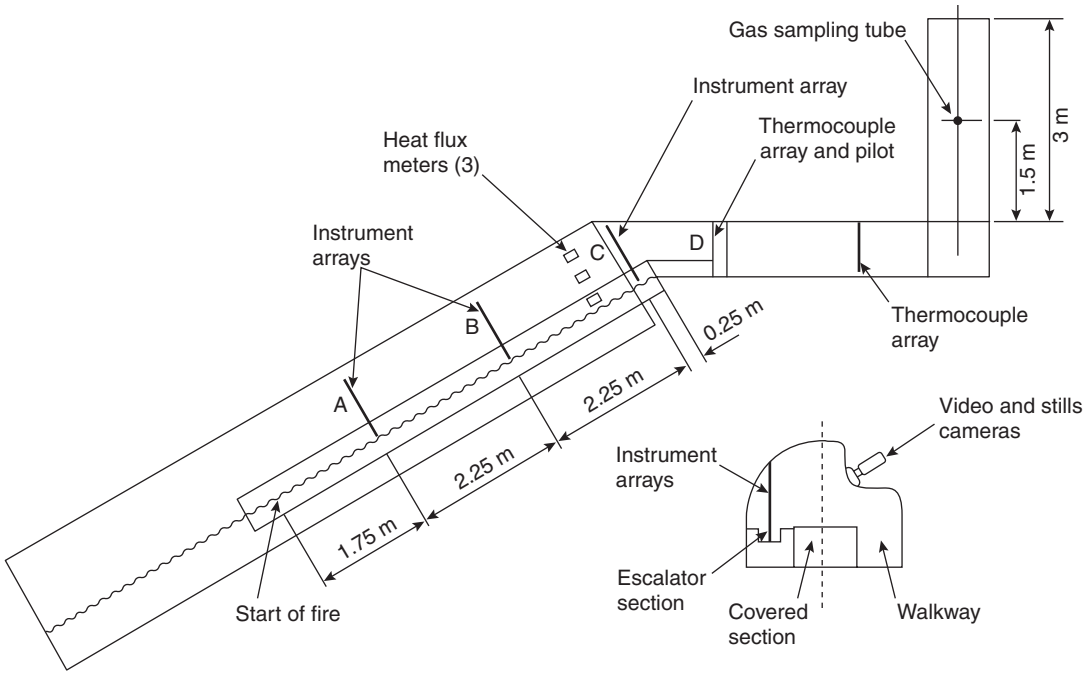

FIGURE 2.2.5 King's Cross Underground Station Fire Scenario (Source: Reprinted from K. Moodie and S. F. Jagger, "The King's Cross Fire: Results and Analysis from the Scale Model Tests," *Fire Safety Journal,* Vol. 18, 1992, p. 92. Crown copyright. radiant thermal energy can escape, heat losses from the burning material surfaces (especially char-forming surfaces that have elevated temperatures) and from the flames on these surfaces are reduced significantly. As a result, (1) a much smaller heat source is required to initiate self-sustained burning and accelerated fire growth and (2) heat fluxes to the combustible surfaces from the combined surface flames can be substantial since flames can more easily approach an optically thick condition. The fire behavior that can be expected for a given material composition is dependent on two quantities: the ratio of the width (i.e., the horizontal dimension) of the combustible surface to the minimum (separation) distance between the two surfaces and the ratio of the height of the surfaces to the separation distance.

If the width to separation distance ratio of the parallel surfaces is greater than or equal to 2, the roughly 50 percent reduction in heat losses results in fire growth on a wide variety of materials for a small initiating heat source. As an example, with a surface width of 2 ft (600 mm) and a separation distance of 1 ft (300 mm), only a 57 Btu/sec (60 kW) heat release rate (2 ft [0.6 m] high flame) from a propane sand burner covering the 2 ft × 1 ft (600 mm × 300 mm) space between the surfaces is required to initiate fire growth on a wide variety of fire-resistant materials.

Figure 2.2.6 illustrates this specific configuration where a HRR of only 24 Btu/sec (25 kW) has initiated a fire on polymer surfaces. The heat flux to the parallel surfaces in this example reaches a peak of 2.6 to 3.5 Btu/ft^2·sec (30 to 40 kW/m^2), depending on the surface composition. As the scale of the parallel surface configuration increases or decreases for the same width to separation ratio, different heat source intensities are required to initiate fire growth and different heat fluxes to the burning surfaces (fluxes of 8.8 Btu/ft^2·sec [100 kW/m^2] have been measured) will result. This behavior could be used in a test method to simulate different fire scenarios.

The ratio of surface height to separation distance can also affect fire behavior. It is known that flame thickness for a PMMA wall fire is about one-sixteenth of the height of the single burning vertical surface[12] and the same should apply to most other material compositions. Although the induced gas flow for parallel vertical surfaces will tend to reduce this flame thickness, a height to separation distance ratio greater than the range of 10 to 16 will tend to reduce flame ventilation, leading to reductions in fire growth and burning rates.

CEILING-CORNER SURFACE COMBINATIONS

Vertical combustible surfaces intersecting at a 90° (corner) or 180° (a flat wall) included angle that are combined with a ceiling (or downward-facing combustible surface) occur frequently in all types of compartments and enclosed spaces, whether in rooms and hallways or the interior of building fixtures and equipment. This configuration provides some of the same trapping of thermal radiation from flames and hot surface char discussed in relation to parallel vertical surfaces, above, when a fire is initiated at the base of the surface intersection.

There are distinctive patterns of fire growth in these ceiling-corner or ceiling-wall configurations, depending on the corner angle (whether 90° or 180° or other angle) and whether or not flames from the corner surfaces reach the ceiling. Figures 2.2.7

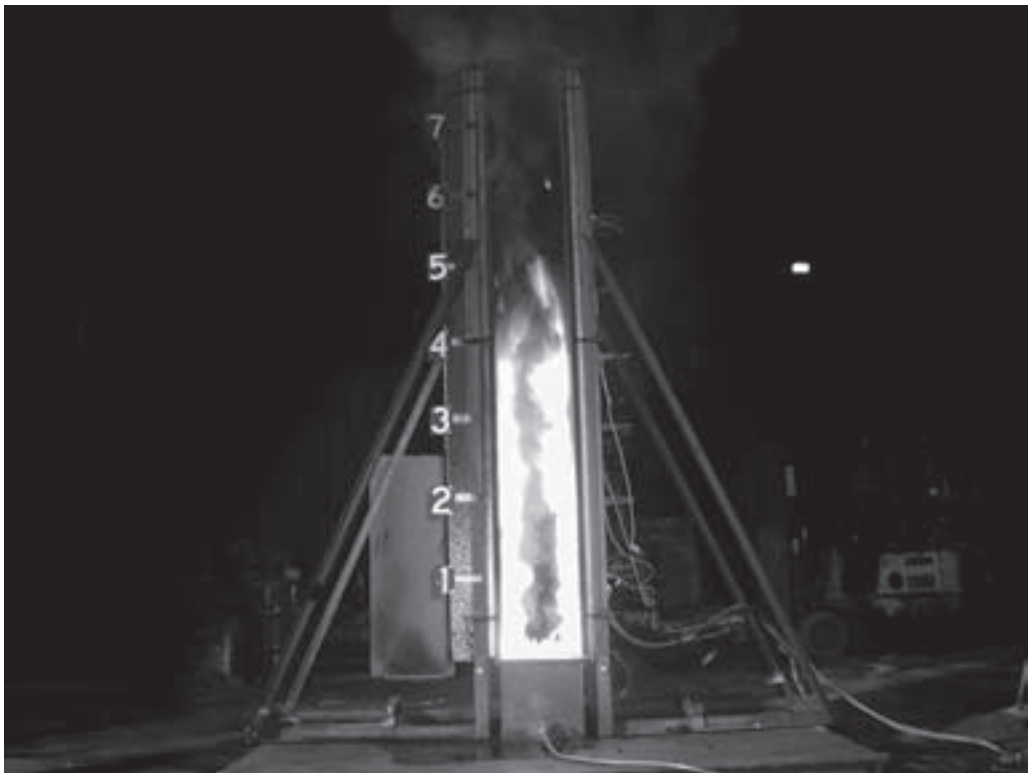

FIGURE 2.2.6 Fire Between Parallel Facing Combustible Polymer Walls

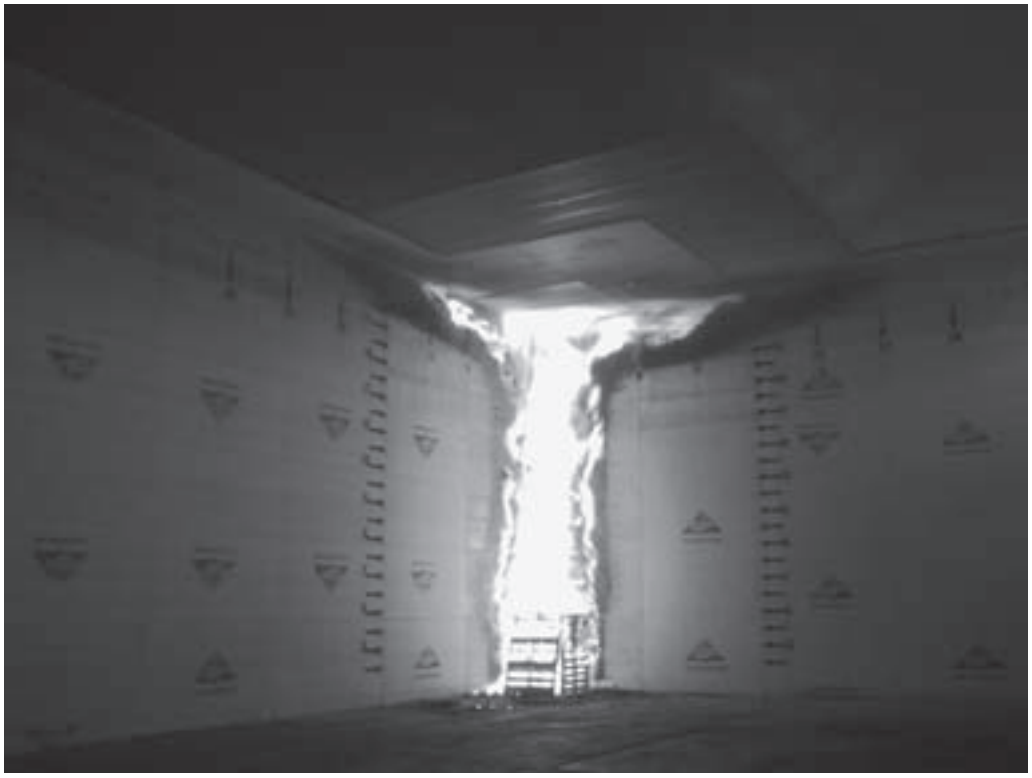

FIGURE 2.2.7 Peak Growth Phase of Fire in Corner Formed by Fire-Retardant Plywood Walls and Inert Ceiling

and 2.2.8 illustrate these patterns in a fire in a 90° corner formed by fire-retardant plywood walls and an inert ceiling during the growth and decay phases, respectively. In Figure 2.2.7 note that all surfaces labeled "GP" are inert cement board.

An extensive survey of past experimental work by Mitler[17] and careful observations of fire growth in such configurations by Saito[18] have shown that upward flame spread rates near a 90º wall intersection are increased, roughly by a factor of 3 compared to a flat wall, due to radiative reinforcement and the convective induced flow that controls flame position. In addition, vertical surface flames that impinge on an inert or combustible ceiling tend to spread most rapidly along the wall-ceiling intersection, forming a "T" shape that leads to rapid involvement of the upper wall at great distances from the point of flame impingement. Once there is fire involvement of the vertical wall surfaces at the corner and ceiling intersections, further flame spread occurs by the slow "creeping" or opposed flow mechanism (see the discussion of flame spread in the previous section "Pools or Horizontal, Upward-Facing Surfaces") laterally from the corner on the vertical surfaces and downward from the ceiling intersection.

COMBUSTIBLE DUCTS

Vertical or horizontal ducts that exhaust or transport corrosive vapors in process industries are often composed of combustible polymers, either as an internal lining or as the entire duct structure. In such cases, flames from a small fire outside the duct can be drawn into the duct and lead to the rapid growth of duct fire flames due to trapping of thermal flame radiation and radiant heat transfer forward to new sections of the duct. Whether flames are transmitted extensively along the duct length depends to a great extent not only on the composition of the duct polymer but also on the adequacy of ventilation, that is, the supply of fresh air for continued fire spread.

SUMMARY

Defining characteristics of fires in different geometric configurations have been discussed in terms of flame behavior, heat flow, and fire growth. The potential impact of a fire on the local environment is strongly dependent on the configuration and scale of the combustible surfaces that become involved. Generally, pool or horizontal, upward-facing surface fires are associated with the lowest rates of flame spread (a constant spread velocity that results in a t^2 HRR dependence), the highest heat flux from the flame envelope, and the highest burning rates. Wall or vertical surface fires are associated with the highest rates of upward flame spread (an exponential increase of flame height with time) and somewhat lower flame heat fluxes and burning rates than for pool fires of the same scale. Ceiling or horizontal, downward-facing, surface fires are characterized by thick, moving cellular flames. Small changes in the inclination of both upward-facing and downward-facing surfaces can result in abrupt changes in flame behavior and the heat flux environ-

FIGURE 2.2.8 Decay Phase of Fire in Corner Formed by Fire-Retardant Plywood Walls and Inert Ceiling

ment. Finally, configurations that represent combinations of the preceding single combustible surfaces have distinctive flame behavior and heat transfer characteristics that are important in many practical fire scenarios.

Chapter 3

Flammability Hazard of Materials

Daniel Madrzykowski ❏ David W. Stroup

Chapter Contents

Material Response to Incident Heat Flux
Ignitability
Ignition Test Methods
Heat Release Rate
HRR Test Methods
Flame Propagation Propensity
Flame Spread Test Methods
Smoke Yield
Smoke Yield Test Methods
Extinguishability

Key Terms

ASTM, calorimeter, char, corner test, fire test, flame, flame propagation, flame spread, flammability hazard, gasification, heat flux, heat release rate (HRR), heat transfer, ignitability, ignition temperature, ignition time, intumescence, pyrolysis, smoke generation, smoke yield, smoldering, thermal inertia

Any material capable of burning with a flame is considered flammable.[1] A flame is a stream of the gaseous fuel and oxidizing agent involved in the combustion process that produces heat (including radiant energy and usually visible light, according to NFPA 921, *Guide for Fire and Explosion Investigations*) and combustion products. The most elementary view of flammability is provided by the fire triangle, which indicates that three components, fuel, oxidizing agent, and heat, are necessary to start a fire. However, the fire triangle does not describe all the conditions for a flaming fire because it does not include the chemical chain reactions and reactive molecules in flame gases. Highly reactive molecular species, referred to as free-radicals, must be present in sufficient concentrations to insure the continuation of chemical chain reactions. Otherwise, flames are extinguished. A more complete visual image of flammability is therefore provided by the fire tetrahedron, which recognizes that in order for flames to exist and not be extinguished, uninhibited chain reactions are necessary in addition to fuel (in a gaseous or vapor state), oxidizing agent, and heat. Whereas the fire triangle identifies the conditions necessary to start a fire, the fire tetrahedron recognizes the conditions sufficient for a flaming fire. These conditions include the availability of gaseous fuel or fuel vapors, which can only be generated if there is sufficient heating from external sources or heat feedback from a burning material's own flames.

The flammability hazard posed by a material is really a quantification of the conditions under which copious amounts of fuel vapors capable of supporting uninhibited chemical chain reactions will be generated in typical occupied environments. Quantification of flammability hazard is usually expressed in terms of ease of flaming ignition, damaging heat and product output from flames, and spread of flame to involve new material surfaces or new locations in damaging flame behavior. In addition, the difficulty of extinguishment of the burning material should be included as part of flammability hazard, following Emmons.[2]

Although it may be simple to determine if a material is capable of supporting flaming combustion, measuring or predicting the flammability hazard of a material is a challenging and complex task. The flammability hazard of a material is dependent on many parameters of its fuel content, including the chemical composition and physical properties of the fuel (see Section 2, Chapter 1, "Physics and Chemistry of Fire"), the geometric configuration of the fuel (see Section 2, Chapter 2, "Physics of Fire Configuration") and the products of combustion. Flammability can also be dependent on scenario factors such as ventilation, oxygen concentration, and radiation feedback from the surroundings. There is no single test or simple index for flammability that adequately captures all these fuel parameters and scenario factors. As a result, performance in one type of

Daniel Madrzykowski, P.E., is an engineer with the fire fighting technology group, Fire Research Division, Building and Fire Research Laboratory, National Institute of Standards and Technology. He is a member of NFPA's Technical Committee on Residential Sprinkler System and Technical Committee on Fire and Explosion Investigation. He is chair of NFPA's Research Section.

David W. Stroup, P.E., is a fire protection engineer with the fire-fighting technology group, Fire Research Division, Building and Fire Research Laboratory, National Institute of Standards and Technology. He is a member of NFPA's Technical Committee on Alternative Approaches to Life Safety and Technical Committee on Sprinkler System Discharge Criteria.

flammability test cannot easily be extrapolated to determine performance for a different type of flammability test.

Given the number of parameters that affect the flammability hazard of a material, it is not surprising that there are many standardized test methods for characterizing flammability. The development and acceptance of each test method can easily take a decade of research and validation, resulting in extensive documentation. Standardized fire test methods are used to compare the behavior or response of different materials to a given or limited set of test conditions. These test conditions may, or most likely may not, represent the material's response under actual fire conditions. If data from such test methods are to be used directly for fire safety design or assessment, the test conditions should be compared carefully with the conditions assumed for the design fire scenario or fire conditions of interest. Property data derived from these numerous test methods can also be used in analytical models to predict flammability hazard for a range of actual fire conditions.

This chapter will provide background information and a description of test methods by which the ignitability, heat release rate, flame spread propensity, smoke yield, and extinguishability components of flammability hazard are measured or characterized for solid combustibles. The discussion of flammability test methods is introduced by a review of how solid combustibles may respond to heat flux from flames or other sources, which begins the process of generating fuel vapors.

See also Section 2, Chapter 1, "Physics and Chemistry of Fire"; Section 2, Chapter 2, "Physics of Fire Configuration"; Section 2, Chapter 7, "Theory of Fire Extinguishment"; Section 6, Chapter 1, "Fire Hazards of Materials"; Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety"; and Section 6, Chapter 3, "Concepts and Protocols of Fire Testing."

MATERIAL RESPONSE TO INCIDENT HEAT FLUX

When a material is heated, depending on its chemical composition and physical properties, it may respond in a variety of ways. Each of the material responses described below results not only in degradation of the material initially exposed to heat flux but also in life safety and physical damage effects on the surroundings.

Smoldering

Smoldering is a slow, exothermic surface reaction. Smoldering is usually characterized by glowing, or incandescence, and smoke production (NFPA 921). There is no flaming. Since smoldering is a surface effect it is strongly dependent on environmental conditions in addition to the properties of the fuel and the availability of oxygen. Smoldering is a serious fire hazard for two reasons: (1) it is an inefficient form of combustion so carbon monoxide will form a larger percentage of the combustion products relative to flaming fire conditions,[3] and (2) smoldering provides a means to flaming from heat sources normally too small to generate a flame.[4] Figure 2.3.1 illustrates two examples of smoldering.

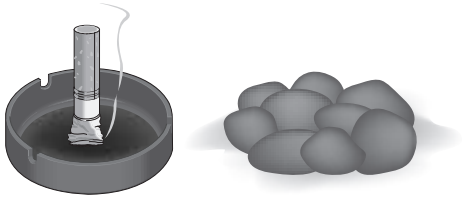

FIGURE 2.3.1 Cigarette and Charcoal/Wood as Examples of Smoldering Combustion

Pyrolysis and Heat of Gasification

Pyrolysis is the chemical decomposition of a material into one or more other substances due to heat alone (NFPA 921). All solid combustibles must undergo pyrolysis in order to generate gaseous fuel vapors for flaming combustion. The process of converting a solid to gaseous vapors can take many physical paths depending on the chemical composition of the fuel. Cellulosic materials, such as wood, decompose directly to gaseous vapors when heated, leaving behind a residue. Thermoplastics such as polypropylene undergo a two-step pyrolyzation process. As the thermoplastic is heated it melts and turns into a liquid, and then this liquid melt is vaporized into the gaseous fuel. Other materials such as flexible polyurethane foams can decompose by different mechanisms which can produce liquid polyols and gaseous isocyanates[5] (Figure 2.3.2).

The energy required to convert a solid material into a vapor through pyrolysis is termed the *heat of gasification.* This quantity can be obtained from laboratory calorimeters having a controlled atmosphere capability (for example, the Fire Propagation Apparatus[6] described in ASTM E2058, *Standard Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus [FPA]*), by substituting pure nitrogen for the air or oxidant normally flowing in the calorimeter and then measuring the mass loss flux from a specimen in nitrogen at different applied heat flux values covering the range expected for real-scale burning objects. In general, the heat of gasification determined from this type of laboratory measurement is not a constant, independent of the heat flux or independent of time during pyrolysis, but for many materials, a representative average heat of gasification can legitimately be defined. The lower the heat of gasification, the greater will be the flammability hazard, since less heat will be required to produce fuel vapor that can react in a flame. As will be discussed later, it is actually the ratio of the heat of combustion to the heat of gasification that is important, since it is the parameter controlling heat release rate and hence, flammability hazard.

Physical Changes During Pyrolysis

A variety of physical changes result from pyrolysis, including char development, intumescence, melting, and vaporization.

Char. Char is a black, carbonaceous, porous residue. The char is a thermal degradation (physical change) of the material being pyrolyzed (chemical decomposition). Organic materials such as wood, wood products, thermoset plastics, and some thermoplas-

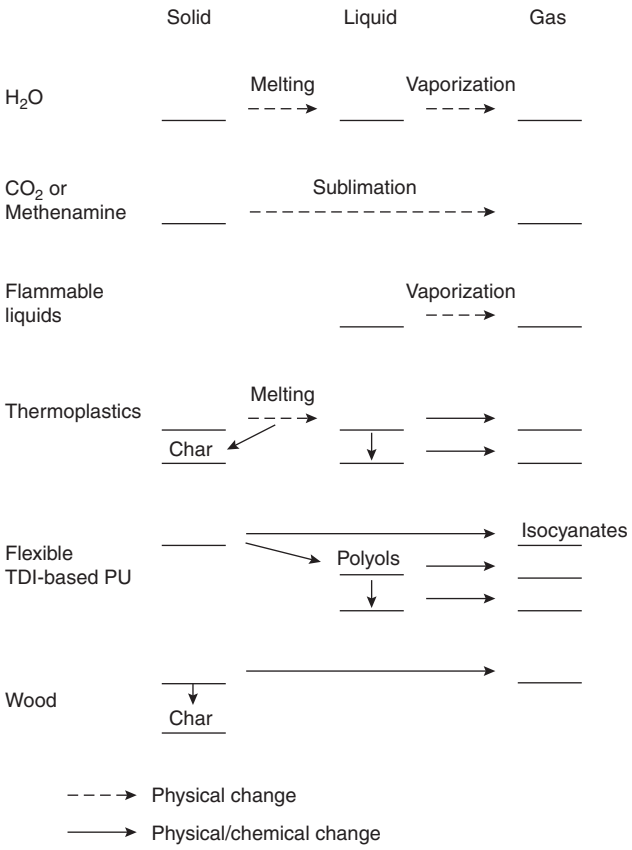

FIGURE 2.3.2 Physical and Chemical Changes During Thermal Decomposition (Courtesy Society of Fire Protection Engineers)

FIGURE 2.3.3 Charred Wood and a Charred Thermoset Plastic (Courtesy of National Institute of Standards and Technology)

tic polymers form a char layer as they are pyrolyzed. As the char layer develops, it acts as an insulating barrier between the external heat source and the unpyrolyzed fuel under the char. This will slow the pyrolysis rate unless the external heat flux increases to compensate for the insulating char layer.[5] Thermoplastics when exposed to heat tend to soften and melt without forming char. For example, polymethylmethacrylate (PMMA) pyrolyzes with very little melt and leaves no residue. However, rigid polyvinyl chloride (PVC) chars when burned, as do some polyurethane foams.[7,8] Examples of charred wood and a charred thermoset are shown in Figure 2.3.3.

Intumescence. Intumescence is defined as the process of swelling up or bubbling up. There are many intumescent coatings on the market for fire protection purposes. These coatings, when heated, increase in volume and decrease in density, simulating the development of a char layer. As the intumescent "char" layer is formed, a blowing agent (a substance used to create bubbles in the material) is released, which creates a low-density, relatively thick carbonaceous layer. Intumescent reactions are typically endothermic due to chemically bound water in hydrates. As the material expands the water is released, maintaining the surface temperature. Once the water has been expended, the remaining "char" layer acts as insulation to the material underneath. The "char" can expand 50 to 100 times the original thickness of the intumescent coating.[9–12]

Melting. When most thermoplastic materials are heated, they melt or soften prior to being vaporized (Figure 2.3.4). The rate at which melting occurs compared to the burning rate and the melt viscosity, are important for determining the fire hazard.[5] For example, if initial exposure to a heat flux and subsequent burning produces a copious amount of melt having a low viscosity, then there is the potential for extensive fire spread to the surroundings as this melt, possibly supporting flames, comes in contact with new material surfaces. This would be especially dangerous if the melting substance is part of a wall or ceiling lining.

IGNITABILITY

Ignitability is the ease of initiating self-sustained flaming combustion due to a heat flux exposure. To determine the level of flammability hazard based on ignitability, the primary information needed is the time it takes to ignite the material with a given heat flux exposure. For a given initial heat flux exposure scenario, the greatest flammability hazard results from a material configuration and composition that requires the shortest

FIGURE 2.3.4 Melted Plastic (Source: Figure 4.11, *User's Manual for NFPA 921,* 2005 edition, courtesy Jones and Bartlett Publishers)

time for ignition. Hence, data on ignitability that gives predicted or estimated ignition times for a variety of heat flux exposures with different fuel configurations and compositions will be most valuable for determining this particular aspect of flammability hazard.

Ignition Energy and Critical Heat Flux for Ignition

As defined in NFPA 921, the ignition energy of a material is the quantity of heat energy per unit exposed surface area that must be absorbed by the material in order to pyrolyze, ignite, and burn. This energy is the product of the heat flux absorbed by the material and the time of exposure until ignition. A material with a given ignition energy will ignite faster if exposed to a high incident heat flux and slower if the incident heat flux is low. The amount of energy required for ignition also depends on the physical and chemical properties of the material, especially its thermal inertia and ignition temperature. However, the heat flux exposure must be greater than a certain critical value. For a heat flux less than or equal to this value, the ignition time is effectively infinite; i.e., ignition will not occur. This is the definition of the *critical heat flux for ignition.*

Thermal Inertia

The thermal inertia of a material is the direct product of three physical properties: thermal conductivity (k), density (ρ), and heat capacity (C). Thermal inertia characterizes the rate of surface temperature rise of the material when exposed to heat. Low values of thermal inertia lead to elevated surface temperatures for a given applied heat flux scenario, and hence, to more rapid ignition and a greater flammability hazard if the material is combustible. Although values for thermal conductivity, density, and heat capacity can be found for some materials in the literature, the way that the properties are measured can affect the resulting thermal inertia magnitude. Table 2.3.1 presents data on thermal conductivity, density, and heat capacity for selected materials.

TABLE 2.3.1 Thermal Properties of Selected Materials

Material	*Thermal Conductivity (k) (W/m·K)*	*Density (ρ) (kg/m³)*	*Heat Capacity (C_p) (J/kg·K)*
Copper	387.00	8940	380
Concrete	0.8–1.4	1900–2300	880
Gypsum plaster	0.48	1440	840
Oak	0.17	800	2380
Pine (yellow)	0.14	640	2850
Polyethylene	0.35	940	1900
Polystyrene (rigid)	0.11	1100	1200
Polyvinyl-chloride	0.16	1400	1050
Polyurethane foam*	0.034	20	1400

*Typical values; properties vary.
C_p = Heat capacity at constant pressure.

Many materials are not homogeneous in their composition. Therefore they may have varying values for thermal conductivity, density, or heat capacity. Although this may not be a surprise when considering modern composites with visible layers of different materials, it may be surprising to find that wood is not homogeneous. The thermal conductivity of wood is higher in the direction parallel to the grain of the wood. As a result, to ignite the end grain of a piece of wood would require more energy and or more exposure time for a given heat source than to ignite the surface of the wood where the heat flow is perpendicular to the grain.[13] The higher thermal conductivity transfers heat through the wood faster, thereby slowing the storage of heat at the wood surface and increasing the time for reaching the ignition temperature. The thermal conductivity in wood may not only vary with position, but it can also vary with direction at a fixed position. This is an example of a nonisotropic material property.

Further as the wood increases in temperature, the thermal conductivity, density, and specific heat will change due to the evaporation of moisture in the wood. As would be expected, it takes more energy to ignite a piece of wood with higher moisture content.[14] As the wood begins to pyrolyze and a char begins to develop, the physical properties of the wood continue to change. This may also have an impact on the amount of ignition energy required. Hence the assumption that wood, or other materials, behave as inert materials until they ignite is false.[15] These changes are most significant during the ignition process.

Even though there are many variables to consider when assessing the ignitability of a material, average values can still be useful to compare the potential for ignition of two materials. For example, compare the properties given for pine in Table 2.3.1 with those for polyurethane foam. Even though the values for pine may vary during the ignition process, given that the thermal conductivity is more than 4 times that of polyurethane, the density more than 30 times greater, and the heat capacity

is 2 times greater, it is clear that polyurethane cannot transfer heat away from its surface as effectively as wood and therefore would require less ignition energy.

A fire occurred on the night of February 20, 2003, in The Station, a nightclub at 211 Cowesett Avenue, West Warwick, Rhode Island. A band performing that night used pyrotechnics. The sparks from the pyrotechnics ignited polyurethane foam insulation that was installed on the walls and ceiling of the platform being used as a stage. The fire spread quickly along the walls and ceiling area over the dance floor. Smoke was visible in the exit doorways in a little more than one minute, and flames were observed breaking through a portion of the roof in less than five minutes. Egress from the nightclub was hampered by crowding at the main entrance to the building. One hundred people lost their lives in the fire.

In experiments conducted by NIST after the tragedy, birch veneer plywood paneling and ether-based polyurethane foam were exposed to pyrotechnic devices similar to the ones used in the nightclub. The wall-mounted polyurethane foam ignited within 10 seconds. The sparks from the pyrotechnics did not have enough energy to ignite the plywood.[16]

Ignition Temperature

As defined in NFPA 921, ignition temperature is the minimum temperature a solid material must attain in order to ignite under specific test conditions. Generally, the ignition temperature will be within the range of temperatures at which a material begins to pyrolyze and produce copious vapors, whether by mainly thermal mechanisms controlled by thermal inertia as previously discussed or by chemical bond-breaking processes or a combination of both. The ignition temperature is related to the ignition energy, but it is less fundamental because the manner in which the material is heated, the rate of energy transfer to the material, and the physical and chemical composition of the material affect the ignition temperature. The lower the ignition temperature, the greater the flammability hazard due to ignition.

A review of research literature on the ignition temperature of solid wood shows that the ignition temperature increases as the incident heat flux (energy transfer to the material surface) increases. The ignition temperatures ranges from a minimum of 250ºC to initiate smoldering combustion with a low incident heat flux on the order of 5 kW/m^2 to approximately 360ºC with a "medium" incident heat flux on the order of 20 kW/m^2 for the piloted ignition of softwoods.[17]

Ignition Time

Ignition time is the time between the application of an ignition source (usually an imposed heat flux) to a material and the onset of self-sustained flaming either on or near the material. Just as with the ignition energy and the ignition temperature, the time to ignition is also a function of the rate of heat transferred from the ignition source, as well as the physical and chemical properties and geometric configuration of the material. As outlined in previous sections, high incident heat flux, low thermal inertia, and weak chemical bonds will result in faster time to ignition and greater flammability hazard due to ignition.

IGNITION TEST METHODS

There are many test methods[18] that have been developed to examine the ignitability of a material. Most of these test methods are not quantitative in the sense that a prescribed heat flux is not provided or the test method does not yield quantitative data useful for an engineering prediction of ignition time and hence the ignition aspect of flammability hazard. Although not a standardized test, NFPA 705, *Recommended Practice for a Field Flame Test for Textiles and Films,* is a recommended practice for field flame testing of fabrics and plastic films, to determine their tendency to ignite and sustain burning. It is mentioned here because it is the most basic flammability test, which fire safety professionals can use to determine if further testing is required. The procedure calls for a material sample, at least 12.7 mm × 101.6 mm to be exposed to an open flame from a common wood kitchen match for 12 seconds. The flame should not extend the length of the sample or a distance of 101.6 mm for longer samples. There should not be more than 2 seconds of afterflame on the sample, and materials that break or drip flaming particles on the floor below the sample would fail if the materials continue to burn after reaching the floor. If the test results in the ignition and rapid consumption of the sample, clearly the material is a flammability hazard. On the other hand, if the test results in no ignition, it does not mean that the material complies with applicable fire safety standards. The test results can be affected by environmental conditions, sample size, and flame exposure size. Additional testing is required to quantify the flammability of the material.

The few quantitative test methods that provide data on the ignition aspect of flammability are listed below:

1. Cone calorimeter[19] (NFPA, ASTM and ISO versions; see description later in this chapter), in which a horizontal or vertical 100 mm by 100 mm specimen is exposed to a known heat flux from a conical heater and the time to ignition is measured.
2. Fire propagation apparatus[6] (NFPA and ASTM versions; see description later in this chapter), in which a 100 mm circular horizontal specimen is exposed to a known heat flux from tungsten-quartz heaters and the time to ignition is measured. From data on ignition time at various applied heat flux values, the test method yields the minimum heat flux required for ignition and also the product of the square root of thermal inertia and the excess of ignition temperature above ambient for the test specimen.
3. Lateral ignition and flame spread (LIFT) apparatus[20] (ASTM and ISO versions; see description later in this chapter), in which a vertical 155 mm by 155 mm specimen is exposed to a known average heat flux from a gas-fired radiant panel and the time to ignition is measured. From data on ignition time at various applied heat flux values, the test method contains formulas that yield the minimum heat flux required for ignition and also the ignition temperature and thermal inertia of the test specimen.
4. Intermediate-scale calorimeter (ICAL)[21] (ASTM and ISO versions; see description later in this chapter), in which a 1 m by 1 m vertical specimen is exposed to a known heat flux from a gas-fired radiant panel and the time to ignition is measured

HEAT RELEASE RATE

Heat release rate is probably the most important quantity used to characterize the flammability hazard represented by a given material. It is a measure of the rate at which a burning item releases chemical energy and is usually expressed as heat released per unit exposed surface area of a burning material or specimen (i.e., kW/m^2). Used as an input to a computer fire model, the heat release rate can provide information on fire size, fire growth rate, available egress time, and suppression system impact if all the parameters affecting heat release rate are known (see below). The heat release rate of a burning item is the product of mass loss rate (i.e., the mass burning rate) per unit of exposed surface area and its actual (not complete or theoretical) heat of combustion under the conditions of interest. When this heat of combustion is known, the heat release rate can be estimated from the measured mass burning rate. Alternatively, the heat release rate can be determined directly from measurements of the composition of product gases collected in an exhaust hood of a calorimeter. Generally, the greater the heat release rate per unit of exposed surface area of material or per unit floor area of a complex material configuration, the greater is the flammability hazard.

Laboratory calorimeters can provide useful information concerning heat release rate using small material specimens. However, these calorimeters often do not represent the actual performance of a material when used in real life. Laboratory calorimeters do not usually test the same size materials as found in most fire scenarios and the laboratory results can be influenced by the relative closeness of the material edges to the center of the flame zone. There is also little or no geometry consideration included in small-scale tests. Intermediate and large-scale calorimeters attempt to provide a more realistic scenario for testing of materials.

Parameters Controlling HRR

Although the heat release rate (HRR) of real material configurations can be obtained from full-scale tests (see discussion below), it is impractical to test materials in every possible configuration and fire scenario (e.g., within enclosed spaces of different sizes or in different warehouse storage arrangements) to determine the flammability hazard due to heat release rate. For this reason, materials are often tested in a reference fire scenario, such as a room test or a corner test or a commodity evaluation test having one or two geometric scales that are characteristic of a wide range of practical situations. Even these full-scale reference tests can be expensive, so predictions of flammability hazard due to heat release rate that are based solely on laboratory property measurements would be highly desirable. For this to be done, the parameters controlling heat release rate must be identified and then characterized by practical test methods.

Similar to the case for ignition, the net heat flux absorbed by a material and the heat of gasification of a material determine the mass loss flux of fuel vapors from a burning material surface. Here, the net heat flux is the heat flux absorbed from a material's own flames and from any heat source surrounding the burning material (e.g., from other burning objects, from a hot gas layer in an enclosure, or from heated enclosure surfaces) minus any heat losses from a material's own pyrolyzing hot char or melt layer (such as the glow of wood char in a fireplace). In the simple situation of a constant net heat flux and constant heat of gasification, it is the ratio of net heat flux to heat of gasification that yields the fuel mass loss flux. As noted above, the product of the mass loss flux and the relevant heat of combustion then yields the heat release rate of the burning material. Hence, it is the ratio of the heat of combustion to the heat of gasification, together with the net absorbed heat flux, that determines the heat release rate. The greater the magnitude of this ratio, which has been called the heat release parameter (HRP) by Tewarson,[22] the greater is the flammability hazard. HRP can often be measured directly in a laboratory calorimeter if there is a linear dependence of heat release rate on the applied heat flux to a material specimen over a range of applied heat flux and material thermal thickness estimated to cover the fire scenarios of interest. If such is the case, HRP is simply the slope of the linear relationship. Otherwise, the heat of combustion and heat of gasification can be measured individually in a calorimeter, the former as the ratio of total heat released to total mass lost and the latter from mass loss data at several precisely known imposed heat fluxes in a nitrogen environment.[6]

Tabulation of HRP values[22] shows that materials known to have a very low flammability hazard typically exhibit an HRP approaching unity while more hazardous materials have an HRP greater than 10. Alpert[23] has developed an algebraic model utilizing HRP values obtained from heat of gasification tests in nitrogen together with flame heat flux values determined from calorimeter data on smoke yield (discussed in the next section). This algebraic model predicts both heat release rates and the propensity for fire propagation in a parallel panel configuration, thus yielding a prediction of flammability hazard (see Parallel Panel Test later in this chapter). Nam[24] has extended and perfected this parallel panel model.

Flame Heat Transfer

In any prediction of heat release rate and hence flammability hazard, the heat flux from the flame of a burning material is critical, as explained above. If heat release rate is not being measured in a full-scale fire scenario by a large-capacity calorimeter, then flame heat transfer must be simulated in a laboratory calorimeter by using electrical or gas-fired radiant heating elements in the calorimeter apparatus. Obviously, the heat release rate measured in the apparatus will be determined by the choice of the imposed heat flux. To avoid the problem of choosing an imposed heat flux that accurately simulates full-scale flames, the heat release rates of many material specimens are often compared by testing at the same imposed heat flux selected to be representative of what would be expected in typical fire scenarios. However, materials having flames with a higher flame heat transfer than simulated in the apparatus would presumably have a higher flammability hazard and those with lower flame heat transfer a lesser hazard. Typically, materials are tested in laboratory calorimeters at an imposed heat flux of 50 to 75 kW/m^2, which is a flux known to occur in many types of real scale fires. Under such conditions, measured heat release rates less than 50 to 100 kW/m^2 often indicate a relatively low flammability hazard.

The heat transfer from real-scale flames is primarily due to thermal radiation, which, as discussed in Section 2, Chapter 1, "Physics and Chemistry of Fire," depends both on flame temperature and flame emissivity primarily determined by soot concentration profiles within the flame. The configuration of the burning material will also affect flame heat transfer, as discussed in Section 2, Chapter 2, "Physics of Fire Configuration." Significant progress is being made to understand flame heat transfer through the development of empirical correlations (e.g., in room-corner configurations[25] and in parallel panel configurations[25]) guided by simplified models.[26] These correlations show that the smoke yield of the flame for a burning material specimen, as obtained in a laboratory apparatus, is a critical determinant of flame heat transfer levels. Generally, higher smoke yields imply sootier flames with higher flame heat transfer and a greater flammability hazard. Note that at a sufficiently high smoke yield, combustion efficiency, or the actual heat of combustion, will be reduced to such an extent that heat release rates (and hence the flammability hazard) are reduced in spite of enhanced flame heat transfer.

HRR TEST METHODS

The heat release rate of actual material configurations can be measured in large-scale calorimeters, some of which are capable of safely handling tens of megawatts. In that case, the measured heat release rate (either peak or average values) can be used directly to estimate flammability hazard. Otherwise, laboratory-scale calorimeters must be used to obtain quantitative data from material specimens ranging in size from 100 mm up to 1 m across.

Measurement of Heat Release Rate

The oxygen consumption method has been identified as the most accurate means for determining heat release rate. This technique was refined in the late 1970s and early 1980s by researchers at the National Bureau of Standards. Using the principle of oxygen consumption, it is possible to calculate the heat release rate of burning materials when the products of combustion are collected in an exhaust hood. Thornton[27] found in 1917 that many organic materials produced almost the same amount of heat per unit mass of oxygen consumed. Hinkley et al.[28] suggested using oxygen concentration in exhaust gases to determine the heat release rate of wood cribs in 1968. Parker[29] used this technique to determine the heat release rate of specimens in the ASTM E84, *Standard Test Method for Surface Burning Characteristics of Building Materials,* tunnel test. Huggett[30] calculated an average value for the heat release from a fire involving typical organic fuels to be 13.1 MJ per kilogram of oxygen consumed. However, for materials with very low heat release rates (e.g., below 100 kW/m^2) or very sooty flames, comparable or greater accuracy can be obtained by measuring the generation rate of product gases such as carbon dioxide and carbon monoxide, as long as the elemental composition of the material specimen is known (or measured by readily available and inexpensive laboratory techniques).[31]

The calculation of heat release rate of fires burning in normal air, whether using oxygen consumption or product gas generation, requires a minimum of two measurements, the flow rate of the products of combustion through the exhaust system and product gas concentration in the exhaust products. Parker[32] presents several sets of equations for calculating heat release rate using oxygen consumption. The appropriateness of each set of equations depends on the combustion products being measured.[31] A paper by Janssens[33] proposes a form of the equations for calculating heat release rate specifically for full-scale fire test applications. These equations use mass flow rates instead of volumetric flow rates. Volumetric flow rates can lead to confusion because of the need to choose an arbitrary reference temperature and pressure. Figure 2.3.5 shows a schematic of a sampling system for measuring heat release rates.

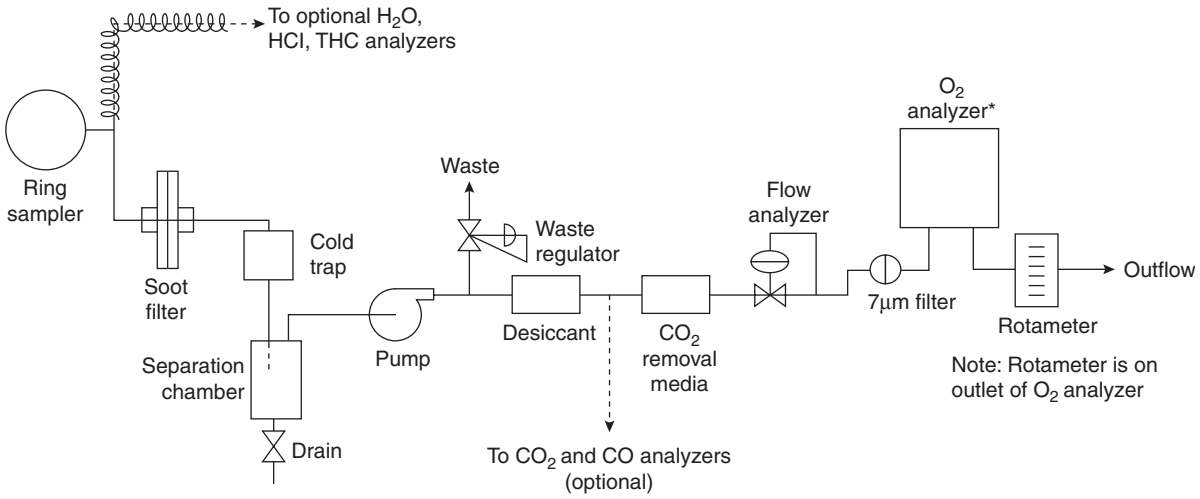

FIGURE 2.3.5 Schematic of Sampling System for Measuring Heat Release Rates from Burning Items. *To include absolute-pressure transducer. (Source: National Institute of Standards and Technology)

Laboratory-Scale Calorimeters

Early calorimeters functioned by measuring the temperature increase in the exhaust stream resulting from the combustion of a flammable item.[34] Developed in 1959, the FM Global Construction Materials calorimeter is probably the earliest example of a device designed to measure heat release rate using the potentially very accurate substitution principle.[35] The test specimen, approximately 1.22 m by 1.22 m and oriented face-down, was exposed to an oil burner fire. A second test would be conducted with a noncombustible blank exposed to the oil burner flames while auxiliary propane gas burners were adjusted to reproduce the measured exhaust gas temperature increase. The energy release rate from the propane burners would correspond to (or "substitute for") the energy release rate of the test specimen. This device was considered cumbersome, requiring two tests for each specimen and did not see widespread use. Subsequently, a similar calorimeter using a 0.46 m by 0.46 m sample mounted vertically was built by the U.S. Forest Products Laboratory.[36]

The National Bureau of Standards NBS-I calorimeter improved upon earlier calorimeter designs with the addition of a feedback loop.[37] As the specimen burned, the system would reduce the quantity of propane being added to the system, thus keeping the energy in the system constant. The energy release accounted for by the reduced propane flow would represent the heat release rate of the flammable item. The NBS-I could expose vertically oriented samples 114 mm by 152 mm and up to 25 mm thick to a maximum heat flux of 100 kW/m^2 for short durations. Although this system eliminated some of the early problems, its complexity, sensitivity to exhaust pressure fluctuations, and long equilibrium times limited its widespread use. The NBS-I inspired the development of a similar calorimeter at Stanford Research Institute with a maximum heat release rate measurement capability of 120 kW/m^2.[38]

OSU Apparatus. The Ohio State University (OSU) calorimeter, designed by E. E. Smith, is one of the most widely used bench-scale calorimeters.[39] Unlike many other bench-scale calorimeters that functioned by adding or substituting an energy source, this calorimeter operated by measuring the temperatures of the incoming air and the exhaust gases while the sample burns in an insulated box. This method of operation was referred to as the "sensible enthalpy rise method." Although attempts were made to limit heat losses, it was impossible to totally eliminate them. Therefore, calibration runs using a gas burner were still necessary to develop a correlation between heat release rate and exhaust gas temperature. Using radiant heaters, vertically oriented specimens, up to 0.15 m by 0.15 m, could be exposed to a peak heat flux of 65 kW/m^2. Sample size was limited to 0.11 m by 0.15 m and a peak heat flux of 50 kW/m^2 when tested horizontally using an aluminum reflector. The OSU calorimeter was adopted as ASTM E906, *Standard Test Method for Heat and Visible Smoke Release Rates for Materials and Products,* in 1983.[40] Although the ASTM standard test method has changed little since its adoption, a number of researchers have modified the OSU calorimeter for oxygen consumption measurements. Figure 2.3.6 illustrates the OSU calorimeter.

Fire Propagation Apparatus. At FM Global in 1975, Tewarson first described a small-scale flammability apparatus for measuring heat release rate.[41] The convective component of the total heat release rate was obtained from measurements of the enthalpy of the exhaust stream. The total heat release rate was calculated from the specimen mass loss rate, oxygen bomb heat of combustion, and the generation rates of carbon dioxide and carbon monoxide. Alternative calculations using oxygen consumption or carbon dioxide and carbon monoxide generation in lieu of oxygen bomb measurements were also implemented. Test specimens, up to 100 mm in diameter and 50 mm thick, could be exposed to a peak heat flux of 65 kW/m^2 using tungsten/quartz heaters. A larger version of this calorimeter was implemented as the intermediate-scale flammability apparatus with a capability to expose samples up to 305 mm in diameter and 75 mm thick. The intermediate-scale apparatus could test items with heat release rates up to 500 kW, whereas the small-scale apparatus was limited to peak heat release rate measurements of 10 kW. In 2000, test methods based on the small-scale apparatus were adopted as ASTM E2058, *Standard Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus (FPA).*[6] In 2001, test methods based on the same apparatus with smoke and corrosion measurement capabilities added to characterize the hazards of materials in commercial cleanrooms were adopted as NFPA 287, *Standard Test Methods for Measurement of Flammability of Materials in Cleanrooms Using a Fire Propagation Apparatus (FPA).* Figure 2.3.7 illustrates the Tewarson fire propagation test apparatus. Figure 2.3.8 illustrates the ASTM E2058 apparatus.

Cone Calorimeter. The cone calorimeter is probably the most versatile oxygen consumption method for measuring heat re-

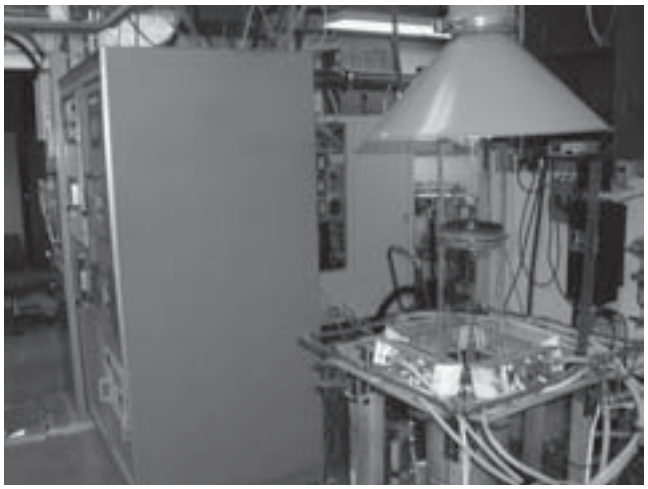

FIGURE 2.3.7 Quartz Heaters and Controlled Combustion Environment of the Fire Propagation Apparatus (Courtesy Ronald Alpert)

lease rate. It was developed at NIST in the 1980s[42] and is presently the most commonly used bench-scale rate of heat release apparatus.[43] The cone calorimeter has been adopted as ASTM E1354, *Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter*.[19] It has also been adopted by the National Fire Protection Association in NFPA 271, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter,* and as an international standard, ISO 5660-1.[44]

The cone calorimeter consists of a heater, spark ignitor, sample holder, and load cell located underneath an exhaust hood. Typically, the sample is located in the open with free access of air to the combustion zone. The heater consists of a 5 kW electrical heating element inside an insulated stainless-steel conical shell. Samples can be tested in either a horizontal or vertical orientation. When tests are performed in the horizontal configuration, the specimen is positioned approximately 25 mm beneath the bottom plate of the cone heater. Flames and products of combustion pass through a circular opening at the top of the heater. The heater can expose samples to a maximum irradiance of approximately 100 kW/m^2. Figure 2.3.9 is a schematic of the cone calorimeter.

For piloted ignition tests, an electric spark ignitor is positioned at the top of vertical samples and over the center of horizontal samples. Samples are typically 100 mm by 100 mm, and they can be wrapped with aluminum foil to minimize edge effects. Combustion products and dilution air are extracted through the hood and exhaust duct by a high temperature fan. The flow rate can be adjusted between 0.01 and 0.03 m^3/sec.

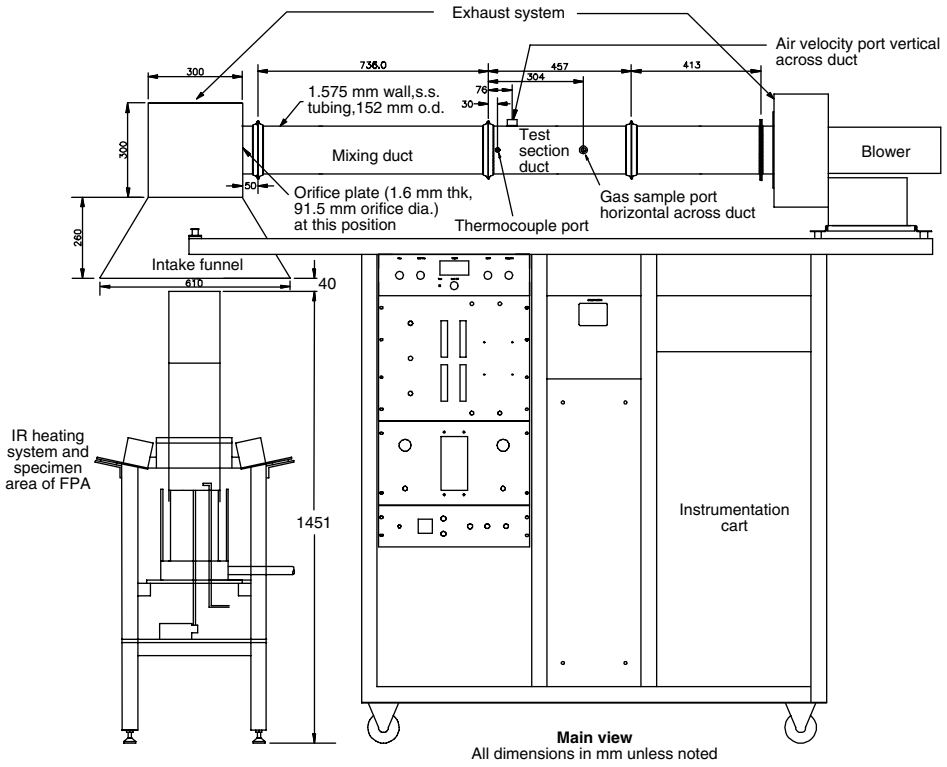

FIGURE 2.3.8 ASTM E2058 Apparatus (Source: Reprinted, with permission, from ASTM E2058, *Standard Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus (FPA),* Annex A1, copyright ASTM International, W. Conshohocken, PA)

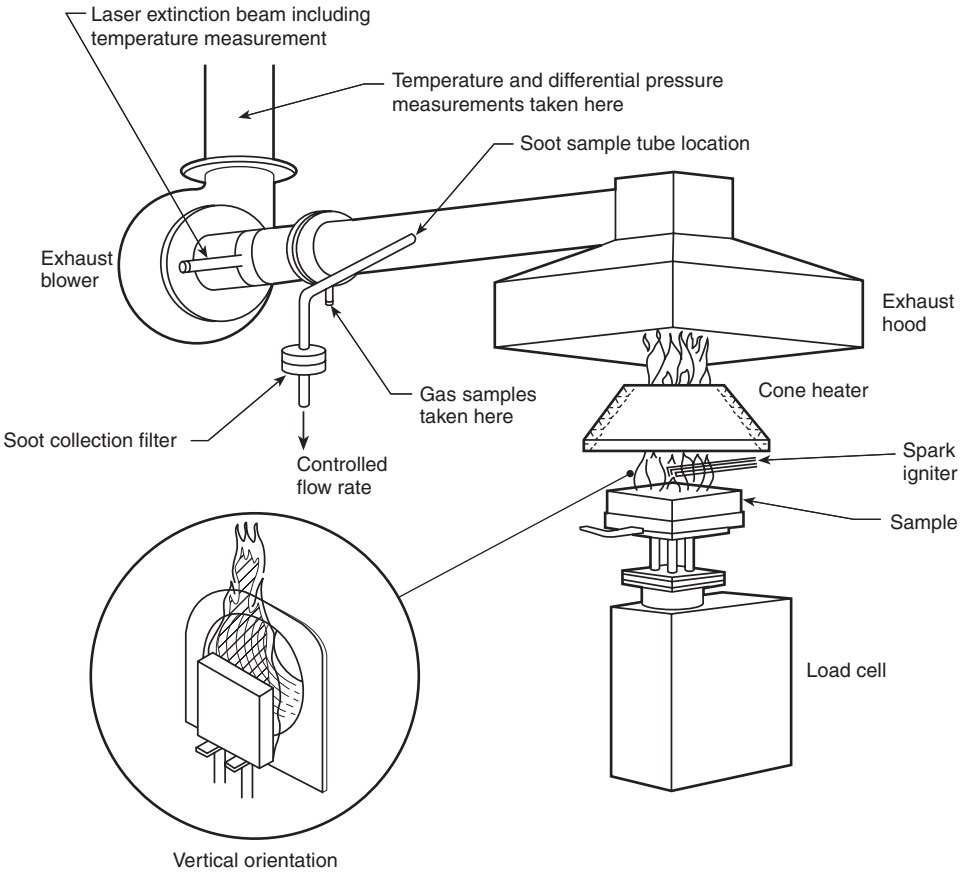

FIGURE 2.3.9 Schematic View of the Cone Calorimeter (Courtesy Society of Fire Protection Engineers)

The volumetric flow rate is kept constant during testing. The sample is mounted on a load cell to determine mass loss rate during a test, and smoke obscuration is measured using a laser light source. The gas flow rate in the exhaust duct is calculated from the pressure drop across and temperature at an orifice plate in the duct. Finally, the concentrations of oxygen, carbon dioxide, carbon monoxide, and other gases are measured using appropriate instruments. Heat release rate is calculated from the gas concentration and mass flow measurements.

Single Burning Item Test. The single burning item test method, or EN 13823, is a CEN (European) standard[45] with the objective of reproducing the transient heat release rate results from the full-scale ISO 9705 room-corner test (discussed later). Two heat release parameters are measured: the ratio of the peak heat release rate to the time at which this peak HRR occurs, or the fire grow rate (FIGRA) index, and the total heat release over the first 600 seconds of the test (THR600). Whether this 1.5-m-high corner test accomplishes the stated objective is definitely open to question since the 31 kW heat release rate of the initiating propane flames from a triangular gas burner produces a rather small incident heat flux on the test specimen. In particular, test specimens consisting of sandwich panels with a combustible insulating core and a metal covering have not yielded the same result in the EN 13823 test as in the ISO 9705 room since the exposure heat flux has not been sufficient to penetrate the metal cover.

Large-Scale Calorimeters

The oxygen consumption technique has been successfully implemented in a number of intermediate and large-scale calorimeters. These large-scale calorimeters have been developed to measure heat release rate from an assortment of different flammable items. These items range from single pieces of furniture, such as couches or mattresses, to entire rooms. Typically, the item or items of interest are burned under a large collection hood or in a room vented to this large hood. The hood would be instrumented to measure the temperature and velocity of the exhaust gases. In addition, the concentrations of oxygen, carbon dioxide, and carbon monoxide would also be measured during the experiments. Burning materials inside a room enclosure has the advantage of including the impact of the room; however, the potential lack of oxygen in the room would prevent the complete combustion of the items of interest. The calorimeter would be unable to distinguish between burning of the object in the room and burning of the gases outside of the room. Measuring the heat release rate from an item burning in the open with excess

oxygen would allow for complete combustion and a better measure of the item's total heat release rate.

Room-Corner Fire Test for Surface Linings. Several standard room fire tests have been developed. A room calorimeter developed at Monsanto Chemical was one of the earliest attempts to build a room-size calorimeter.[46] This test used exhaust gas temperature measurements and statistical analysis to determine heat release rate in lieu of oxygen consumption calorimetry. The American Society for Testing and Materials developed a standard room fire test in the early 1980s,[47] which was standardized in 2003 as ASTM E2257, *Standard Test Method for Room Fire Test of Wall and Ceiling Materials and Assemblies*.[48] The ASTM room measures 2.4 m by 3.7 m in size and is 2.4 m high. The room has a single doorway in one wall measuring 0.76 m wide by 2.03 m high. A standard guide, ASTM E603, *Standard Guide for Room Fire Experiments,* for conducting and instrumenting room fire tests[49] is also available. Many years ago, the work on room fire tests in ASTM inspired the ISO 9705 standard[50] that has been designated in Europe as a reference fire scenario for the evaluation of surface lining flammability hazard. NFPA 286, *Standard Methods of Fire Tests for Evaluating Contribution of Wall and Ceiling Interior Finish to Room Fire Growth,* is a slightly different version of this ISO standard. Another room fire test was developed for use as a potential standard room fire test by NORDTEST.[51]

Furniture Calorimeters. A number of open calorimeters have been developed by various research organizations throughout the world. One of the first was the NBS Furniture Calorimeter.[52] This device used oxygen consumption to determine heat release rate. In addition, mass loss, smoke concentration, and heat flux were measured during combustion of the sample. Other open calorimeters have been developed by NORDTEST,[53] Underwriters Laboratories,[54] FM Global Research,[55] and Statens Provningsanstalt.[56]

ICAL. The ICAL is an intermediate-scale calorimeter that has been designed to measure heat release rate, mass loss rates, and visible smoke development from a 1 m × 1 m vertically oriented, nonmelting material under well-ventilated conditions. The test sample is exposed to a uniform heat flux up to 50 kW/m^2 from a gas-fired radiant panel. This device is documented in ASTM E1623, *Test Method for Determination of Fire and Thermal Parameters of Materials, Products and Systems Using an Intermediate Scale Calorimeter (ICAL)*[21] as well as in ISO 14696.[57] Figure 2.3.10 illustrates the ICAL calorimeter.

Commodity Fire Tests. Several test methods have been developed for measuring the heat release rate from various commodities in specific arrangements. Standards exist for testing stacked chairs,[58] upholstered chairs,[59] and mattresses[60] in open calorimeters as well as in room enclosures while test methods have been established in the United States and Europe to determine the extinguishability of commodity array segments using an applied water droplet flux during the measurement of heat release rate by collecting combustion products in an exhaust hood (see Section 2, Chapter 7, "Theory of Fire Extinguishment").

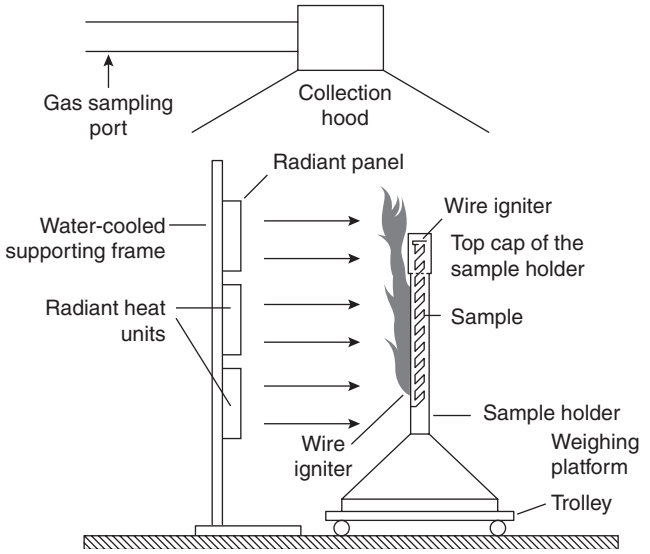

FIGURE 2.3.10 Intermediate-Scale Calorimeter (ICAL) (Source: Reprinted, with permission, from ASTM E1623, *Standard Test Method for Determination of Fire and Thermal Parameters of Materials, Products, and Systems Using an Intermediate Scale Calorimeter (ICAL),* copyright ASTM International, W. Conshohocken, PA)

Certain interior finish materials are tested in a room-corner arrangement, described in NFPA 265, *Standard Methods of Fire Tests for Evaluating Room Fire Growth Contribution of Textile Coverings on Full Height Panels and Walls,* and NFPA 286. The heat release rate data obtained from these larger calorimeters can be used as an estimate of the hazard potential from the respective item. In the United States, several of the nongovernmental fire test laboratories—FM Global, Underwriters Laboratories, and Southwest Research Institute—have increased the size of their large scale calorimetry labs in order to accommodate larger commodity fire testing.

FLAME PROPAGATION PROPENSITY

Another important parameter for determining the flammability hazard of an item is its propensity to support flame spread. The buoyancy flow induced by a fire and natural wind flow can aid the spread of flames or hinder it. When the flames spread in the direction of the fire-induced flow or with the wind, it is termed "wind-aided" spread (e.g., flame spread up a vertical surface, as discussed in Section 2, Chapter 2, "Physics of Fire Configuration"). "Opposed-flow" flame spread occurs when the flame motion is opposite the direction of fire-induced air flow or into the wind[61] (e.g., flame spread down or laterally on a vertical surface and flame spread over a horizontal surface, as discussed in Section 2, Chapter 2, "Physics of Fire Configuration"). The flame spread across the surface of a solid material is characterized by two moving boundaries or fronts. The front where visible flaming occurs in the gas phase and a pyrolysis region moving through the solid phase within the flame front. The

velocity of this flame front and the associated pyrolysis front can be useful for determining fire hazard, especially in the case of opposed-flow flame spread where such velocities are easily measured. However, in the case presenting the greatest danger, namely wind-aided or upward flame spread, it may be equally important to determine whether or not a material configuration and fire scenario will lead directly to self-sustained flame spread, which could result in rapid movement of the flame and pyrolysis front over the entire upward extent of the material surface. Obviously, the greater the velocity and/or extent of flame spread on a material, the greater the flammability hazard.

Upward or wind-aided flame spread propensity or velocity on a single vertical surface can be used to characterize flammability hazard in test methods. However, conclusions in this case may be incorrect because radiant heat losses from charring materials can prevent flame spread altogether whereas spread velocities for noncharring, nonmelting materials may be very high and not very reproducible. Lateral, downward, or opposed-flow flame spread velocity and the extent of flame spread on surfaces can also be used in test methods to characterize flammability hazard. The disadvantage with test methods involving opposed-flow flame spread is that such configurations are not sensitive to flame radiant heat transfer and hence may not correctly predict flammability hazards in realistic configurations and sizes. Tests involving wind-aided (upward) flame spread propensity in a parallel panel configuration, by eliminating much of the radiant heat losses, have provided useful measures of flammability hazard for materials ranging from wood to highly fire-resistant, engineered polymers. In addition, the propensity for limited (a steady flame front) or unlimited (an accelerating flame front moving upward) flame spread in the parallel panel configuration has been modeled successfully.[23,24]

FLAME SPREAD TEST METHODS

Tunnel Test

The Steiner tunnel test is one of the earliest test methods developed for assessing the flammability hazard of materials through measurement of flame spread. This test, ASTM E84,[62] provides a normalized flame spread rating for materials mounted on the ceiling of the test apparatus under forced-flow conditions. A test specimen 7.6 m long and 1.67 m wide is mounted on the ceiling of a tunnel measuring 8.7 m long by 0.45 m wide and 0.31 m high. The sample is exposed at one end to a 79 kW gas burner with a forced draft through the tunnel of 1.2 m/sec. Relative indexes of flame spread and smoke developed are determined from measurements obtained during the 10 minute test. The test materials are compared to test performance of inorganic cement board and red oak flooring, which have flame spread indexes of 0 and 100 respectively. While the values obtained from this apparatus have been used for regulatory purposes over the last several decades, its relationship to real-world applications has not been established. The requirement to mount a test specimen on the ceiling, its limited ability to test materials that melt and drip, and the limited ventilation available for some polymer foams that produce high volumes of pyrolysis and combustion products are some of the limitations of this apparatus. This test is also documented in NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials*.

Radiant Panel Test

Unlike the tunnel test, which is considered a wind-aided flame spread configuration, the radiant panel test provides a measure of downward, opposed-flow flame spread.[63] This test method has also been used extensively in building codes for regulatory purposes. The apparatus measures the surface flammability of materials using a gas-fired radiant panel. A specimen approximately 152 mm × 457 mm is exposed to a radiant panel that is 305 mm × 457 mm. The specimen is sloped away from the panel at a 30° angle with the top of the specimen being closest to the panel. The slope provides a decreasing heat flux along the specimen. A relative index of flame spread is calculated based on the distance the sample burns. This test method is referenced for building products as ASTM E162, *Standard Test Method for Surface Flammability of Materials using a Radiant Energy Source*[64] and for cellular plastics as ASTM D3675, *Standard Test Method for Surface Burning Characteristics of Building Materials*.[65] Figure 2.3.11 illustrates the radiant panel test apparatus.

LIFT Apparatus

Another test apparatus to measure opposed-flow flame spread is referenced in ASTM E 1321, *Standard Test Method for Determining Material Ignition and Flame Spread Properties*.[20] This apparatus, often referred to as the lateral ignition and flame spread test (LIFT), uses a gas-fired radiant panel to measure surface ignition and lateral spread of flames on materials under opposed-flow conditions. The radiant panel is installed at a 15 degree angle to

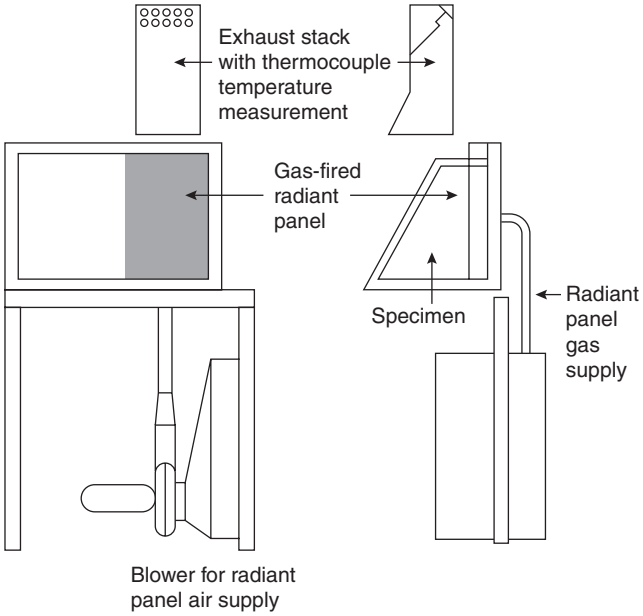

FIGURE 2.3.11 Radiant Panel Test Apparatus from ASTM E162 (Source: National Institute of Standards and Technology)

the test specimen and can provide up to 65 kW/m^2 of heat flux at the 50 mm position. The sample size is 155 mm by 800 mm. A modified version of the test with a different sample orientation is identified as the horizontal ignition and flame spread test (HIFT). Unlike many older test methods, this apparatus provides information in engineering terms. Data obtained from these tests (LIFT and HIFT) allow the flame spread velocity and external heat flux required for flame spread to be determined. The resulting information can be used to evaluate the potential opposed-flow flame spread flammability hazard of many different materials. The LIFT apparatus is also used to examine the flammability of marine surface finishes, and ASTM E1317, *Standard Test Method for Flammability of Marine Surface Finishes,* governs its use for maritime applications.[66] ISO 5658-2[67] is a version of the apparatus nearly identical to ASTM E1321.

Radiant Panel Flooring Test

As a result of some major fires where flame spread on carpeting was a major factor, a radiant panel flooring test was developed at NBS. This test method was adopted as ASTM E648, *Standard Method of Test for Critical Radiant Flux of Floor-Covering Systems Using a Radiant Heat Energy Source*[68] or NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source*. A 1 m long test specimen is mounted horizontally beneath an air-gas-fueled radiant panel. The panel is inclined at 30°, providing a heat flux on the test specimen varying from 10 kW/m^2 at the point closest to the panel to 1 kW/m^2 at the farthest point. The critical radiant flux corresponds to the flux at the point of maximum flame propagation. This parameter can also be used in engineering analysis of fire performance of materials. A similar test designed to evaluate attic insulation is referenced in standard ASTM E970, *Standard Test Method for Critical Radiant Flux of Exposed Attic Floor Insulation Using a Radiant Heat Energy Source*.[69]

Vertical Burn Test

The UL 94 vertical burn test provides a measure of a thin material's resistance to self-sustained ignition in an upward flame spread configuration.[70] This test method can be used to select materials for use in electronic devices or applicances. A standard laboratory Bunsen burner (ASTM D5025, *Specification for a Laboratory Burner Used for Small-Scale Burning Tests on Plastic Materials,* burner at 105 mL/min flow rate)[71] is used to produce a 50 W premixed methane-air flame for the ignition source. The flame is applied for 10 seconds and is intended to simulate a short duration ignition such as from an electrical short. The test method utilizes a sample 125 mm long and 13 mm wide mounted 30 cm above a piece of loose cotton. The tested material receives a V-rated classification based on the results from a set of five tests. If the material fails to meet any of the criteria, a V-fail or V-not rating is assigned. The V-ratings are summarized below.

V-0 Classification

1. The afterflame time for each individual specimen is less than 10 seconds.
2. The total afterflame time for any condition set is less than 50 seconds.
3. The cotton indicator is not ignited by flaming particles or drops.

V-1 Classification

1. The afterflame time for each individual specimen is less than 30 seconds.
2. The total afterflame time for any condition set is less than 250 seconds.
3. The cotton indicator is not ignited by flaming particles or drops.

V-2 Classification

1. The afterflame time for each individual specimen is less than 30 seconds.
2. The total afterflame time for any condition set is less than 250 seconds.
3. The cotton indicator is ignited by flaming particles or drops.

An important caveat associated with this test method is that even the V-0 classification does not ensure the material will not spread flames in real fire scenarios. (The 50 W [not 50 kW] exposure flame is meant to reproduce a very small ignition source. The danger of course is that someone not knowledgeable about flammability hazards will misinterpret the applicability of these ratings.)

Parallel Panel Test

A parallel panel apparatus for evaluating the fire propagation hazard of exposed polymer materials was developed at FM Global Research in the 1970s. This parallel panel configuration has most often been used to determine if polymeric materials represent a flammability hazard when installed in wall linings and equipment in highly sensitive commercial fabrication areas where even a small fire cannot be tolerated, such as a cleanroom in a fabrication facility. The apparatus, which now qualifies materials for use in commercial semiconductor clean rooms[72] following the ANSI FM 4910 protocol,[73] consists of two parallel 2.4 m high × 0.6 m wide panels separated by a 0.3 m × 0.6 m horizontal sand burner. Each panel is faced with a test specimen attached to a 25 mm thick sheet of calcium silicate board, which, in turn, is attached to a 13 mm thick sheet of plywood. The test specimen panels are exposed to the sand burner flames for 20 minutes only after the burner has reached a steady heat release rate of 60 kW. During the test, the total heat release rate and smoke generation rate of the panel assembly are obtained from gas and soot concentration measurements in an exhaust hood, the mass loss rate of the assembly is obtained from load transducer measurements, panel flame heat flux is obtained from imbedded gauges and video observations are recorded of flame front position beyond the 0.6 m height of the exposure flames. All of these measurements are used to determine the flammability hazard of the panel specimen in a specific fire scenario. This test is sufficiently large that, as in most dangerous fires, flame radiation is dominant. There is also ample air access and confinement of heat so that the test is rigorous and realistic.

The relatively simple test geometry both increases the likelihood of modeling success and provides access to instrumentation. Yet the surface area of the material specimen required is small enough to make testing economical.

The parallel panel configuration and sand burner has also been used with double height panels (4.88 m high instead of the usual 2.44 m) to evaluate flame spread on polymer insulated cables in a simulated vertical cable tray configuration, which provided the technical basis for the FM 3972 cable standard.[74] Results from this larger configuration when there is negligible flame spread beyond the exposure fire are in excellent agreement with the UL 910/NFPA 262, *Standard Method of Test for Flame Travel and Smoke of Wires and Cables for Use in Air-Handling Spaces,* plenum cable test based on the ASTM E84 tunnel apparatus. Research on the parallel panel configuration now in progress[24] has shown that by increasing the scale of the panels and the heat release rate of the sand burner, it is very likely that a correlation can be obtained with flame spread results in very large-scale corner tests (see below).

Large-Scale Corner, Room and Façade Tests

There are several large-scale test methods[75–78] that expose wall and ceiling lining materials (in many cases, only sandwich-type panels of metal covering polymer foam core) or external façade materials to a high heat flux exposure over significant specimen heights from 4 to 10 m. Heat flux exposure is generated by large-scale flames from pallet stacks, wood cribs, or gas burners that are adjacent to open corners, within rooms, or near façades. During the various tests, observations are made to determine if self-sustained flame spread occurs to the top or lateral boundaries of the apparatus. Such flame spread indicates the presence of a flammability hazard for the particular type of fire scenario that is being simulated by the test method.

SMOKE YIELD

Smoke has long been identified as the most significant hazard to people during fire.[79] Smoke and the toxic gases contained in it are the primary cause of fatalities in fires. Smoke can also impair visibility and prevent escape from threatened areas. The rate of production of smoke and other products of combustion is very dependent on the fire scenario (type and configuration of material burning, flaming or nonflaming combustion, level of external heat flux) as well as the scale of the fire. In addition, the ventilation air supply and stage of the fire (pre- or postflashover) will also significantly influence the production of smoke and other species. Building codes have attempted to regulate the amount of smoke likely to be produced by various materials during a fire. Specifically, interior finishes are often required to have a smoke developed rating less than 450 when measured using the ASTM E84 tunnel test.[80] The smoke-developed rating is determined by comparing the light absorption curve from a test material to the light absorption results from inorganic cement board and red oak flooring, which have smoke-developed indexes of 0 and 100 respectively.

Smoke production is measured by weighing the particulates collected on a filter, by determining the optical density of a quantity of smoke collected in a known volume, or measuring the optical density as an assumed plug flow of smoke moves through an exhaust duct. The optical density measurements in a duct flow are most convenient but also provide only an indirect measure of smoke production. Typically, the smoke produced during a test is reported as a smoke yield, which is a mass of smoke per unit mass of material burned,[81] with a higher smoke yield representing a greater flammability hazard for two reasons: (1) a higher yield implies that combustion products from a fire will produce more direct damage to life and property for each unit of material that burns and (2) a higher yield implies that there may be more soot in the flame to enhance radiant flame heat transfer, leading to higher heat release rates, more extensive flame spread, and higher burning rates.

Note that every test method for flammability hazard that uses an exhaust collection hood or duct to measure heat release rate will also provide a measure of smoke generation rate using the optical density data coupled with the exhaust duct flow rate. This measurement, together with the mass loss measurement, if available, allows the smoke yield to be calculated for the evaluation of flammability hazard. Although the ASTM E84/NFPA 255 tunnel test does not measure heat release rate, this test method does provide an index representing the amount of smoke produced by the burning sample. The index is determined by using a white light source and a photocell to measure the light absorption occurring in the exhaust duct and is referenced to red oak which has a value of 100 (NFPA 255).

The cone calorimeter and fire propagation apparatus are two laboratory calorimeters that can also be used to obtain smoke obscuration data.[82] The attenuation of light from a He-Ne laser beam passing through the exhaust duct is measured as a function of time. An extinction coefficient is calculated from the data and used to determine a specific extinction area in the cone test methods whereas a smoke yield is calculated from a smoke generation rate in the fire propagation apparatus test methods. These equivalent quantities can be regarded as an effective material property and measure of flammability hazard. Figure 2.3.12 depicts the smoke measuring portion of cone calorimeter and fire propagation apparatus.

SMOKE YIELD TEST METHODS

Smoke Chamber Test

The NBS smoke chamber was developed specifically to measure obscuration by smoke particulates.[83] The apparatus consists of a 3 ft (0.914 m) wide, 3 ft (0.914 m) high, and 2 ft (0.61 m) deep enclosure. A 3 in. × 3 in. (75 mm × 75 mm) specimen is exposed in the vertical orientation to an electric heater. Tests can be conducted with or without small pilot flames impinging at the bottom of the specimen. A white light source is located at the bottom of the enclosure, and a photomultiplier tube is mounted at the top to measure obscuration and optical density of the smoke as it accumulates inside the enclosure. This method is described in ASTM E662, *Standard Test Method for Specific Optical Density Generated by Solid Materials*.[84] Three tests are conducted at a heat flux of 25 kW/m^2 with pilot flames and without pilot flames. These conditions are referred to as

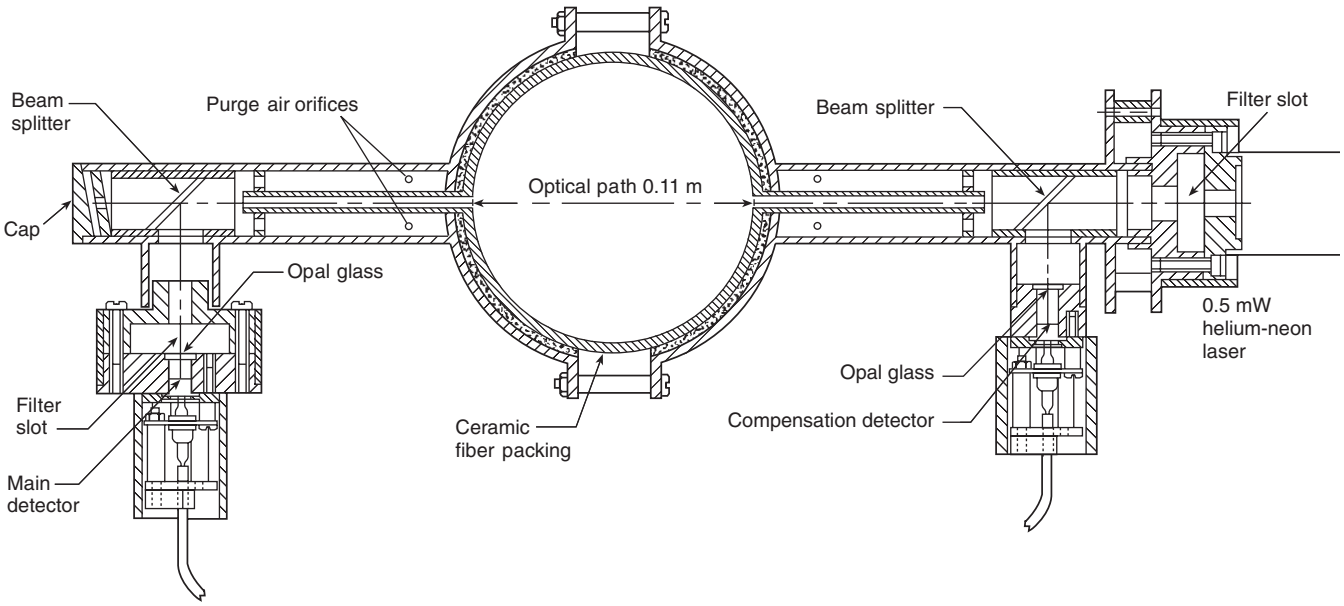

FIGURE 2.3.12 Schematic of Laser Photometer or Smoke Measuring Portion of Cone Calorimeter (Courtesy Society of Fire Protection Engineers)

the flaming and nonflaming modes, respectively. The latter is misleading because specimens often ignite spontaneously, leading to flaming combustion without the pilot flames. The test has been subjected to criticism because the smoke generated by the specimen accumulates inside the chamber and eventually affects combustion. The test conditions, therefore, are not well controlled and partly depend on the burning behavior of the product itself.

Guide for Measurement of Fire Gases

Fires can generate not only smoke particulates but also toxic products of combustion, primarily in gaseous form. A wide range of techniques is used to measure toxic gas concentrations in fire tests, ranging from simple qualitative sorption tube methods to sophisticated spectroscopy techniques. ASTM E800, *Standard Guide for Measurement of Gases Present or Generated During Fires,*[85] describes the most common analytical methods and sampling considerations for many gases. Fourier transform infrared (FTIR) spectroscopy has emerged in recent years as the method of choice for real-time continuous analysis of fire gases. Animal tests have been used to determine toxic potency, but their use has become increasingly limited. One of the test procedures which minimizes the number of animal tests is described in ASTM E1678, *Standard Test Method for Measuring Smoke Toxicity for Use in Fire Hazard Analysis*[86] and NFPA 269, *Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling*. In this test procedure, a specimen is exposed to a radiant heat flux of 50 kW/m^2 and the products of combustion are collected in a 0.2 m^3 (7 ft^3) chamber. Test duration is 30 minutes. A mathematical correction is made to the analytical measurements to account for the increase in CO production in underventilated postflashover fires. This is important because the majority of U.S. fire deaths occur remote from the fire room, especially for fires that have proceeded past flashover. Figure 2.3.13 illustrates the smoke density test apparatus used in ASTM E1678.

EXTINGUISHABILITY

There are very few engineering methods to determine the extinguishability of materials or material systems for use in the evaluation of flammability hazard. One method already mentioned in connection with heat release rate is the large-scale required delivered density of water (RDD) test for storage commodities (see a full description in Section 2, Chapter 7, "Theory of Fire Extinguishment"), in which a material array (typically cartons with vertical and horizontal flue spaces) burns under

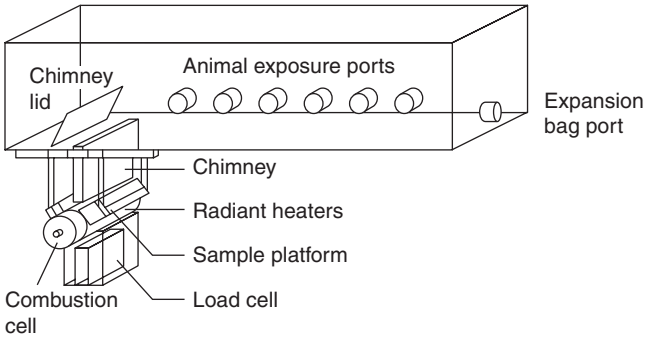

FIGURE 2.3.13 Smoke Toxicity Test Apparatus from ASTM E1678 (Source: National Institute of Standards and Technology)

an exhaust measurement hood. A fixed, known water flux is applied to the top surface of the commodity array at the time when sprinkler actuation would be expected to occur. Through multiple tests of this type, the critical water flux that will cause a permanent decay in heat release rate after the initial peak value can be determined. With regard to the flammability hazard of an isolated material surface, a laboratory measurement method to determine the critical water flux for extinguishment of horizontal (facing upward) or vertical burning material panels was described by Magee and Reitz[87] in the 1970s (see Section 2, Chapter 7, "Theory of Fire Extinguishment"). Obviously, the greater the water flux required for extinguishment, the greater is the flammability hazard.

SUMMARY

By definition, any material capable of burning with a flame is considered flammable, but the flammability hazard of a material in a specific fire scenario is not easily quantified. Different aspects of flammability hazard can be defined or categorized and for each such category, a test method is available to measure the magnitude of a material characteristic that can be used to evaluate, if not quantify, flammability hazard. These different aspects of flammability include type of response to heat flux, ease of ignition, generation of heat and smoke, extent of flame spread, and ease of extinguishment. The flammability of a material is dependent on many parameters, such as its chemical composition, physical properties, geometric configuration, and combustion products. As a result, flammability is really a characterization of multiple fire hazards. There is no single measure that will adequately describe a material's performance in a real fire scenario.

Given the large number of parameters that play a role in determining flammability hazard, it is important to use a variety of flammability test methods and models in order to have a more reliable and accurate assessment applicable to realistic fire scenarios.

Chapter 4

Dynamics of Compartment Fire Growth

Richard L. P. Custer

Chapter Contents

Fire Growth
Classifications of Fire
Effects of Compartment Boundaries on Fire

Key Terms

compartment fire, fire dynamics, fire growth, fire (stage of), flashover, fuel load, heat release rate, incipient fire, plume, steady-state fire, *t*-squared fire

Over the past 25 years, research scientists and engineers have worked to develop an understanding of the factors and physical processes that enter into and control the growth and spread of fire and its products. Much of the work has focused on two general types of fires: (1) the pool fire and (2) the compartment fire. Research on pool fires has developed an understanding of energy production from a burning liquid surface and the dynamics of the plume of hot gases and other products of combustion that rise from the surface. Understanding of compartment fires, in part, is built on the work involving pool fires in order to define the characteristics of a simplified fire plume environment, without the effects that compartment boundaries (such as walls and ceilings) and compartment openings or vents (such as doors and windows) have on the development of the growth rate of the fire. Other work has produced literally hundreds of test fires in compartments with varying fire sources, compartment dimensions, materials of construction, and venting arrangements. As a result of this work, it is now possible to quantify many aspects of pool and compartment fires in order to predict their effect for use in hazard analysis, analysis and design of fire protection systems, and fire reconstruction. Fire spread and growth in the context of this chapter is limited to the compartment of origin and the fuel packages within it.

The purpose of this chapter is to provide the reader with a basic understanding of the concepts involved in modern-day applied fire dynamics as the basis for using the calculation methods described elsewhere in this handbook. It is intended to introduce the general concepts of fire growth in a compartment, not to focus on the detailed mathematics involved. A few equations, however, are provided to demonstrate some of the basic relationships. Further references to other chapters of this handbook and to the published literature will be provided, as needed, to guide the reader to sources of information for additional study.

For the purpose stated above, the discussion will deal with fire growth from the time of established burning to the time when the fire involves the entire compartment and the burning rate is controlled by airflow into and out of the compartment vents.

Established burning is defined as the point in fire development when the size of the flame on a burning material is sufficiently large that flaming combustion will continue without an independent external ignition source and the fire will grow to the extent permitted by the amount of fuel or oxygen present. The flame height at established burning is frequently considered to be approximately 10 in. (254 mm) on a horizontal fuel surface. It is suggested that, at this point, there is sufficient energy feedback from the flame to the fuel so that there will be adequate production of fuel vapors for combustion and the flame will not go out without external influences such as oxygen depletion or fire extinguishment activities.

Richard L. P. Custer, M.Sc., FSPE, is associate principal and technical director of Arup Fire in Westborough, Massachusetts. Mr. Custer is a fellow of the Society of Fire Protection Engineers and the past chair of the NFPA Technical Committee on Fire and Explosion Investigation.

FIRE GROWTH

The following discussion assumes that ignition has taken place and the fire has reached the point of established burning. Beginning with the first materials ignited, the early stages of a fire provide the driving force for growth and spread, both within the compartment and to other portions of the building. The fire serves not only as a source of energy, providing flame and heated gases for the spread of fire, but also as the source of smoke particulates and the toxic and corrosive gases that form the products of combustion. The rate and amount of energy produced by the initial fire in a compartment will frequently determine whether the fire will spread beyond that compartment.

The fuel available for fire growth and spread can be characterized in two ways: (1) the rate at which it burns and releases energy into the compartment environment and (2) the total energy available that could be released from the fuel. Each of these characteristics is used to describe compartment fire hazard or potential fire severity in a compartment.

Rate of burning is commonly described in terms of how fast energy is being released at a given time, using *heat release rate* (HRR) measured in kilowatts (Btu per second) to quantify this aspect of fire growth. The higher the HRR in a given compartment, the faster the compartment fills with hot gases and products of combustion.

The concept of potential hazard or fire severity is expressed as fire loading or fuel loading and is based on the amount of energy that would be available if all the fuel were to be consumed, not on how fast the material burns. Fire or fuel load is generally expressed in terms of kilograms of fuel per square meter (pounds per square foot) of floor area of the space being evaluated. Fuel load can also be expressed in energy terms as megajoules (MJ) per square meter (Btu per square foot). Fuel loading does not consider the speed at which the fuel burns or the rate at which the fire grows, but rather addresses the issue of how long a fire might burn until the fuel is consumed. A high fuel load does not necessarily mean a dangerously fast-growing fire. These concepts are discussed in detail in the following sections.

Heat Release Rate

The amount of heat released by a fire per unit of time (HRR) depends on its heat of combustion (which is the amount of energy produced for each unit of fuel mass burned), the mass of fuel consumed per unit of time (mass loss rate), and the efficiency of the combustion process. The HRR is then determined by multiplying the mass loss rate (mass consumed/unit of time) by the heat of combustion (energy available/unit of mass) and the combustion efficiency (fraction of the mass converted to energy) to yield the HRR, in units of energy produced per unit of time. Various units are used, such as kilowatts (kW), Btu/sec, or J/sec. The kilowatt (1055 Btu/sec) is the most common unit. The HRR is important during the growth phase of the fire, when air for combustion is abundant and the characteristics of the fuel control the burning rate. During this phase, the instantaneous HRR increases over time. Equation 1 describes this relationship between the HRR ($\dot{Q}$), mass loss ($\dot{m}$), and heat of combustion (h_c):

$$\dot{Q} = \dot{m}\Delta h_c \qquad (1)$$

The burning rate of a given fuel is controlled both by fuel chemistry, by fuel configuration or geometry, and its form. Fuel chemistry refers to the composition of the fuel—for example, cellulosic versus petrochemical. Cellulosic materials include wood, paper, cotton, fabric, and so on. Petrochemical materials, in general, refer to petroleum liquids or to plastics that are largely composed of formulations derived from petroleum. The configuration of the material—that is, its size, shape, and arrangement—also has an effect on the burning rate, as explained in Section 2, Chapter 2, "Physics of Fire Configuration."

One way of looking at the fuel configuration is in terms of the surface area available to burn compared to the mass of the material, which is called the surface-area-to-mass ratio. In the case of cellulosic materials, for example, a solid block of wood weighing 2.2 lb (1 kg) will burn much more slowly than will the same mass if converted into thin sheets of paper, and may burn explosively if converted into very fine wood dust and dispersed throughout a compartment volume. This concept can be applied to understanding the difference in burning behavior between expanded and unexpanded as well as melting and nonmelting polymer materials, as discussed below.

Foamed, expanded polymers, in general, burn more rapidly than a similar formulation in rigid, unexpanded form. Two examples are (1) flexible urethane versus solid, rigid urethane and (2) Styrofoam™ versus rigid polystyrene. The flexible, expanded foam is of low density and generally has a higher HRR than the rigid, unexpanded material. Another difference in physical characteristics related to burning characteristics of plastics is whether or not the plastic melts when it burns. Those polymers that produce a liquid melt when heated are referred to as thermoplastics. The melting may produce a pool with a large surface area, thereby releasing energy more rapidly than those polymers that remain solid when heated. The latter are referred to as thermosetting plastic materials. Thermosetting materials generally tend to form a char layer and burn more slowly. It should be noted that the peak HRR for ignitible liquids is related to the amount of surface area that is burning. Table 2.4.1 provides some examples of peak

TABLE 2.4.1 Representative Peak Heat Release Rates (Unconfined Burning)

Fuel (lb)	*Peak HRR (kW)*
Wastebasket, small (1.5–3)	4–18
Trash bags, 11 gal (46.6 L) with mixed plastic and paper trash (2½–7½)	140–350
Cotton mattress (26–29)	40–970
TV sets (69–72)	120–290
Plastic trash bags/paper trash (2.6–31)	120–350
PVC waiting room chair, metal frame (34)	270
Cotton easy chair (39–70)	290–370
Gasoline/kerosene in 2 ft^2 (0.61 m^2) pool	400
Christmas trees, dry (14–16)	500–650
Polyurethane mattress (7–31)	810–2630
Polyurethane easy chair (27–61)	1350–1990
Polyurethane sofa (113)	3120

Source: NFPA 921, *Guide for Fire and Explosion Investigations,* 2004 edition, Table 5.4.2.1.

burning rates of representative materials and products. Although this is not an exhaustive discussion of fuel burning characteristics, it does present some factors that the reader might consider in assessing the potential HRR or growth rate of a fire, given certain types of fuels. More detailed discussions of individual fuels are found in the appropriate chapters of this handbook.

Fuel Loading

The concept of fuel loading is one way of characterizing the hazard of a compartment fire or building fire in terms of the length of time the building would be expected to burn, based on the total amount of fuel available and the total energy produced.

Fuel loading is determined by adding up all fuel present and dividing it by the plan area of the compartment or fire space. The fuel load can be expressed as the mass of fuel equivalent to wood. When plastics or other materials are present, multiplying the number of pounds (kilograms) of plastic or other materials by the heat of combustion for those materials and dividing by the heat of combustion for wood provides a conversion. This conversion produces an equivalent number of pounds (kilograms) of wood for plastics or other materials present.

Fuel loading is related to the expected length of time a fire will burn once it is controlled by the amount of air available for the fuel to burn at a steady rate. The air that is supplied through openings, such as doors and windows, controls the amount of heat produced by a fire during this time. For fire duration analysis, all doors and windows are generally assumed to be open.

A fire burning at a constant HRR burns fuel mass at a constant rate as well. Given the mass of material being burned per minute and the amount of material available to be burned, it is possible to estimate the total burning time.

CLASSIFICATIONS OF FIRE

It is frequently useful to classify fires in order to simplify communication regarding certain common characteristics. Fires have been characterized in four general ways: (1) type of combustion process, (2) growth rate, (3) ventilation, and (4) fire stage.

Classification by Type of Combustion Process

Perhaps the simplest description of a fire classification would be to divide the fire into three regimes: (1) precombustion, (2) smoldering combustion, and (3) flaming combustion. No specific sequence is necessarily implied by this classification. Precombustion is the process of heating fuels to their ignition point, during which time vapors and particulates are released from the fuel. Smoldering is defined as glowing combustion on the fuel surface and may or may not be related in any way to the oxygen content in the vicinity of the smoldering process. What is implied here is that the fuel vapor production rate and temperatures involved may not be sufficient to support flaming combustion. Flaming combustion is almost self-explanatory in that the production of sufficient energy and a fuel vapor mixture with air in a flammable range is the condition that underlies and supports the presence of flame.

These conditions of burning may exist simultaneously within a given fire. As flames spread from one point to another on a given item of fuel or within the building, the precombustion or preignition situation will exist at the perimeter of the fire. The presence of both smoldering and flaming, even in the same compartment, is quite common as the fire spreads through different types of fuels by different mechanisms.

Classification by Rate of Growth

Fires may also be classified on the basis of growth rate. Fire growth can be either positive (increasing growth rate) or negative (decreasing growth rate).

A fire that increases its instantaneous energy output or heat release rate over time is said to be a growing fire. Typically, growing fires have more air available than is needed for combustion of the fuel gases being generated and will continue to grow until limited either by the amount of fuel available or the amount of air for combustion.

A second category based on growth rate is the steady-state fire. Under steady-state conditions, the fire's heat output or heat release rate remains relatively constant over time. This is not to say that there will not be variations, but there is no rapid continuing increase or continuing decrease in energy release rate. An example of this phenomenon might be a flammable liquid pool fire of fixed diameter where, once the entire surface is involved in flame, the amount of energy produced is controlled by the surface area and will be essentially constant until the fuel is exhausted. Another example would be the production of energy from a fire becoming limited due to air supply. In situations where the air supply is increased, perhaps by breaking of windows, a steady-state fire may resume growing if there is sufficient fuel available.

A third category is the burnout or decay condition, where there is plenty of air for combustion but the HRR is decreasing, as fuel is consumed.

See Figure 2.4.1 for a graphical representation of growing fire, steady-state fire, and decay.

Growth rate, or the speed at which growth accelerates, is another way to classify fires. Such fires are considered "time-dependent" fires. Typical fires in buildings such as residences

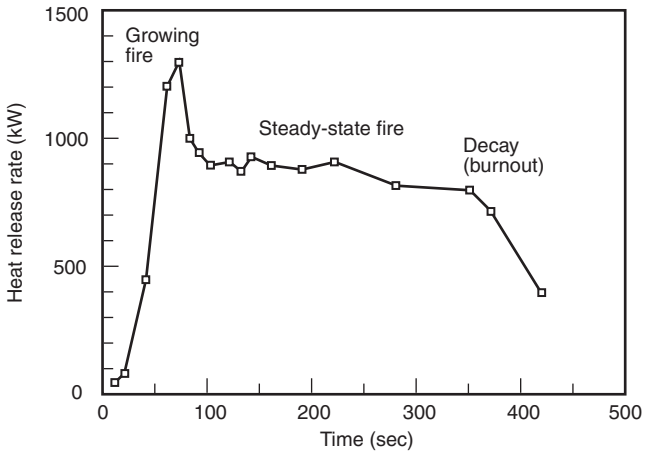

FIGURE 2.4.1 Categories of Fire Growth, Based on Growth Rate

and offices have been determined to grow as a function of the square of time and are referred to as "*t*-squared" fires. The *t*-squared fire can be characterized by Equation 2.[1]

$$\dot{Q} = \alpha t^2 \quad (2)$$

where

$\dot{Q}$ = Heat release rate at a given time

α = Fire growth constant

t = Time

The fire growth constant (α) represents the combined effects of fuel chemistry and configuration on the speed of fire growth governed by the *t*-squared relationship. For many fire protection applications such as prediction of systems actuations or onset of hazardous conditions, *t*-squared fires are classified based on the fire growth constant as follows:[1]

Slow	$\dot{Q} = 0.00293t^2$
Medium	$\dot{Q} = 0.01172t^2$
Fast	$\dot{Q} = 0.0469t^2$
Ultrafast	$\dot{Q} = 0.1876t^2$

Typically, upholstered furniture fires would fall in the range of fast fires while ignitable liquid fires would fall in the range of ultrafast fires.

Classification on the Basis of Ventilation

Fires may also be classified based on whether the fire is controlled by the amount of fuel available to burn or by the amount of oxygen or air available for the combustion process to continue. When a fire is burning in the open, or is in the early stages of development within a compartment where there is excess air for combustion, the fire is said to be fuel-controlled. In a compartment fire with sufficient fuel available, the window or door openings may ultimately serve to control the amount of air available for combustion within the compartment. Once the fire develops to a point where it produces more fuel vapors than can be consumed in the compartment with the available air, it is considered to be a ventilation-controlled fire. The effect of ventilation on HRR is related to the dimensions of the ventilation opening as shown in Equation 3.[2]

$$\dot{Q} \propto A\sqrt{h} \quad (3)$$

where

$\dot{Q}$ = Heat release rate

A = Area of the opening

h = Height of the opening

As noted above, with regard to classification by burning rate, changes in ventilation conditions can affect the fire behavior classification. In this case, an increase in compartment ventilation, such as from opening doors or breaking windows, would result in a fuel-controlled condition as long as this results in excess air compared to the fuel vapors being produced.

Classification by Fire Stage

It is often useful for the purposes of general discussion to classify fires by stage based on the concurrent energy production conditions. Four stages are commonly used, as follows:

- Incipient fire
- Fire growth
- Steady state
- Fire decay

Incipient fire refers to that stage when there is smoldering but insufficient flaming for established burning. The *fire growth* stage represents increasing fire growth with respect to heat release over time. During this stage the fire would be considered fuel controlled. When the heat release rate is basically constant the fire is considered to be in the *steady-state* stage. Here the heat release rate may be controlled by the fuel package size and geometry (i.e., the surface area available to burn) or by the available ventilation to support combustion (i.e., a ventilation-controlled fire). In the *fire decay* stage, the heat release rate is decreasing over time. This may be due to consumption of fuel in a fuel-controlled fire or continued oxygen depletion in a ventilation-controlled scenario. In the latter situation, a change in the enclosure conditions, such as a window or wall failure, may return the fire to the growth stage and possibly reach steady state depending to the amount of fuel present and the ventilation conditions.

EFFECTS OF COMPARTMENT BOUNDARIES ON FIRE

The presence of compartment boundaries, such as ceilings and walls, can have a significant influence on the manner in which a fire grows and spreads by affecting and controlling heat losses and the HRR.

Fire in the Open

The simplest arrangement of a fire is in the open where it is unaffected by either walls or ceilings. A fire in the open is considered a free-burning fire and is fuel controlled. Figure 2.4.2 shows a steadily burning fire in the open, with no confining ceiling or walls. This situation can either represent a fire outdoors, a fire in a compartment with a high ceiling or an atrium, or the early stages of a compartment fire that has not grown to the size that the compartment boundaries have an influence.

Directly above the fire shown in Figure 2.4.2, a column of partially or completely visible flame and combustion products that include smoke particles and hot gases rises into the air. This column is referred to as the fire plume. Under stable conditions, the plume will be symmetrical about the center or axis of the fire.* The action of the hot gases rising due to buoyancy causes cooler air to flow in along the boundaries between the plume and the ambient surroundings. This process is called entrainment. Above any flames, which have relatively constant temperatures, both the temperature and the upward velocity on the

*This is referred to as an axisymmetric plume.

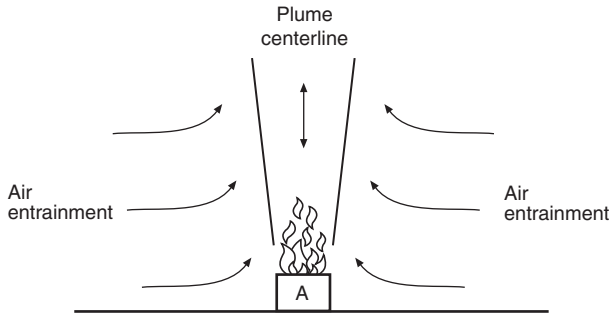

FIGURE 2.4.2 Fire in the Open. Note: A = source of fire.

plume centerline decrease with height due to the cooling effects of the entrained air. At the same time, the plume diameter above the flames increases with height due to the additional volume of gases entrained. Within the flame region, upward gas velocity on the plume centerline will increase from near zero at the base of the flames (the lowest fuel elevation actively burning) up to a maximum value at about half the flame height, remaining at that value up to the flame tip, before decreasing with height in the plume, as noted. At locations outward from the plume centerline, temperature and velocity profiles have a Gaussian contour, decreasing gradually and approaching ambient values at the plume periphery. When the temperature at the plume centerline reaches the temperature of the surrounding air, the gases and smoke stop rising. This phenomenon is frequently observed, particularly on a calm day when smoke from a chimney or industrial stack rises to a certain level and suddenly stops and begins to spread out horizontally, since there is no longer a buoyant force causing the gas to rise vertically. These same conditions can develop in tall spaces within buildings, such as in atria, resulting in stratification of the smoke and hot gases. Such a phenomenon may result in delayed operation of sprinklers or detectors or, in some cases, failure to operate at all.

An additional feature of a fire in the open, which is evident when the minimum base dimension of the fire plume is greater than 6 to 19 ft (1.8 to 5.8 m), is the presence of an obscuring mantle of smoke, beginning near the flame tip and covering more of the flame as the fire plume base dimension increases above the preceding values. For very large-scale fires, such as the total involvement of a large warehouse, the resultant smoke mantle will almost totally obscure the flames, with only brief glimpses of flame being visible from time to time above a bright flame band at the base of the fire plume. This flame obscuration, as expected, sharply reduces the radiant output from the flame portion of the plume since the obscuring smoke is relatively cool. There is presently no comprehensive model that can accurately predict the extent and properties of the smoke mantle under a wide range of burning conditions, such as the nature and size of the fire.

Fire Under an Unobstructed Ceiling

When a ceiling is located above a fire plume, the rising hot gases and combustion products impinge on the ceiling and begin to flow radially outward away from the plume centerline. On a smooth, flat (nonsloping) ceiling, this flow would ideally be equal in all directions. The radially outward flow due to fire plume impingement is defined as a ceiling jet. Figure 2.4.3 shows the general effects of a ceiling. When a plume impinges on a ceiling, the flow near the ceiling can be considered to have two regions: (1) the impingement or turning region, comparable in diameter to that of the plume, and (2) the ceiling jet region, which extends outward along the ceiling from the turning region until obstructed by walls, draft curtains, or beams. In the turning region, the plume centerline upward velocity changes in direction, but not significantly in magnitude, as the flow turns parallel to the ceiling. At the same time, the plume centerline gas temperature decreases only slightly due to heat losses at the ceiling surface. Since the ceiling surface area in the impingement region is rather small, these temperature decreases are minimal.

In a ceiling jet that is not caused by direct flame impingement, maximum temperature and velocity decrease steadily as the radial distance from the plume centerline increases due to a combination of air entrainment from below the jet and heat loss to the ceiling above the jet. As a result, plume velocities and temperatures are much greater than nonflaming ceiling jet velocities and temperatures. For the axisymmetric ceiling jet resulting from plume (not flame) impingement on an unobstructed ceiling, the thickness of the ceiling jet tends to be reduced as radius increases but is increased by addition of ambient air entrained from below. As a result, the thickness of the axisymmetric, nonflaming ceiling jet tends to a nearly constant value equal to about 10 percent of the ceiling height above the base of the fire plume when the flame height is negligible compared to the ceiling height. When flame height is such that there is direct flame impingement on an unobstructed ceiling, the length of flame along the ceiling plus the flame height in the plume below the ceiling is roughly equal to the total flame height in effect if there were no ceiling present.

It should be noted that for a line fire (e.g., a flammable liquid burning in a long trench), where the depth of the flames is very much less than the length of burning material, the variation

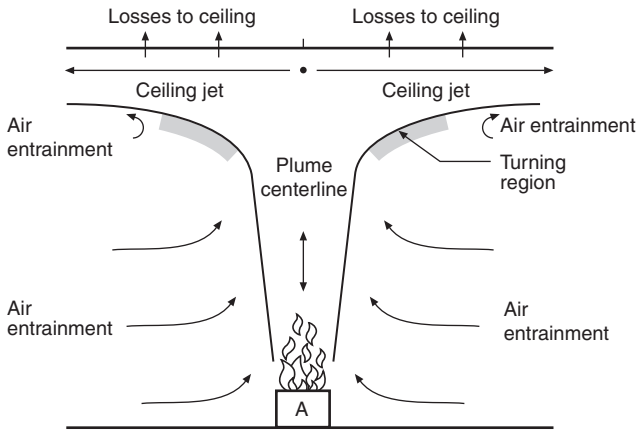

FIGURE 2.4.3 Fire Under Ceiling, Far from Walls. Note: A = source of fire.

of centerline plume velocity and temperature with height and the variation of maximum ceiling jet velocity and temperature with distance along the ceiling from the impingement zone differ from the axisymmetric situation described above. In a line fire, the thickness of the ceiling jet increases steadily as the flow moves outward from the location of plume impingement.

Research has shown that one set of relationships holds for the impingement or turning region where the plume turns to flow out horizontally underneath the ceiling. In this region, the flow gas is buoyancy-dominated, and the temperatures and velocities are a function primarily of the height of the ceiling above the base of the fire, since the height affects the amount of entrainment. Although the actual temperature in the plume is related to the heat release rate of the fire, for any given fire, the temperature along the centerline or inside the turning radius of an axisymmetric, nonflaming plume can be predicted by the general relationship given in Equation 4.[3]

$$\Delta T = 16.9\frac{\dot{Q}^{2/3}}{H^{5/3}} \quad \text{for} \quad \frac{r}{H} \le 0.18 \tag{4}$$

where

ΔT = Temperature rise above ambient

$\dot{Q}$ = Heat release rate

H = Height of ceiling above fire

r = Radius of the plume at the ceiling

The temperature of the axisymmetric, nonflaming ceiling jet outside of the turning region is a function of the distance or radius from the plume. Temperatures will decrease as the radius increases, due to heat losses to the ceiling and to the entrainment of cooler air from the surroundings. A general relationship for this phenomenon is given in Equation 5.[3]

$$\Delta T = 5.38\frac{(\dot{Q}/r)^{2/3}}{H^{5/3}} \quad \text{for} \quad \frac{r}{H} > 0.18 \tag{5}$$

Flow rate outside the turning radius is dominated more by momentum (the force of the moving mass of gas) than by buoyancy (the force due to temperature differences between hot and cool gases).[1]

Understanding plume and ceiling jet relationships based on fire growth and compartment geometry is important for several reasons. The plume and ceiling jet act as the transport mechanisms for the heated gases and other products of combustion such as smoke and toxic species and thus affect the operation of sprinklers and heat and smoke detectors. This aspect is discussed in Section 2, Chapter 1, "Physics and Chemistry of Fire," and Section 2, Chapter 2, "Physics of Fire Configuration." The plume and ceiling jet also act to develop a layer of hot gases that affect the conditions in a compartment fire and the onset of full room involvement and spread to other compartments as discussed below.

Fire in a Compartment

Figure 2.4.4 represents the early stages of a compartment fire with a single vent where there is no effect of the compartment. There are two items in the compartment: A and B. A is the source of the fire, and B is an initially unignited target sufficiently far from A that it cannot be ignited directly.[4] A thin layer of hot gases and smoke begins to accumulate at the ceiling.

As the heat release from the fire in object A increases, the gases accumulating at the ceiling spread out and become trapped by the soffit of the door. As the fire continues to produce smoke and hot gases, the layer at the ceiling will thicken and begin to flow out under the soffit into the next compartment, which may be another room or a hallway (Figure 2.4.5). If the fire stops growing or becomes steady state at this time, the thickness of the upper layer in the fire compartment will become essentially constant, with the excess combustion products leaving the compartment at a constant rate.

However, if the fire continues to increase in heat release rate and the opening is too small to carry away the combustion products at the rate at which they are generated, the upper layer will continue to increase in thickness and descend to the floor, even though there is a vent (Figure 2.4.6).

At this time, it is useful to take a look at the various component parts of the compartment fire "system." A simple con-

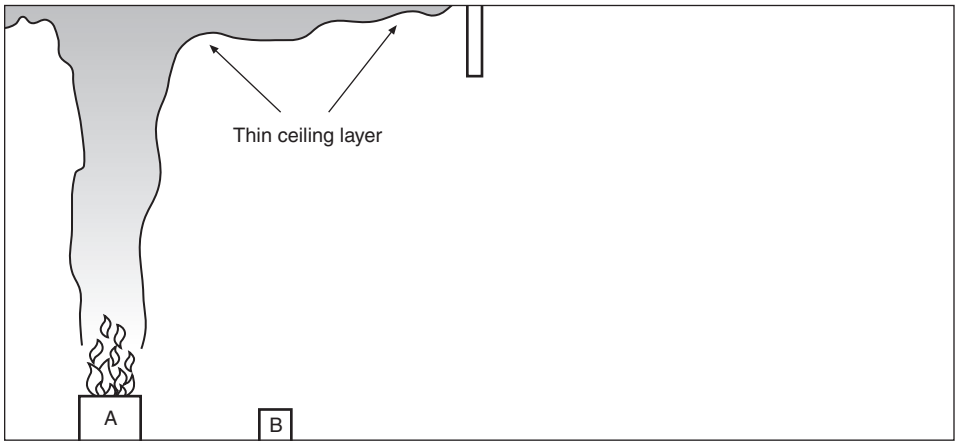

FIGURE 2.4.4 Initial Ceiling Effect. Note: A = source of fire. B = target fuel.

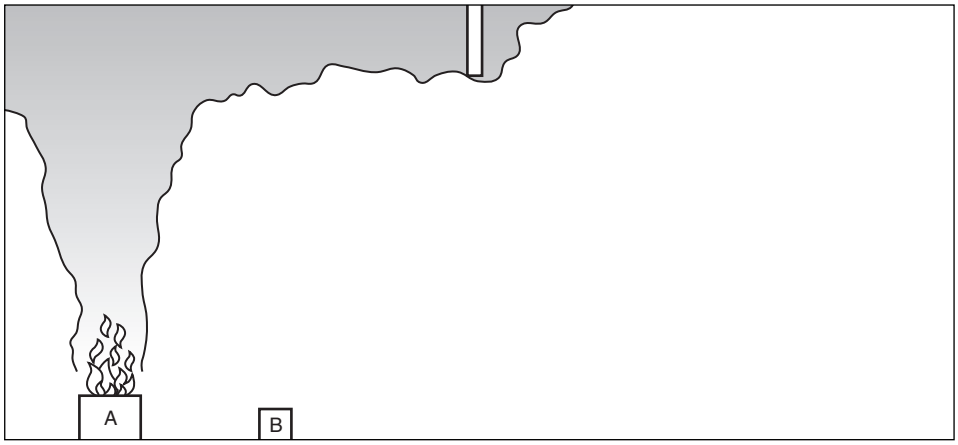

FIGURE 2.4.5 Initial Smoke Discharge from Compartment of Origin. Note: A = source of fire. B = target fuel.

ceptual model for this compartment fire system consists of a plume of hot gases above the initially burning object or objects, a heated upper gas layer, and a cool layer below. This model is commonly referred to as a 2-layer zone created by the hot gases inside and the cool gases outside (Figure 2.4.7). This results in a positive pressure in the hot gases leaving the compartment, relative to the outside of the compartment, and a negative pressure in the cool gases relative to the inside. The resulting airflow is shown in Figure 2.4.8, along with the ceiling layer and plume. In the doorway, there will be a boundary layer between the outflowing hotter gases (resulting from the positive pressure) and the inflowing cooler gases (resulting from the negative pressure). This boundary layer or boundary zone is commonly referred to as the neutral plane—that is, neutral or equal with respect to pressure inside and outside the room.

Figure 2.4.7 can also be used to discuss the general heat balance within the zones of a compartment fire. Energy is generated in the combustion region of the fire. The plume acts as a pump to provide combustion products and hot gases to the upper layer. This is the $\dot{Q}_{\text{fire}}$ in Figure 2.4.7. Energy in the hot upper layer is lost in a number of ways. Heat is lost by radiation from the hot gases to the cool area below and by convection of hot gases out the door. Heat is lost to the wall and the ceiling materials by conduction from the hot gas layer. If the fire is burning at a constant heat output, the layer thickness and the losses through the door or vent and to the compartment boundaries will remain constant after some period of time to establish an equilibrium between the heat generated and the heat lost. If the fire continues to grow, conditions will change. Temperatures in the upper layer will continue to rise, and the thickness of the upper layer will continue to increase. The increasing layer temperature and the decreasing distance of the layer from the floor results in greater radiation heat transfer to unignited objects elsewhere in the compartment.

The development of the ceiling layer plays a significant role in compartment fire growth. In addition to acting as a radiator to heat other objects in the room, radiation from the layer also increases the burning rate of the items already ignited.[5]

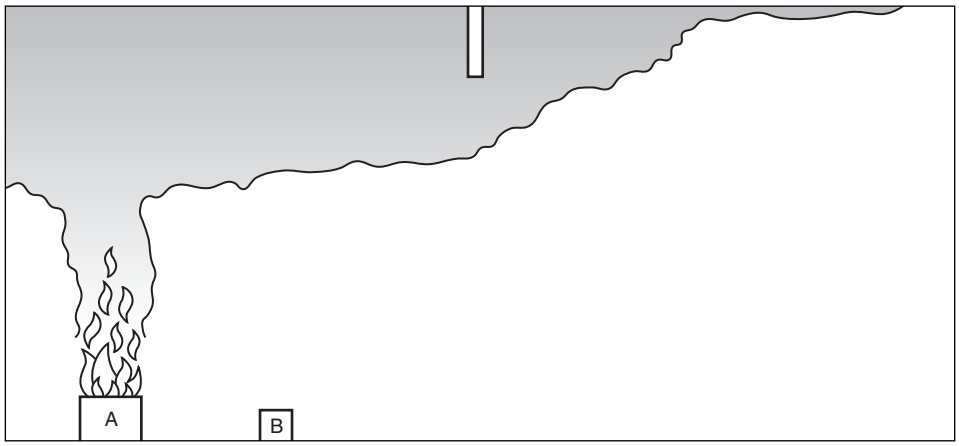

FIGURE 2.4.6 Increasing Fire Size and Layer Depth. Note: A = source of fire. B = target fuel.

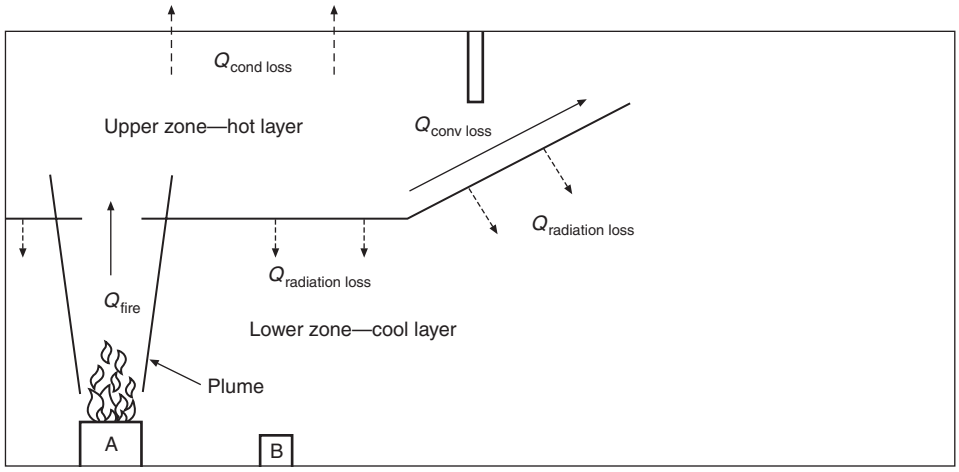

FIGURE 2.4.7 Compartment Fire Zones and Heat Transfer. Note: A = source of fire. B = target fuel.

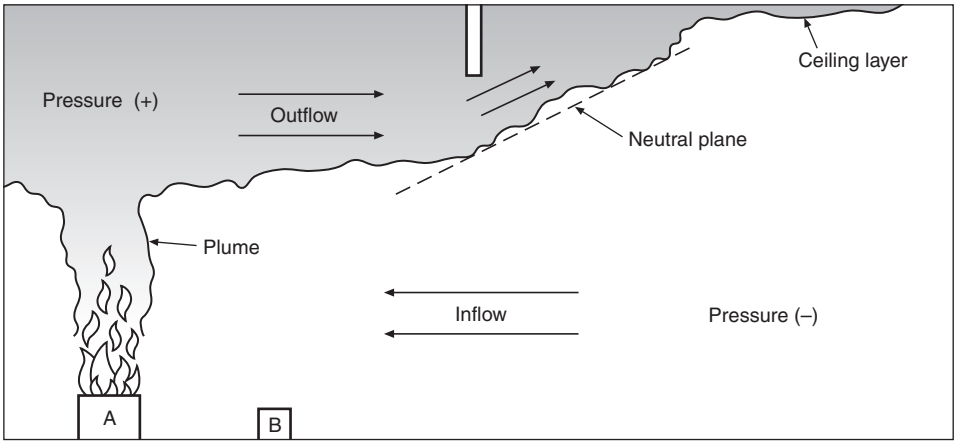

FIGURE 2.4.8 Compartment Fire Pressure and Airflow. Note: A = source of fire. B = target fuel.

Typically, as the fire continues to grow in the compartment, with a corresponding increase in the thickness and temperature of the upper gas layer, a transition will occur from a fire that is dominated by the first materials ignited to a fire that is dominated by the burning materials throughout all of the room. This transition is called *flashover.* Ventilation at flashover becomes controlled by the size of the room openings and the position of the layer in the opening. As the layer descends, the effective ventilation area of the opening is decreased.

The triggering conditions[6] for the flashover transition are reached when (1) the upper gas layer is approximately 600°C and (2) the radiant flux on unignited materials in the room is approximately 20 kW/m^2. Figure 2.4.9 represents flashover, the transition stage between preflashover and the fully involved compartment fire (called *full-room involvement*).

Full-room involvement, as shown in Figure 2.4.10, is characterized by the production of excess fuel vapors that cannot be consumed within the compartment with the combustion air available. This results in flame extension through vent openings into adjacent compartments or out of windows, should they fail. Window failure generally occurs shortly before or after flashover conditions are reached and can provide additional ventilation area. The HRR needed for flashover is related to the vent openings of the compartment and can be generally predicted using Equations 6 and 7.[2]

$$\text{Babrauskas' equation: } \dot{Q}_{fo} = 750A_0\sqrt{H_0} \tag{6}$$

$$\text{Thomas' equation: } \dot{Q}_{fo} = 7.8A_T + 378A_0\sqrt{H_0} \tag{7}$$

where

$\dot{Q}_{fo}$ = Heat release for flashover (kW)

A_0 = Area of vent opening (m^2)

H_0 = Height of venting (m)

A_T = Total area of compartment enclosing surfaces (m^2)

Flashover is not an inevitable result of a compartment fire. In the event that the fuel is limited or that there is a sufficiently large

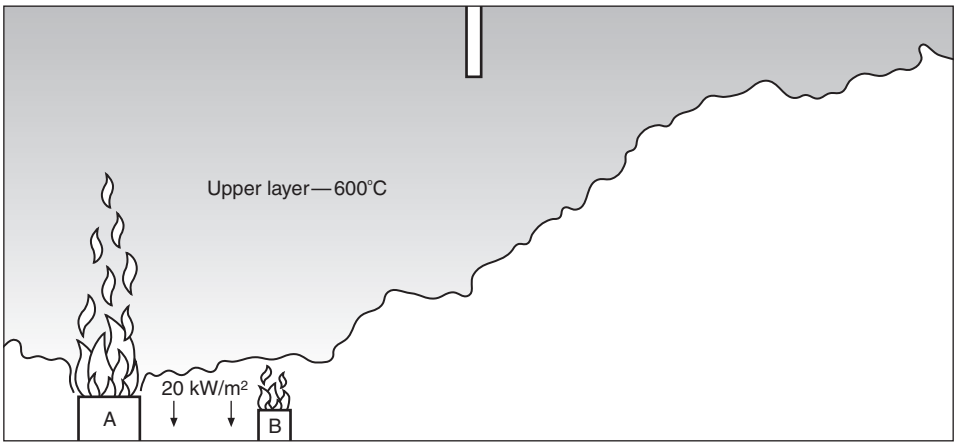

FIGURE 2.4.9 Flashover—Transition to Full-Room Involvement. Note: A = source of fire. B = target fuel.

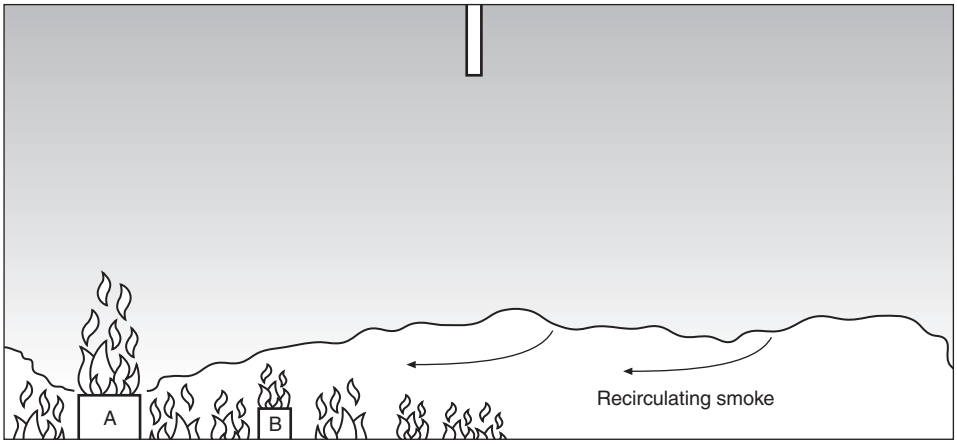

FIGURE 2.4.10 Full-Room Involvement (Postflashover). Note: A = source of fire. B = target fuel.

ventilation opening, the ceiling layer may not develop adequately to make the transition through flashover to full-room involvement. Application of suppression agents, either automatically or manually, can also interrupt the process at or prior to flashover. It should be noted that some research indicates that the heat release rate of burning objects, such as mattresses, can be increased by a factor of two in a postflashover or full-room involvement fire.[5]

Once flashover occurs and full-room involvement begins, the fire approaches ventilation control. Smoke from under the neutral plane is frequently recirculated back toward the fire, along with smoke that may be accumulating in adjacent compartments in the hallway. This process, called *vitiation,* reduces the oxygen available for combustion, causing a reduced heat release rate. Under these conditions, the fire approaches steady-state burning.

Effects of Fire Location in a Compartment

Under some circumstances, the location of the fire in a compartment can have an effect on the rate of growth of the fire, in terms of ceiling jet temperature and velocity.[3] When a fire is burning in a compartment far from walls, air is free to be entrained into the plume from all directions (Figure 2.4.11). If the fire is very close (i.e., virtually in contact) to a wall or in a corner, the amount of air entrainment into the plume is reduced, leading to higher temperatures and velocities and a reduced volume of gases. These effects can be simulated by making adjustments for heat release rate in the correlations used to calculate temperature and velocity. For fires adjacent to a wall, $2Q$ is substituted for Q; for a fire in a 90° corner, Q is multiplied by 4 in the correlations. It should be noted, however, that experiments have shown that if a circular burner is placed so that only one point is in contact with the wall, the fire behaves almost identically to a fire away from the wall.[7]

SUMMARY

This discussion was presented to provide the reader with an overview of the processes involved in fire growth and spread in

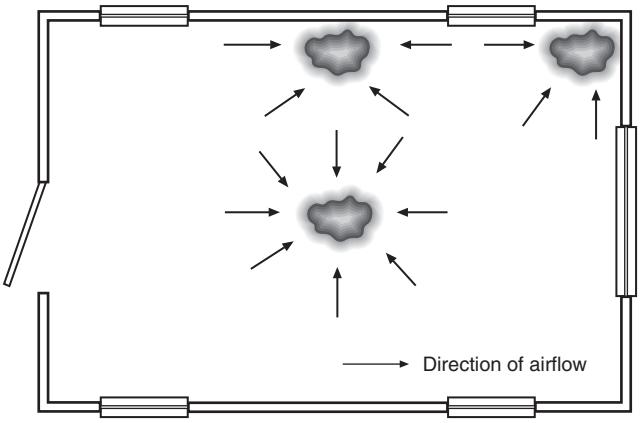

FIGURE 2.4.11 Effect of Fire Location on Air Entrainment

and beyond the compartment. For additional information, the reader is encouraged to study the equations and relationships discussed elsewhere in this handbook.

An acceptable level of fire protection is accomplished in the design stage of a building through compliance with local regulations, which are typically based on national *model building codes.* Fire protection of buildings addresses all aspects of fire safety and consists of a combination of active and passive measures. *Active fire protection* devices require manual, mechanical, or electrical power for their operation. *Passive fire protection* measures do not require any external power. There are essentially the three following types of passive fire protection measures:

1. *Rate of fire growth.* The rate of fire growth inside or outside a building can be controlled to some extent by using interior finishes or external cladding/roofing with specific ignition, flame spread, and heat release characteristics. A slow-growing fire leaves more time for safe egress of building occupants and generally results in reduced property damage at the time of manual or automatic suppression.

2. *Containment.* Should a fire inside a building grow to full involvement of the enclosed space of origin, an important objective is to contain the fire within that enclosed space or a nearby area, at least for a certain time. Thus, fire spread to other parts of the building or adjacent buildings is delayed or prevented. This containment process for interior fires is referred to as *compartmentation.* It is accomplished by providing fire-resistive floor, wall, and ceiling assemblies and by protecting openings and penetrations through enclosure boundaries. Containment of interior fires also involves protecting structural elements and assemblies to avoid or delay partial or total collapse in the event of fire. Should a fire be initiated and grow to a hazardous scale outside of a building, an important objective is to maintain a sufficient fuel-free space or fire break around the building so that the integrity of the building envelope is preserved when exposed to the external fire hazard. This containment process for exterior fires is referred to as providing a safe separation distance. Containment of external fires also covers measures to prevent ignition of, surface flame spread over, and penetration through exterior wall and roof surfaces should there be a nearby ignition source such as firebrands or flames ejected from windows.

3. *Emergency egress.* The third type of passive fire protection measure pertains to emergency egress. Escape corridors, doors, and stairways have to be wide enough to accommodate the flow of people in case of emergency evacuation. Occupants must have access to a sufficient number of emergency exits within a maximum allowable distance so that they can reach a safe area before conditions become untenable.

This chapter provides a discussion of the engineering basis for model building code provisions that pertain to several aspects of fire containment, including some fundamental concepts related to providing a safe separation distance. For both fire containment and safe separation distance, the fundamental objective is to prevent damage from flame heat fluxes that are greater than a critical material ignition or system endurance level.

The building code provisions pertaining to fire containment have traditionally been prescriptive, meaning that they consist of specific requirements for building materials, products, and elements that are based on performance in a test. Fire safety objectives are not explicitly stated in traditional building codes, and it is assumed that an acceptable level of fire safety is obtained if the prescriptive code requirements are fulfilled. The main objective of building codes is life safety of

Marc L. Janssens, Ph.D., is director of the Fire Technology Department at Southwest Research Institute (SwRI) in San Antonio, Texas.

building occupants and fire fighters. The protection of neighboring property is secondary. The model building codes do not directly provide for property conservation. However, any fire protection features that contribute to meeting the primary objective are also likely to reduce property and indirect fire losses.

Sometimes it is not possible to meet the containment requirements in the model building codes. For example, changing the use of a building may lead to a new set of fire protection requirements that cannot be accomplished through retrofitting. Another common example is when the architect wants to use an innovative system that cannot be tested according to the accepted procedures. All model building codes have a clause that allows the authority having jurisdiction (AHJ) to accept a noncompliant design. A technical rationale or engineering analysis, or both, usually has to be presented to demonstrate that the level of fire safety of the proposed design is at least as good as that of a comparable code-compliant building. This process is referred to as *code equivalency.*

New types of building codes, known as performance-based codes, have emerged in recent years. These codes focus on building performance by requiring that specific fire safety goals and objectives be met. Increased design flexibility and opportunities for cost savings are the main advantages of performance-based codes over the traditional prescriptive approach. (See Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety," for more information.)

The chapter begins with a discussion of the test and design procedures that serve as the basis for fire containment requirements in the model building codes. Alternate methods that demonstrate prescriptive code equivalency or performance-based code compliance are also discussed. How the safe separation distance requirement would be calculated in a performance-based environment is then presented. First, however, some important terminology is defined.

See also Section 2, Chapter 1, "Physics and Chemistry of Fire"; Section 2, Chapter 2, "Physics of Fire Configuration"; Section 2, Chapter 4, "Dynamics of Compartment Fire Growth"; Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety"; and Section 6, Chapter 3, "Concepts and Protocols of Fire Testing."

TERMINOLOGY

General Terms

Active Fire Protection. The operation of active fire protection devices requires manual, mechanical, or electrical power. For example, a sprinkler system requires sprinklers to open and a water supply at a sufficient flow rate and pressure after activation to be delivered through the system. A smoke control system relies on roof vents that open or a mechanical system to operate when a fire is detected. A detection and alarm system requires electric power to operate.

Code Equivalency. Code equivalency is the process of demonstrating compliance with the intent of prescriptive code provisions through technical reasoning, engineering analyses, or both.

Compartmentation. Large buildings are typically segmented into smaller compartments with fire-resistive boundaries and protected openings through the boundaries. The objective of compartmentation is to confine a fire to a limited area for a specified time and thus slow down fire spread through a building to leave more time for safe evacuation of the building and to reduce property and indirect losses.

Fire Resistance. The fire resistance of a building element characterizes its ability to confine a fire or to continue to perform a given structural function, or both.

Fire Resistance Rating. The fire resistance rating of a building element is a measure of the elapsed time during which the element continues to exhibit fire resistance when exposed to a standard fire in a furnace test. The rating corresponds to the time to failure in the furnace test. Failure criteria are based on thermal penetration, integrity, or structural collapse.

Heat Flux. The rate of heat transferred per unit area perpendicular to the direction of heat flow is referred to as heat flux (see Section 2, Chapter 1, for a discussion of heat transfer modes and the importance of each). Heat flux is a measure of the potential for damage. For example, most common combustibles ignite when exposed to a heat flux of 0.9–1.8 Btu/sec·ft^2 (10–20 kW/m^2).

Model Building Code. Local building codes and regulations are based on national model codes that are developed by a consensus process. The model code groups in the United States are International Code Council (ICC) and National Fire Protection Association (NFPA). Some jurisdictions have adopted a model code verbatim, either by reference or by transcription, whereas others have made significant amendments. The extent of changes that can be made at the local level varies from state to state.

Passive Fire Protection. Passive fire protection does not require any external power but relies instead on specific construction features and the use of materials, products, and building elements that meet well-defined fire performance requirements.

Performance-Based Code. Performance-based codes are concerned with the performance of the building as a whole and require that specific fire safety goals and objectives be met. No specific methods are mandated to demonstrate compliance. The code-conforming design process involves an engineering analysis, often supported by standard or ad hoc fire test data and fire statistics. A detailed discussion of the steps involved in such a design process is provided in the *SFPE Engineering Guide to Performance-Based Fire Protection.* Increased design flexibility and opportunities for cost savings are the main advantages of performance-based codes over the traditional prescriptive approach.

Plan Dimensions. The dimensions of an object in the plan view (i.e., the projection of an object onto a horizontal plane generally at the base of the object) are the plan dimensions. For a rectangular burning material assembly that is the source of a fire, the plan dimensions are the length and width of the footprint of the assembly.

Prescriptive Code. Model building codes and other fire safety regulations are largely prescriptive and consist of specific requirements for building materials, products, and elements that are based on performance in a test. They also include prescriptive provisions to establish adequate means of egress. The fire safety objectives are not explicitly stated, and it is assumed that an acceptable level of fire safety is obtained if the prescriptive requirements are fulfilled.

Wildland Vegetation. Extensive areas of forest, living plants, and brush are termed *wildland vegetation.* This vegetation may extend for great distances, interfacing with buildings and the built environment in many locations.

Terminology of Materials, Products, and Assemblies

Materials form the basic ingredients of the components and contents of structures. Materials are combined into *products* in a form that is suitable for practical application. For example, gypsum, paper, glass fibers, and other fillers are combined in the form of sheets that are used as protective membranes in the construction of fire-rated wall and ceiling assemblies. One or more products are used in the construction of *assemblies.* For example, wood-frame wall assemblies consist of wood studs that are protected on one or both sides by a membrane such as gypsum board or plywood, and the cavities between the studs may be filled with thermal insulation. Fire resistance requirements pertain to assemblies.

FIRE RESISTANCE

Despite the active and passive fire protection measures affecting the growth stage, fires often develop beyond *flashover.* (Flashover is a transition phase in the development of a compartment fire in which surfaces exposed to thermal radiation reach ignition temperature more or less simultaneously and fire spreads rapidly throughout the space, resulting in full room involvement or total involvement of the compartment or enclosed space.) The objective of passive measures is then to contain the fire to a limited area for a specified duration. This is accomplished by subdividing buildings into smaller compartments that are separated from each other by fire-resistive wall and floor/ceiling assemblies. Openings in the separations, such as doors and cable penetrations, need to be protected to avoid or delay fire spread from one compartment to another. Structural members need to fulfill their load-bearing function for the specified duration because premature collapse will allow fire spread to a larger area. The fire resistance of a building element is usually determined through furnace testing, which is discussed in detail in the following three subsections. Alternative approaches based on analytical methods and computer modeling form the subject of the next two subsections. This section concludes with some pertinent findings and recommendations by the National Institute of Standards and Technology (NIST) as a result of its investigation of the World Trade Center disaster.

General Concepts of Fire Resistance Furnace Testing

Wall and floor/ceiling assemblies, roof structures, doors, windows, and so on are mounted in a vertical or horizontal frame. The frame is placed against an open wall furnace or on top of an open ceiling furnace and is exposed to the standard fire. The latter is quantified by a specified furnace temperature-time curve. Figure 2.5.1 shows an example of a wall assembly shortly after the start of a test. The specimen consists of a double swinging glass door mounted in a glass wall. The burner flames and furnace interior can be observed during the first few minutes of the test. The glass consists of several panes separated by a transparent film. When the film reaches a critical temperature, it expands and forms a thick insulating layer.

Fires can spread from the fire compartment to a neighboring compartment if the heat transfer results in a temperature rise that is high enough to ignite common combustibles on the side not exposed to the fire or if cracks develop that allow the passage of flames and hot gases. End-point criteria for separating non-load-bearing assemblies in fire resistance furnace tests are, therefore, based on heat transmission and integrity. Heat transmission is measured with thermocouples attached to the unexposed side of the assembly. The end-point criteria for heat transmission are exceeded when the temperature rise of the thermocouples, either on average or individually, reaches a specified limit. The integrity of an assembly is maintained as long as there is no passage of flames and gases hot enough to ignite cotton waste on the unexposed side. The time when the first end point is reached determines the fire resistance rating of the assembly and is reported to the nearest minute.

Fires can also spread when load-bearing assemblies or structural members cease to support the load. The resulting partial or total building collapse adversely affects life safety of building occupants and fire fighters and dramatically increases property loss and indirect fire costs. Fire resistance furnace tests on load-bearing assemblies and structural members, therefore, also determine whether the test specimen is capable of supporting the applied load for a specified duration. Steel and concrete columns are generally not tested under load, and failure is based on the temperature at which the structural or reinforcing steel starts to yield. This approach cannot be used for wood columns and testing under load is necessary. The National Research Council of Canada and Underwriters Laboratories are the only fire testing laboratories in North America that are capable of performing column tests under load. Columns and beams can be tested with full or partial exposure of the perimeter, depending on simulated end-use conditions.

Steel-framed floor/ceiling and roof assemblies are tested under restrained or unrestrained conditions. The former uses a stiff frame that resists the forces due to thermal expansion of structural steel. Testing under restrained conditions is required for building elements that are part of a structure that is capable of resisting substantial thermal expansion throughout the range of anticipated elevated temperatures. Wood-frame assemblies do not need to be tested under restrained conditions because thermal expansion is negligible. See also Section 6, Chapter 3, "Concepts and Protocols of Fire Testing."

FIGURE 2.5.1 Vertical Furnace Test on a Glass Door and Wall Assembly (Courtesy Southwest Research Institute)

Experimental Variables in Fire Resistance Furnace Testing

Although all standard fire resistance furnace test methods are based on the same concepts, there are significant differences in the details between methods. As a result, some methods are more stringent than others and the resulting fire resistance rating of a building element will be different even if the same end-point criteria are used. The effect of different experimental variables on the severity and the results of the test are discussed in this subsection.

Thermal Exposure Conditions. The fire resistance of a building element is a function of the severity of the fire. In order to provide a uniform basis for measuring the fire resistance in the laboratory, a number of standard fires have been defined. These standard fires are expressed in the form of a furnace temperature-time curve. Figure 2.5.2 shows three commonly used temperature-time curves. The test standards specify that the furnace be controlled so that the average of the readings of a specified number of thermocouples follows the standard temperature-time curve within acceptable tolerances. The standards typically require that at least nine thermocouples (eight for immersed columns exposed from four sides) are distributed in the furnace to measure the furnace temperature near all parts of the specimen.

Based on the standard temperature-time curves one would conclude that ISO 834, *Fire-Resistance Tests—Elements of Building Construction,*[1] is slightly more severe than ASTM E119, *Standard Test Methods for Fire Tests of Building Con-*

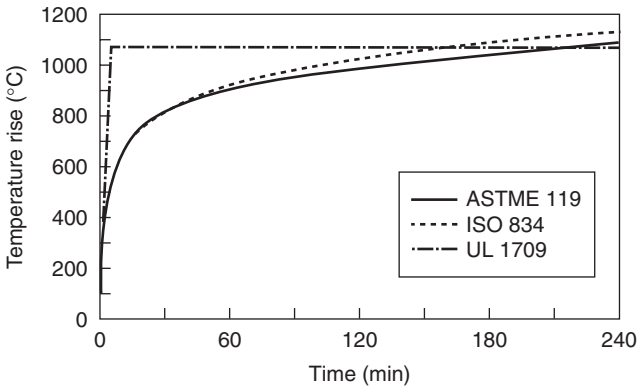

FIGURE 2.5.2 Three Commonly Used Time-Temperature Curves (Courtesy Southwest Research Institute)

struction and Materials.[2] However, the severity of the test is not only a function of the temperature-time curve but also depends on how the furnace temperature is measured. ASTM E119 specifies that thermocouple assemblies be enclosed in a porcelain or steel pipe so that the time constant is between 5 and 7.2 minutes. The 1975 edition of ISO 834 specifies exposed-junction thermocouples with a time constant of 2 minutes or less. The recent revision of ISO 834-1, *Fire-Resistance Tests—Elements of Building Construction—Part 1: General Requirements,*[3] prescribes the use of plate thermometers to control the furnace temperature-time curve. The plate thermometer (see Figure 2.5.3) was originally developed in Sweden and introduced to harmonize between fire resistance furnaces in different countries of the European Union.[4,5] The exact reasons are not completely known, but the improved consistency is probably due to the fact that the plate thermometer temperature is affected primarily by the incident heat flux and is less sensitive to convection than exposed-junction thermocouples. Although plate thermometers have a slower response than exposed-junction thermocouples, they respond significantly faster than the shielded thermocouples specified in ASTM E119. The net result is that ASTM E119 is more severe than ISO 834-1, in particular during the first 10 minutes of a test.[6] The directional flame thermometer[7] is similar to the plate thermometer and is currently being considered by ASTM E05.11 as a device for measuring and controlling the thermal environment in fire resistance test furnaces.

Furnace Pressure. The pressure in a room due to a fire varies with height. Figure 2.5.4 shows a simplified situation of a room with an open window and a closed door. The pressure difference between inside and outside the room is positive at the top

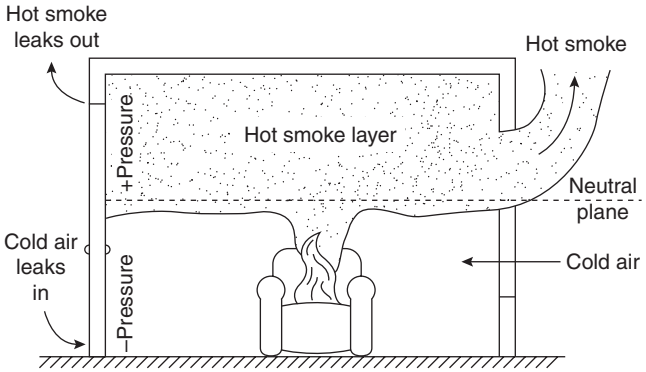

FIGURE 2.5.4 Pressure Effects in a Room Fire (Courtesy Southwest Research Institute)

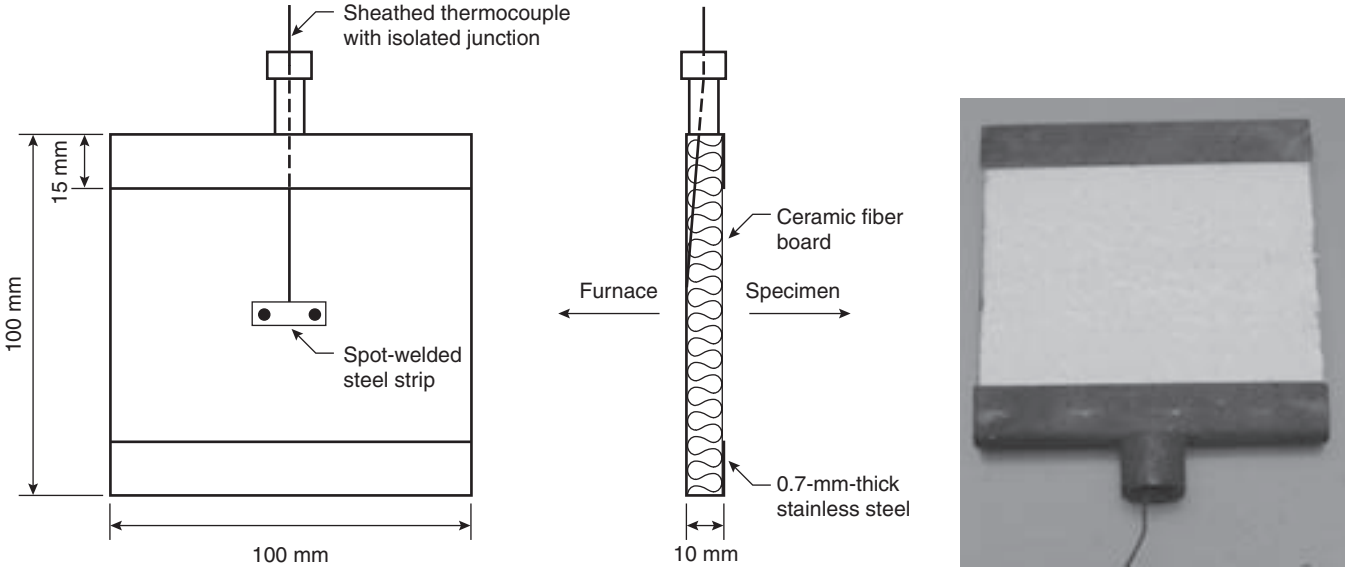

FIGURE 2.5.3 (a) Plate Thermometer Schematic and (b) Plate Thermometer (Courtesy Southwest Research Intitute)

of the door and negative at the bottom. The height at which the pressure differential is zero is referred to as the neutral plane. If the door is not completely sealed, which is typically the case, cold air will flow into the room around the perimeter of the door pane below the neutral plane and hot gases will leak from the fire room above the neutral plane. The location of the neutral plane and the direction and magnitude of flows are affected in actual fires by factors such as wind, stack effect in high-rise buildings, and so on.

The discussion in the previous paragraph indicates that the differential pressure between the fire side and the cool side is likely to be positive over the upper part of a door. Hot gases leaking from the fire room above the neutral plane can have an adverse effect on the ability of a door to maintain its separating function. Therefore, it seems to make sense to conduct fire resistance tests on doors and similar assemblies under positive pressure over the top half of the test specimen. North American fire resistance test standards have traditionally not specified the furnace pressure, which in practice resulted in door tests being conducted with the neutral plane at the top of the test specimen. An extensive research program resulted in recent changes to the fire resistance test standards for doors and windows so that these tests now have to be conducted under slightly positive pressure.[8–10] For example, as a result of the research ASTM E152, *Standard Test Methods of Fire Tests of Door Assemblies,*[11] and ASTM E153, *Standard Test Methods of Fire Tests of Window Assemblies,*[12] have been withdrawn on January 1, 1995, and were replaced by ASTM E2074, *Standard Test Method for Fire Tests of Door Assemblies, Including Positive Pressure Testing of Side-Hinged and Pivoted Swinging Door Assemblies,*[13] and ASTM E2010, *Standard Test Method for Positive Pressure Fire Tests of Window Assemblies,*[14] respectively. Fire resistance testing under positive pressure has been common practice in other parts of the world for a very long time.

The questions remain of what the magnitude of the positive pressure should be and how it should be measured. Differential pressures in room fires are due to differences in density between cold and hot gases. This is similar to the stack effect illustrated in Figure 2.5.5.

The pressure at the bottom of the stack is equal to the pressure at the top of the stack plus the pressure due to the weight of the hot gas column in the stack:

$$p_1 = p_0 + \rho_h g H \tag{1}$$

where

p_1 = Pressure at the bottom of the stack (psf or Pa)

p_0 = Pressure at the top of the stack (psf or Pa)

ρ_h = Density of the hot gas in the stack (slug/ft^3 or kg/m^3)

g = Acceleration of gravity (32.174 ft/sec^2 or 9.81 m/sec^2)

H = Height of the stack (ft or m)

The pressure outside the stack at the same height as the bottom of the stack is given by

$$p_2 = p_0 + \rho_\infty g H \tag{2}$$

where

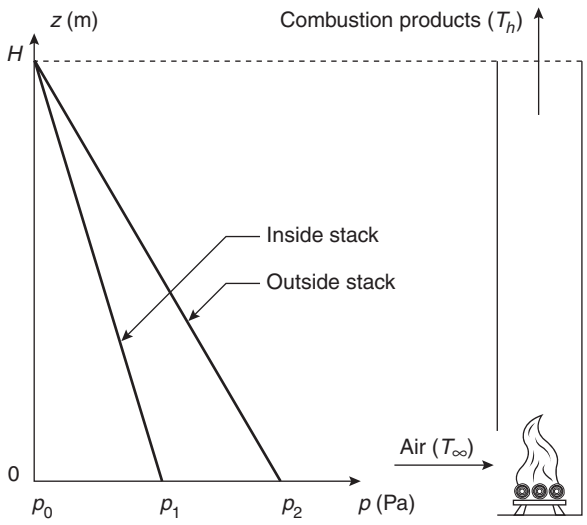

FIGURE 2.5.5 Stack Effect (Courtesy Southwest Research Institute)

p_2 = Pressure outside the stack at the height of the bottom of the stack (psf or Pa)

ρ_∞ = Density of ambient air (slug/ft^3 or kg/m^3)

The differential pressure at the bottom of the stack is, therefore, given by

$$\Delta p = p_1 - p_2 = (\rho_h - \rho_\infty) g H \approx C\left(\frac{1}{T_h} - \frac{1}{T_\infty}\right) H \tag{3}$$

where

C = Constant (39.59 in English units or 3455 in SI units)

T_h = Temperature of the hot gases in the stack (°R or K)

T_∞ = Ambient temperature (°R or K)

Note that the expression on the far right of Equation 3 is obtained from the ideal gas law at constant pressure, assuming that the composition of the gases in the stack is close to that of ambient air. This is a reasonable assumption because combustion air is usually supplied at a rate that far exceeds the stoichiometric rate. Moreover, the primary component of combustion products is nitrogen, which accounts for approximately 79 percent by volume of dry air. It is also reasonable to assume constant pressure because p_0 is of the order of 10^5 Pa, whereas the rightmost term on the right side of Equations 1 and 2 is at least three orders of magnitude smaller. Note that the density of dry air at 492°R (273 K) and atmospheric pressure is equal to 0.0025 slug/ft^3 (1.29 kg/m^3). The density of air at temperature T_h and the same pressure can, therefore, be estimated from

$$\rho_h \approx \frac{\rho_r T_r}{T_h} = \frac{C}{T_h} \tag{4}$$

where

ρ_r = Density of air at the reference temperature (0.0025 slug/ft^3 or 1.29 kg/m^3)

T_r = Reference temperature (492°R or 273 K)

C = Constant (1.2275 in English units or 352 in SI units)

Since $T_h > T_\infty$, Equation 3 indicates that the differential pressure at the bottom of the stack is negative. This implies that ambient air is drawn into the stack at the bottom to support combustion. The hot products of combustion rise due to buoyancy. The differential pressure per unit stack height is shown in Figure 2.5.6 as a function of $T_h - T_\infty$ with T_∞ = 527°R = 68°F (293 K = 20°C). Positive pressure testing according to ASTM E2074 requires that the positive pressure differential at the top of the door is approximately 0.21 psf (10 Pa). Figure 2.5.6 implies that the neutral plane is located approximately 4.25 ft (1.3 m) below the top of the door after 5 minutes of testing (i.e., when the standard furnace temperature rise is 1018°F [548°C]). The neutral pressure plane is located approximately 3.6 ft (1.1 m) below the top of the door after 120 minutes of testing (i.e., when the furnace temperature rise is 1777°F [987°C]).

Load. Fire resistance furnace test standards require that load-bearing assemblies and structural members be loaded so that the maximum stresses in the specimen are equal to the allowable design stresses. If the test specimen is loaded below its capacity, the resulting fire resistance rating is only valid if the structure is designed based on the load and the stresses applied in the test. This is inconsistent with the guidelines in ASCE 7, *Minimum Design Loads for Buildings and Other Structures,*[15] which allows for a significant reduction of the load for fire design. The recommendations in ASCE 7 are based on the observations that it is unlikely that a structure will be exposed to the full dead and live loads that are used for structural design at the same time when a fire occurs.

The load in fire resistance tests is typically applied using hydraulic jacks. Figure 2.5.7 shows a load-bearing masonry wall assembly. The forces from the jacks are transferred to the test specimen via a stiff steel distribution beam. The pressure of the hydraulic oil in the jacks is maintained during the test so that the wall is stressed to the specified level.

Floor/ceiling assemblies are usually tested under a uniform load. This can be accomplished by distributing concrete blocks or water-filled barrels over the unexposed surface of the assembly. The drawback of this approach is that the blocks or barrels affect the heat transfer from the unexposed side. This problem can be avoided by using a hydraulic loading system. Such a system is very complicated if the load has to be distributed over a large number of points (Figure 2.5.8).

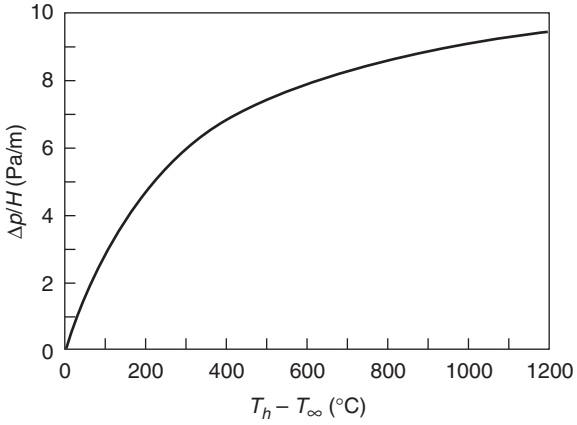

FIGURE 2.5.6 Differential Pressure Due to Stack Effect (Courtesy Southwest Research Institute)

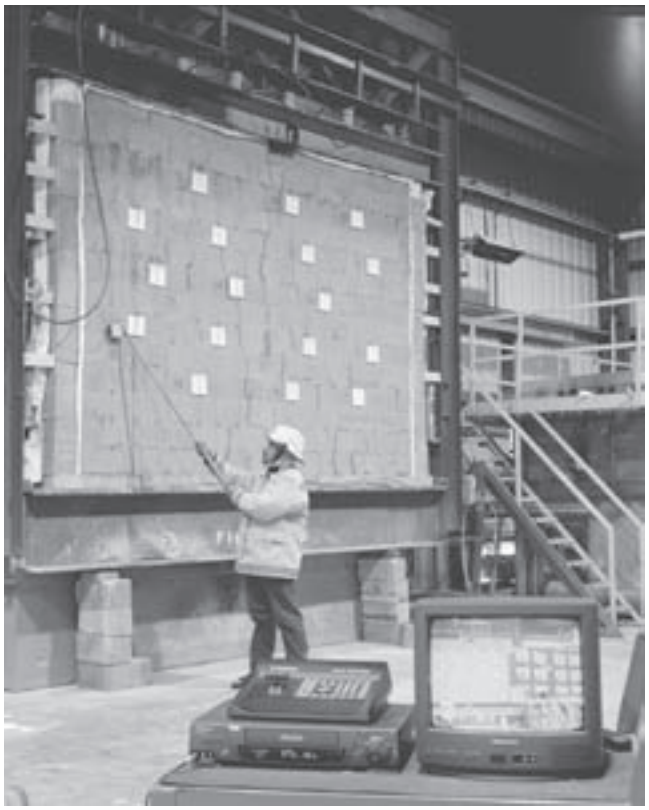

FIGURE 2.5.7 Fire Resistance Test on Loaded Masonry Wall Assembly (Courtesy Southwest Research Institute)

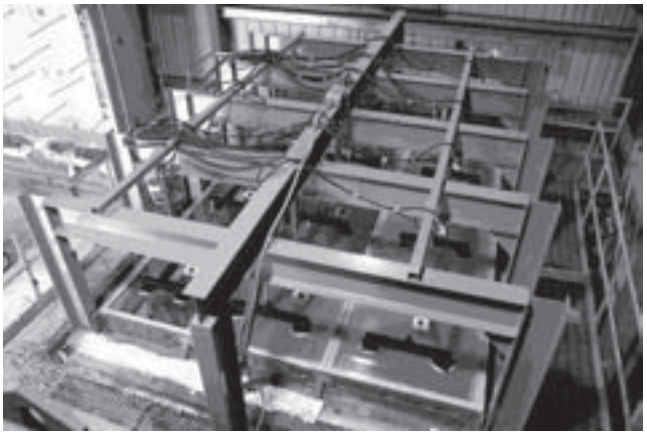

FIGURE 2.5.8 Hydraulic System to Distribute the Load on a Glass Floor Assembly (Courtesy Southwest Research Institute)

End-Point Criteria. Three end-point criteria are used to determine the fire resistance of a test specimen. Although similar criteria are specified in most fire resistance test standards, the following are some subtle differences that are worth noting:

1. *Heat transmission.* Transmission of heat through the test specimen is usually quantified on the basis of the unexposed-side temperature measurements. Each standard specifies the minimum number of thermocouples that must be attached to the unexposed side of the specimen. The end point for heat transmission is reached when the average of all thermocouple readings reaches a limit (typically approximately 250°F or 140°C) or when any of the individual thermocouple readings exceeds a higher limit (typically approximately 325°F or 180°C). The limits are well below the ignition temperature of common combustible materials.[16]

The unexposed-side temperature measurements are a function of how the thermocouples are attached to the surface of the specimen. Typically this is accomplished by covering the thermocouple junction with a felted pad that is glued to the specimen surface. The dimensions and material of the pad affect the temperature measurements. For example, ASTM E119 specifies 6 in. × 6 in. × ⅜ in. (150 mm × 150 mm × 10 mm) pads with a density of 19 pcf (300 kg/m^3). ISO 834-1 requires a pad size of 77/64 in. × 77/64 in. × 5/64 in. (30 mm × 30 mm × 2 mm) and specifies a density of 56 pcf (900 kg/m^3). The heat losses through the ASTM pads are obviously much smaller than those though the ISO pads. Since the temperature limits are essentially identical in both standards, ASTM E119 is more stringent in terms of heat transmission end-point criteria.

Heat transmission through some types of test specimens such as glazing is measured with a radiometer that is located at a specified distance from the unexposed side of the specimen. The end point in this case is a maximum allowable radiant heat flux that is transmitted through the specimen and/or emitted from the unexposed surface of the specimen.

2. *Integrity.* The integrity end point is reached when gases or flames emerging through cracks in the specimen are hot enough to ignite a cotton pad on the unexposed side. Whether ignition occurs or not depends on the size of the cotton pad, the time that it can be held at a particular location, and the distance between the pad and the specimen surface.

3. *Load-bearing capacity.* Structural collapse is an obvious indication that the specimen is no longer able to support the load. Fire resistance tests are usually terminated long before collapse occurs and a maximum deflection or rate of deflection limit is often used to define structural failure.

Specimen. The test specimen has to be representative of the building element as it is installed in the field. Above all, this implies that the specimen must have a minimum size. If the specimen is too small, the test result may not be representative of how the building element will perform in an actual fire. Some building elements, such as cable and pipe penetration fire stops, can perhaps be tested on a small furnace, but most elements need to be evaluated on a furnace that can accommodate vertical elements that are 8 to 10 ft (2.4 to 3 m) in height or horizontal elements that are 13 to 17 ft (4 to 6 m) in span.

Moisture has a significant effect on the performance of many types of building elements in a fire resistance test. A large amount of energy is needed to evaporate water and a high moisture content, therefore, usually improves the fire resistance of a building element. This is not always the case. For example, prestressed concrete with a high moisture content is more susceptible to spalling. Fire resistance test standards require that specimens be dried and cured to reduce the moisture content to a level that is representative of end-use conditions in the field. Sometimes that is not practical as it would require several months of conditioning. In that case a shorter drying period is allowed and the test results may have to be corrected to account for the excessive moisture in the test specimen. For example, ASTM E119 describes a procedure to correct the fire resistance rating of concrete floor slabs based on the actual moisture content during the test versus the typical in-service moisture content.

Standard Fire Resistance Furnace Tests

This section provides an overview of the most commonly used fire resistance furnace test standards. ASTM test standards are discussed first, followed by other domestic and international standards.

ASTM Test Standards. The American Society of Testing and Materials was the first standards development organization in the United States to publish a fire resistance furnace test standard.[17,18] The Baltimore conflagration on February 7, 1904, resulted in the formation of ASTM Committee P on Fireproofing Materials. In 1910 the designation of the committee was changed to C5, and 35 years later it was changed again to E05. From its inception until 1927 the committee was chaired by Professor Ira H. Woolson of Columbia University. Professor Woolson was chosen to lead the committee because a few years earlier he had established the first U.S. station for fire resistance testing in New York City. In 1907 ASTM Committee P issued its first fire resistance furnace test standard. This standard, designated C2, specified a procedure to evaluate floor systems based on tests conducted earlier at the Columbia test station. A wall partition standard, C3, followed in 1909. In 1916 and 1917, the American Society of Testing and Materials and the National Fire Protection Association held a series of meetings to revise the C2 and C3 standards. The resulting standard, C19, superseded standards C2 and C3 and specified the standard temperature-time curve that is still used today. The current version of the standard, now designated ASTM E119, is essentially unchanged from the first edition published in 1918.

ASTM E119 provides procedures for measuring the fire resistance of wall and floor/ceiling assemblies, roof structures, beams, and columns. Variants of this basic standard have been developed to provide specific details for fire resistance testing of doors, windows, and other types of building elements that are not covered by the general standard. A list of the ASTM and equivalent NFPA fire resistance test standards is given in Table 2.5.1. These test standards, with the exception of ASTM E1725, *Standard Test Methods for Fire Tests of Fire-Resistive Barrier Systems for Electrical System Components,*[19] prescribe a supplemental hose stream test procedure to evaluate the ability

TABLE 2.5.1 ASTM and NFPA Fire Endurance Test Standards

ASTM Designation	*NFPA Designation*	*Subject*
E119[2]	255	General
E814[20]	—	Through-penetration fire stops
E1529[21]	—	Simulated hydrocarbon pool fire exposure
E1725[19]	—	Barriers for electrical system components
E2074[13]	252	Door assemblies
E2010[14]	257	Window assemblies
E2226[22]	—	Hose stream test

of the construction to resist disintegration under adverse conditions. The hose stream test is either performed after termination of the fire resistance test or on a duplicate specimen that has been exposed to the standard fire for half the duration of the desired fire resistance classification. A hose stream test is not required for columns, floor/ceiling assemblies, and roof structures; wall assemblies with a fire resistance rating of less than 1 hour; and 20-minute-rated door assemblies. The hose stream requirement is unique to North America and is described in a separate standard, ASTM E2226, *Standard Practice for Application of Hose Stream.*[22]

The fire resistance of a building element is determined on the basis of the time that one of the end-point criteria for heat transmission, integrity, and/or structural performance is first exceeded. The fire resistance time is rounded down to 20 minutes, ½ hour, 1 hour, 1½ hours, 2 hours, 3 hours, 4 hours, and so on.

Other Fire Resistance Furnace Test Standards. The National Fire Protection Association (NFPA), Underwriters Laboratories (UL), and Underwriters' Laboratories of Canada (ULC) each published a general fire resistance furnace test standard that is essentially identical to ASTM E119. The designations of these standards are NFPA 251, *Standard Methods of Tests of Fire Resistance of Building Construction and Materials;* UL 263, *Fire Tests of Building Construction and Materials;*[23] and ULC/CAN-S101-M89, *Standard Methods of Fire Endurance Tests of Building Construction and Materials,*[24] respectively. NFPA and UL also published test standards for doors (NFPA 252, *Standard Methods of Fire Tests of Door Assemblies;* UL 10A, *Fire Tests of Tin-Clad Fire Doors;*[25] UL 10B, *Fire Tests of Door Assemblies;*[26] and UL 10C, *Positive Pressure Fire Tests of Door Assemblies*[27]) and windows (NFPA 257, *Standard on Fire Test for Window and Glass Block Assemblies,* and UL 9, *Fire Tests of Window Assemblies*[28]) that are very similar to the corresponding ASTM standards.

Both NFPA and UL also maintain a number of fire resistance furnace test standards that do not have an ASTM equivalent. For example, NFPA 415, *Standard on Airport Terminal Buildings, Fueling Ramp Drainage, and Loading Walkways,* is used to determine the fire resistance of aircraft loading walkways exposed to the standard ASTM E119 temperature-time curve. UL 1709, *Rapid Rise Fire Tests of Protection Materials for Structural Steel,*[29] is a commonly used fire resistance furnace test standard that does not have an ASTM equivalent, although ASTM E1529 is somewhat similar. The rapid-rise UL 1709 temperature-time curve shown in Figure 2.5.2 simulates the exposure conditions of a large hydrocarbon pool fire. The furnace temperature reaches 1093°C within 5 minutes and remains at that level for the duration of the test. The corresponding heat flux is 18 Btu/sec·ft^2 (204 kW/m^2). UL 1709 is specified to determine the fire resistance of structural members that may be exposed to hydrocarbon pool fires, for example, on offshore installations or in petrochemical plants. UL 1709 is also specified in Appendix A of MIL-PRF-32161, *Performance Specification—Insulation, High Temperature Fire Protection, Thermal and Acoustic,*[30] to determine the fire resistance of U.S. Navy bulkheads and decks.

Outside North America, fire resistance test procedures are based on ISO 834. The general procedure is described in part one,[3] whereas detailed guidelines for testing of different types of building elements are provided in parts three to nine.[31–37] The furnaces used in other parts of the world are conceptually very similar to those used in the United States and Canada. The temperature-time curve specified in ISO 834 is similar to that in ASTM E119 (see Figure 2.5.2). IMO Resolution A.754, *Recommendation on Fire Resistance Tests for "A", "B" and "F" Class Divisions,*[38] describes a furnace test procedure to determine the fire resistance of marine bulkheads and decks. This method is based on the 1975 edition of ISO 834, which uses exposed-junction thermocouples to control the furnace as opposed to plate thermometers that are specified in the recent revision of the ISO standard.

History of Fire Resistance Tests. At the time that ASTM C19 was developed, the relationship between the standard temperature-time curve and real fires was not well understood. Pioneering work by Ingberg at the National Bureau of Standards in the 1920s provided some insight into this question. Ingberg performed a series of room fire tests to establish a relationship between the standard fire and actual fires and introduced the equal-area concept.[39] According to this concept, the duration of standard fire exposure of equivalent severity to an actual burnout fire can be determined on the basis of equal areas under the temperature-time curve as illustrated in Figure 2.5.9. In other words, the severity of a fire can be characterized on the basis of a single parameter, the fire load, which is equal to the area under the temperature-time curve. There are some obvious limitations to the approach. For example, referring to Figure 2.5.9, if a component of the test specimen breaks down at 1832°F (1000°C), the longer standard fire will not be equivalent to the real fire because the critical temperature will not be reached in the test.

The fire resistance requirements in the U.S. building codes are still largely based on Ingberg's relationship between the fire load and the time to burnout of a fully developed compartment fire.[40] The objective is that fire-resistive elements be able to survive complete burnout of a compartment. Each type of occupancy has an associated hazard that is quantified in terms of its fire load.

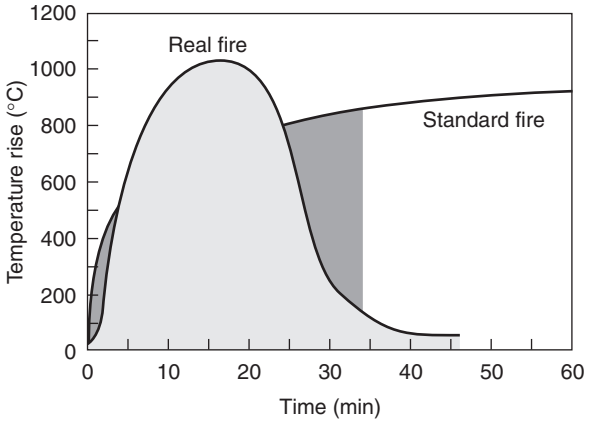

FIGURE 2.5.9 Ingberg's Equal-Area Concept (Courtesy Southwest Research Institute)

Research in Japan in the 1950s demonstrated that the severity of room fire is also affected by the ventilation conditions and the thermal properties of the room boundaries.[41] Room fire tests in the 1960s and 1970s identified the porosity and nature of the fuel as additional variables. The additional effects and variables can be accounted for through mathematical modeling (discussed later). The modeling approach may be used to demonstrate code equivalency or performance-based code compliance.

Analytical Methods to Calculate Fire Resistance

A number of analytical methods have been developed in North America[42] and other parts of the world[43] on the basis of years of experience and extensive fire endurance testing. These calculation methods are accepted by the model building codes in lieu of test results. However, the scope of these methods is limited to relatively simple concrete, masonry, steel, and wood construction in the following ways:

- Analytical methods for concrete slabs and columns specify the thickness of concrete cover that is needed to limit the reinforcing or prestressing steel temperatures.
- The fire endurance of clay and concrete masonry walls is specified as a function of the thickness of the wall.
- The fire endurance of steel columns and beams is a function of the area to heated perimeter ratio and the thermal characteristics and thickness of protective materials (gypsum board, sprayed-on fireproofing, etc.).
- The component additive method estimates the fire endurance rating of a light wood-frame wall, floor/ceiling, or roof assembly on the basis of times assigned to the individual components of the assembly, that is, the protective membrane(s), thermal insulation, structural members, and so on.
- Analytical methods for heavy timber beams and columns estimate the reduction of the load-bearing cross section of the member as a function of time on the basis of experimental charring rate data for wood obtained under standard fire conditions. The estimated fire endurance corresponds to the time when the remaining section is no longer able to support the load.

Structural Fire Modeling

Finite difference or finite element conduction heat transfer models are also used to predict the temperature distribution in building elements exposed to fire.[44] Some of these models have been coupled with strength and stiffness calculations to predict structural performance under fire conditions.[45] The acceptance of this type of computer fire modeling is not as widespread as that of the analytical methods described in the previous section. However, it is a useful tool to demonstrate code equivalency or to support performance-based design. One of the main problems is that accurate thermal and mechanical material properties are needed at elevated temperatures. Such property data are often not available and are difficult to measure. A major advantage of this approach is that the exposure conditions are not limited to the standard fire conditions. Predictions can be made for real fire exposure conditions. These exposure conditions can be based on experimental measurements or on predictions obtained with a model of fully developed compartment fires, such as COMPF2[46] or BRANZFIRE.[47]

NIST Investigation of the World Trade Center Disaster

The National Institute of Standards and Technology (NIST) conducted a 3-year investigation of the collapse of New York City's World Trade Center structures following the terrorist attacks of September 11, 2001. The results of this investigation are described in detail in the final report.[48] This investigation is by far the most comprehensive effort to model structures in fires. NIST's Fire Dynamics Simulator (FDS) was used to simulate the fire environment and a commercial finite element code (ANSYS) was chosen to model the response of the structure.

As part of the investigation, four ASTM E119 fire resistance furnace tests were conducted on the floor assembly of the twin towers as follows:

- Test 1: 35 ft (10.67 m) floor span, ¾ in. (19 mm) insulation, restrained
- Test 2: 35 ft (10.67 m) floor span, ¾ in. (19 mm) insulation, unrestrained
- Test 3: 17 ft (5.18 m) floor span, ¾ in. (19 mm) insulation, restrained
- Test 4: 17 ft (5.18 m) floor span, ½ in. (13 mm) insulation, restrained

The restrained 35 ft (10.67 m) floor system (Test 1) obtained a 1½ hour rating, whereas the unrestrained system (Test 2) obtained a 2 hour rating. This implies that restraining the floor assembly makes the test more stringent. The 17 ft (5.18 m) assembly in Test 3 obtained a 2 hour rating whereas the 35 ft (10.67 m) assembly in Test 1 obtained a 1½ hour rating. This result raises the question of whether fire resistance test results on a 17 ft (5.18 m) floor assembly can be extrapolated to longer spans. Note that there are no laboratories in the United

States that can test assemblies with a span greater than 18 ft (5.49 m).

The NIST report concludes with a list of 30 recommendations for action in the areas of increased structural integrity, enhanced fire resistance of structures, new methods for fire resistant design of structures, enhanced active fire protection, improved building evacuation, improved emergency response, improved procedures and practices, and education and training. Several recommendations pertain to fire resistance testing and fire-resistant building design. For example, NIST recommends (#4 and #5) that the technical basis for the standard fire resistance test (ASTM E119), resulting fire resistance ratings, and pertinent code requirements be improved. NIST also recommends (#8 and #9) that procedures and practices used in the fire-resistant design of structures be enhanced and based on performance objectives.

EXTERIOR FIRE SPREAD

Flame spread over exterior surfaces and heat transmission through the structure from external flame and fire exposure are major concerns. Various test methods have, therefore, been developed to determine the fire performance of facades and roof structures.

Upward Fire Spread over Facades

Exterior Insulation and Finish Systems (EIFS) are very common in the construction of exterior walls for high-rise buildings. Because the systems typically consist of plastic foam insulation and other combustible components, the potential exists for rapid upward flame spread over facades to stories above the fire room. NFPA 285, *Standard Fire Test Method for Evaluation of Fire Propagation Characteristics of Exterior Non-Load-Bearing Wall Assemblies Containing Combustible Components,* describes a test method intended to evaluate the capability of such wall assemblies to resist vertical and, to some extent, lateral flame propagation over the exterior and interior faces and within the core of the assembly.

A full-scale test procedure was developed in 1980 for evaluating the fire performance of EIFS construction using an outdoor 26 ft (8 m) tall two-story building. This procedure became Uniform Building Code (UBC) standard 17-6, *Method of Test for the Evaluation of Flammability Characteristics of Exterior, Non-Loadbearing Wall Panel Assemblies Using Foam Plastic Insulation,*[49] which was incorporated in the 1988 version of the UBC. In 1994 the designation of the test method was changed to UBC 26-4. One of the limitations of the test method was that the facility was located outdoors and affected by the weather.

In the early 1990s, an intermediate-scale indoor version of the UBC 26-4 test apparatus was developed. Comparable performance was obtained in the intermediate-scale tests for wall systems that both passed and failed the UBC 26-4 test. The resulting intermediate-scale test method was recognized by the UBC as an alternate to UBC 26-4 and was published in the 1997 UBC as test standard 26-9, *Method of Test for the Evaluation of Flammability Characteristics of Exterior, Non-Loadbearing Wall Assemblies Containing Combustible Components Using the Intermediate-Scale Multistory Test Apparatus.*[50] NFPA 285, which is functionally identical to UBC 26-9, was first adopted by NFPA in 1998. ASTM recently developed a test method to determine the fire resistance of perimeter fire barriers (i.e., the joint between an exterior wall assembly and the floor system). The resulting test standard, ASTM E2307, *Standard Test Method for Determining Fire Resistance of Perimeter Fire Barriers Using Intermediate-Scale, Multi-Story Test Apparatus,*[51] uses a slightly modified version of the intermediate-scale multistory test apparatus described in NFPA 285.

The NFPA 285 test structure consists of two stories. The interior dimensions of the first- and second-floor rooms are identical and equal to 10 ft (3.05 m) wide by 10 ft (3.05 m) deep by 7 ft (2.13 m) high. Both rooms are constructed of concrete block walls and concrete slabs and are fully enclosed except for the front side. The interior surfaces of the bottom room are protected with gypsum board and ceramic fiber insulation.

The test assembly is mounted against the front of the test structure and covers both stories. There is a window opening of 78 in. (1.96 m) wide by 30 in. (0.76 m) high at 30 in. (0.76 m) from the floor of the first-floor room. The main burner is located inside the first-floor burn room and is supplied with gas so that its heat output increases according to a prescribed regime from approximately 664 Btu/sec (700 kW) at the start of the test to approximately 853 Btu/sec (900 kW) at the end of the 30 minute test. A second burner is located inside the window opening so that flames hit the window soffit, which is the most vulnerable part of the exterior wall assembly for flame penetration into the core (Figure 2.5.10). The heat output of the window burner increases from 0 Btu/sec (0 kW) at the start of the test to approximately 379 Btu/sec (400 kW) at the end of the 30 minute test duration. Acceptance criteria are based on visual observations of flame propagation over the exterior surface and temperature measurements above and at a lateral distance from the window opening.

A similar test method to evaluate upward fire spread over facades is specified in ISO standard 13785-2, *Reaction to Fire Tests for Facades, Part 2: Large Scale Tests.*[52] However, this standard contains a 90° wall corner on one side of the window opening to concentrate heat from the window flames and also uses a high heat release rate propane burner only inside the burn room. The heat flux exposure specified by ISO 13785-2 is 4.84 Btu/sec·ft^2 (55 kW/m^2) at three positions 600 mm above the window opening, which is substantially greater than the heat flux expected at a similar position in the NFPA 285 test. The ISO test method is representative of the situation when there is a corner on the exterior of a building or when there is storage in close proximity to a building facade, which could result in higher heat fluxes than for the case of flames issuing from a window.[53]

Ignition of Exterior Claddings

Model building codes address the problem of fire spread from one building to an adjacent building due to radiant ignition of combustible exterior facades by specifying a minimum distance to the property line. This distance is based on the assumption that the exterior cladding is wood. The commonly accepted threshold for piloted ignition of wood is 1.10 Btu/sec·ft^2 (12.5 kW/m^2).

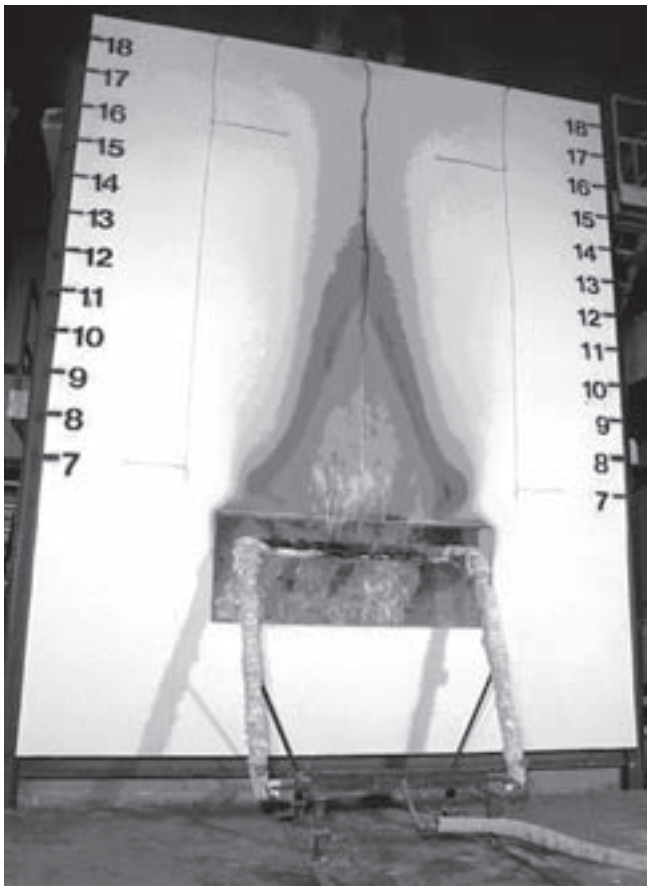

FIGURE 2.5.10 NFPA 285 Intermediate-Scale Multistory Apparatus (Courtesy Southwest Research Institute)

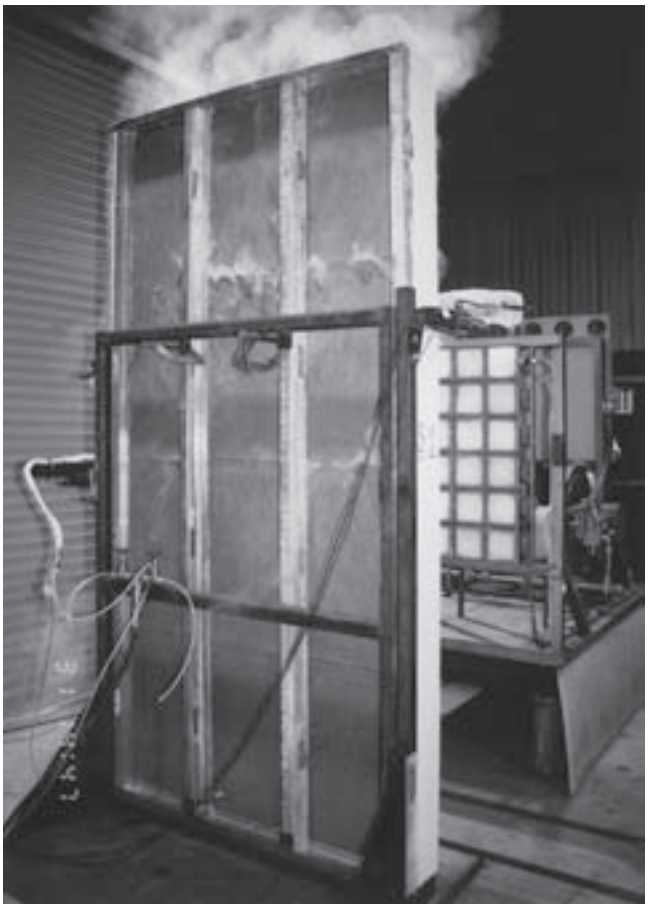

FIGURE 2.5.11 Radiant Panel Test to Measure Ignitability of Exterior Wall Claddings (Courtesy Southwest Research Institute)

However, many different types of exterior wall claddings are now available in the marketplace. To ensure that the model building code provisions are adequate for these products, it is necessary to verify that their ignition threshold is equal to or higher than that for wood. NFPA 268, *Standard Test Method for Determining Ignitability of Exterior Wall Assemblies Using a Radiant Heat Energy Source,* describes a test method that can be used to perform this verification.

The apparatus consists of a vertical 3 ft × 3 ft (0.91 m × 0.91 m) propane-fired radiant panel that exposes the 4 ft × 8 ft (1.22 m × 2.44 m) specimen to a radiant heat flux that is equal to approximately 1.10 Btu/sec·ft^2 (12.5 kW/m^2) over a central 1 ft × 1 ft (0.3 m × 0.3 m) region (Figure 2.5.11). A spark igniter is mounted on the vertical centerline of the test specimen at a point 18 in. (0.46 m) above its horizontal centerline and at ⅝ in. (15.9 mm) from its surface. A product passes if ignition does not occur during the 20 minute test exposure.

Ignition and Fire Spread over Roof Structures

Other possible mechanisms of fire spread involve burning brands landing on a roof surface or flames propagating over a roof covering. ASTM E108, *Standard Test Methods for Fire Tests of Roof Coverings,*[54] and NFPA 256, *Standard Methods of Fire Tests of Roof Coverings,* describe a procedure to measure the relative fire characteristics of roof coverings under simulated fire originating outside the building (Figure 2.5.12). The roof covering is mounted on a 40 in. × 52 in. (1 m × 1.3 m) deck at the required incline. The procedure involves three different tests: an intermittent flame exposure test, a spread of flame test, and a burning brand test. Only the spread of flame test is required for roof coverings mounted on a noncombustible deck. For each test there are three levels of exposure (severe, moderate, and light), leading to Classes A, B, and C, respectively. Additional flying brand tests are required for roof coverings that can be subjected to firebrands, leading to Class A for roofing that can resist ignition from a large burning array of wood sticks, Class B from a moderate-size burning array, and Class C from a burning notched wood block. Rain tests are required when the fire-retardant characteristics of the roof covering or construction may be adversely affected by water.

SAFE SEPARATION DISTANCE

To eliminate ignition and damage at potential target locations on the roof or facade of a building due to likely exterior fire

FIGURE 2.5.12 Burning Brand Test on Roof Covering (Courtesy Southwest Research Institute)

sources, a separation distance between the building and these potential fire sources must be provided. The separation should result in sufficiently low radiant fluxes and/or sufficiently small firebrands arriving at the target during the duration of the exterior fire source. This definition, in essence, is what is meant by a safe separation distance for passive protection of buildings from damaging exposure due to fires in other nearby buildings, outside storage, or even wildland vegetation. In a regulatory environment where model codes prescribe the type of fire protection measures that are required, NFPA 80A, *Recommended Practice for Protection of Buildings from Exterior Fire Exposures,* can provide the information necessary to determine safe separation distance. However, in a performance-based environment, the adequacy of a safe separation distance must be demonstrated based on concepts discussed in the following sections.

Radiant Exposure from Outside Fire Sources

Radiant Flux at Target. As discussed in Section 2, Chapter 1, the radiant flux from an outside fire source to a target on the outside wall or roof of a building is given by the product of the flame emissive power and the configuration (or view) factor. The maximum flame emissive power, typical of hazardous outside fire sources, is about 14 Btu/sec·ft^2 (160 kW/m^2) but is influenced by the amount of smoke produced in the flames, as explained in the next section. To determine the configuration factor, any blockage of radiation by intact walls of a burning building must be taken into account. Most importantly, the shape, orientation, and dimensions of the flame radiant source must be considered, as discussed later.

Smoke Mantle. Fires outside of a building involving an intact or collapsed structure, various types of storage arrays, or vegetation (forests, brush) produce a plume of flame and smoke. It is the exposed flame portion of this plume that is responsible for radiant heat transfer to distant targets (see Section 2, Chapter 1). Once the minimum plan dimension of a fire source is more than a few meters, smoke begins to obscure the upper portion of the flame plume (starting at the flame tip) with the smoke mantle obscuring a greater and greater fraction of the flame as the minimum plan dimension of the fire source increases. Since the smoke is relatively cool compared to the flame, thermal radiation from a plume partially covered by a smoke mantle is reduced significantly (see Figure 2.2.2 in Section 2, Chapter 2). Hence, it is important to be able to estimate either the average emissive power (see Section 2, Chapter 1, Equation 5) of the smoke-covered total flame height as a function of the fire source dimension, following the method of Sokri and Beyler,[55] or to estimate the height of the exposed (smoke-free) flame zone above the fire source but below the smoke mantle as a fraction of the total flame height. The latter method would potentially be more accurate but is much more difficult until better correlations are available or until techniques are perfected to calculate realistic plume flow combustion dynamics.

Radiant Source Shape and Orientation. To determine the configuration factor, information on the general shape of the flame radiant source (i.e., whether cylindrical/conical or planar, etc.) and the effect of wind on flame orientation must be derived from the fire scenario(s) assumed for design purposes. A burning building or outside storage that has a nearly square plan area leads to a cylindrical or conical shape for a radiant source, whereas an elongated structure or a vegetation fire generally leads to a planar radiant source. In either case, wind can tilt the radiant source toward the target and this tilt angle has

been correlated with wind speeds above a critical value. When a flame radiant source tilts toward a target, not only is the distance to the target decreased but the source height and, hence, the apparent area of the source viewed from the target also decreased. Calculation of the configuration factor for this case shows that the reduction in source height is the more important factor (leading to a slight reduction in radiant flux at the target) as long as the flame source is never actually above the target (i.e., as long as the flame length is less than the separation distance).

Radiant Source Dimensions. To determine the configuration factor, both the lateral extent (width) and height of the radiant source must be estimated from the fire scenario(s) assumed for design purposes. Horizontal dimensions of the source are obtained from the prescribed fire scenario(s) either in terms of fire initiation within specified combustibles (e.g., a building or a storage item) or in terms of known lateral fire propagation or flame spread rate and the burning duration at each point in the combustibles. Vertical dimensions of the source are obtained from flame height correlations, which depend on fire heat release rates and to a lesser extent on horizontal dimensions of the burning material. Again, the assumed fire scenario will be needed to determine the identity and, hence, the heat release rate of the fire. Note that for a fire source of unlimited length in one direction, leading to a planar radiation source, the flame height depends on the heat release rate per unit length. If the plan area of the outside fire is sufficiently large, there will not be a single, well-defined fire plume but rather a group of plumes at random locations in the burning material. There are correlations for predicting the existence and flame height associated with this so-called "mass-fire" situation.

Damage Due to Heat Flux. Once a radiant heat flux level is obtained for a given separation distance from an outside radiant fire source, damage due to this heat flux must be estimated. The damage estimation should include a consideration of the critical heat flux needed for ignition of cladding or roofing materials on a building, as obtained from the NFPA 268 test method or from small-scale test methods such as the Cone Calorimeter or the Fire Propagation Apparatus. For exterior building surfaces that are not combustible but have been tested in a furnace apparatus similar to ASTM E119, the exposure flux from the outside source should be compared with the average radiant flux determined from the (fourth power of the) measured furnace temperature during the test duration. If no ignition or damage is expected from the radiant flux exposure, a safe separation distance has been confirmed.

Firebrand Exposure from Outside Fire Sources

Firebrands are carried aloft by the upward gas motion in a fire plume and then, once aloft, are carried by the wind to distant building targets. Upward gas velocity in a fire plume increases from near zero at the base of the plume (the lowest elevation at which material is burning) to a maximum value at the end of the continuous flaming region, a distance of more than half the plume height (see Section 2, Chapter 4). Therefore, the largest firebrands, which require the highest upward velocity to be lofted, must originate from the highest elevations of a burning building, storage array, or vegetation that are still immersed in the fire plume. In addition to maximum fuel elevation, other parameters that affect the lofting height and downwind propagation of a firebrand are firebrand characteristics (shape, burning mode, and density), fire heat release rate, and maximum wind speed. The largest firebrands with high wind-drag shapes, high-temperature glowing char, and lowest density will be lofted the greatest distances and do the most damage. Clearly, upward gas velocities in the plume for lofting firebrands will be highest as heat release rates increase and downwind propagation will be enhanced at the highest wind speeds. All of these parameters can be inferred from the fire scenario(s) assumed for design purposes. Once the foregoing parameters are settled, the size of the largest firebrands that can be carried downwind a given distance from the assumed location of the outside source fire to a target location on a roof can be readily determined.[56] If firebrands of this maximum size will not cause damage at the target location, as demonstrated for example, by the ASTM E108 rating for the roofing material, then smaller-size firebrands of the same type also will not cause damage, as the ignition heat flux from smaller brands is lower. In this case, a safe separation distance from a potential source fire location has been confirmed.

SUMMARY

Fire protection of buildings addresses all aspects of fire safety and consists of a combination of active and passive measures. Active fire protection devices require manual, mechanical, or electrical power for their operation. Passive fire protection does not require any external power. This chapter deals with one aspect of passive fire protection: fire containment. This type of passive fire protection includes test methods to evaluate the performance of interior and exterior assemblies and structural members when exposed to fully developed fire conditions, as well as measures needed to provide a safe separation distance from exterior fire sources.

Fully developed postflashover fires are contained to the enclosed space of origin by using fire-resistive separating and load-bearing building elements. The fire resistance of a building element is determined through furnace testing. The element is exposed to the furnace environment, which follows a standard temperature-time curve. Structural elements are subjected to their design load during the fire test. Steel-frame floor assemblies may have to be tested under restrained conditions. End-point criteria are based on heat transmission and integrity for separating elements and load-bearing capacity for structural members. North American fire resistance furnace test standards may require that the test specimen be subjected to a hose stream test after the fire test is terminated.

Experimental variables that affect the severity and results of a fire resistance furnace test are discussed. These variables include thermal exposure conditions, furnace pressure, load, end-point criteria that are used, and specimen characteristics such as size and moisture content.

The most commonly used ASTM, NFPA, UL, ULC, ISO, and IMO fire resistance furnace test standards are briefly de-

scribed. The relationship between fire resistance furnace tests and real fires, in particular Ingberg's equal-area concept, is discussed. Alternative methods are identified to determine the fire resistance of building elements based on analytical calculations and mathematical fire modeling. Some analytical methods are accepted by the U.S. model building codes in lieu of furnace testing.

The chapter concludes with a discussion of test methods to measure ignition, flame spread, and heat transmission characteristics of exterior building elements such as facades and roof structures and a discussion of the various factors influencing the radiant heat flux and the size of firebrands generated from distant to nearby fires in outside buildings, material storage, or vegetation.

Chapter 6

Fundamentals of Fire Detection

Richard L. P. Custer ❏ James A. Milke

Chapter Contents

Simplified Fire Development
Fire Signatures

Key Terms

aerosol, aerosol signature, ceiling jet, energy release signature, entrainment, fire detection, fire growth, fire plume, fire signature, gas signature, gas yield, multiple signature detection, thermal lag

Most fires, no matter how large they may become, begin as small fires. Small fires, if detected, are easily controlled manually or by fixed fire suppression systems. The earlier a fire is detected, the more likely building occupants are to escape with little or no impact from exposure to fire products. Furthermore, the earlier a fire is detected, the sooner suppression methods can be brought to bear on the fire, thereby reducing damage to property and the environment.

For additional information, see Section 14, Detection and Alarm, of this handbook.

SIMPLIFIED FIRE DEVELOPMENT

In the earliest stages of fire development, fuel materials are heated by an ignition source even before smoldering (i.e., glowing combustion) occurs. Large numbers of extremely small invisible particles are produced and distributed into the surrounding atmosphere. At this point in fire development (prepyrolysis), very little energy is produced to distribute these particles, and they are generally transmitted with the existing air motion. Smoldering fires produce large particles and gases such as carbon monoxide (CO) and carbon dioxide (CO_2).

Following the development of flame, a column of hot gases rises as a plume.[1] As the plume rises, uncontaminated air is drawn or "entrained" into the plume, increasing its volume. As a result of dilution of the hot gases in the plume by the entrained cool air, the gas velocity and temperature in the plume are reduced. Entrainment of air is discussed in Section 18, Chapter 3, "Smoke Movement in Buildings."

For any space, there is a minimum fire size necessary to provide sufficient energy to the plume to enable it to reach the ceiling. Until the smoke reaches the ceiling, ceiling-mounted smoke and thermal detectors are not able to respond.[2]

In some tall atria and indoor sports arenas, the fire size needed to drive the smoke to the ceiling is substantial. This situation is made worse if a hot layer is present before the start of the fire, for example, due to the presence of a solar heat load at the ceiling. In such cases, the smoke may stop rising at a point below the ceiling. This situation is referred to as "intermediate stratification."[3] In these situations, the response of ceiling-mounted detectors is delayed until the fire grows large enough to provide sufficient buoyancy to the plume to force its way through the hot air layer. This may cause a substantial time delay if ceiling-mounted detectors are the only initiating devices present.

If there is a ceiling above the fire, the vertically rising plume will be deflected, and the gases will travel horizontally across the ceiling. The upward movement of the hot gases is accomplished by a mechanism commonly referred to as *convection.* Convection is a combination of heat transfer between the air molecules and the motion of the air resulting from buoyancy.[4] Convection in the plume extends to the horizontal movement of air just below the ceiling, which is called a *ceiling jet.*[5] The plume and ceiling jet transport the smoke particles or aerosols from their point of

Richard L. P. Custer, M.Sc., FSPE, is associate principal and technical director at Arup Fire in Westborough, Massachusetts. Mr. Custer is a fellow of the Society of Fire Protection Engineers and the past chair of the NFPA Technical Committee on Fire and Explosion Investigation.

James A. Milke, Ph.D., P.E., is associate professor and associate chair of the department of fire protection engineering at the University of Maryland in College Park, Maryland.

generation to a detector. Generally, ceiling-mounted detectors respond to heat or smoke transported vertically by the plume and horizontally by the ceiling jet.

As the fire progresses, a layer of hot gases forms at the ceiling, descending over time and spreading to adjacent spaces through open doorways.

FIRE SIGNATURES

Characteristics of Fire Signatures

Custer and Bright first proposed the concept of fire signatures in 1974.[6] From the very beginning, a fire produces a variety of changes in the surrounding environment. Any product or result of a fire that changes the ambient condition is referred to as a *fire signature* and has the potential for use in detection. Production of smoke particles, for example, results in a decrease in light transmission. Not all fire signatures, however, are practical for fire detection purposes. To be useful, a fire signature should generate a measurable change in ambient conditions. In addition, the magnitude of the change must be greater than normal background variations. For example, a sudden increase in temperature could be due to either a fire or normal start-up of a heating appliance.

The magnitude of change in the ambient condition is the signal from a fire signature; the background level, with its normal variations, is referred to as the *noise.* All other factors, such as hazard level at detection and hardware costs, being equal, the preferred fire signature will be one that can generate the highest signal-to-noise ratio at the earliest time in the fire's development.

The best signatures for most applications are those associated exclusively with fire and found in a wide variety of fuels. Fuel-specific signatures, such as the release of hydrogen chloride from polyvinyl chloride (PVC) wire insulation, may be particularly valuable in telecommunications facilities, but they may be of little use for general-purpose applications. Individual signatures are discussed below.

Aerosol Signatures

The process of combustion produces very large numbers of solid and liquid particles, ranging in size from 5×10^{-4} to 10 microns (μm). These particles, suspended in air, are called *aerosols.* The characteristics of smoke aerosols produced in a fire depend on the composition of the fuel, the combustion state (smoldering or flaming), and the amount of air available.

Aerosols resulting from fire actually represent two different fire signatures: invisible and visible. Particles less than 0.3 μm do not scatter light efficiently and are therefore classified as invisible. The larger particles do scatter light and are classified as visible aerosols. Smoke aerosols may change with respect to their particle size distribution. Smoke particles or droplets can collide and adhere to each other. Smoke may coagulate, become deposited on surfaces, and settle out by sedimentation over time.

Invisible aerosols are among the earliest appearing fire signatures and are produced at very low energy levels from the fire. Invisible aerosols can be detected through air sampling systems such as VESDA (very early smoke detection apparatus) or incipient fire detection systems.[6] Larger smoke aerosols can be detected by light-scattering, photoelectric, or ionization detectors. For a discussion of the operating principles of these detectors, see Section 14, Chapter 2, "Automatic Fire Detectors," and the *National Fire Alarm Code® Handbook.*[7]

Additional information on smoke aerosols can be found in the *SFPE Handbook of Fire Protection Engineering.*[8]

Energy Release Signatures

There are two types of energy release signatures: radiative and convective energy release.

Radiative Energy Release Signatures. Throughout its course, fire continuously releases energy into the surrounding environment, producing several detectable signatures. The earliest detectable energy signature is radiated energy. Radiation is emitted across a wide range of wavelengths:

- Ultraviolet (0.10–0.35 μm)
- Visible (0.35–0.75 μm)
- Infrared (0.75–22.00 μm)

The specific wavelength of radiation from a heated material is highly dependent on the characteristics of the material itself. Ultraviolet fire signatures appear in flames as emission from hydroxyl (OH) ions, CO_2, and CO in the 0.27–0.29 μm range.[9] Devices often respond to both ultraviolet and infrared signatures. Video fire detection systems are being developed that block visible light and only pass infrared to the video camera. The detection principle is based on an increase in the area emitting infrared versus time. Curves have been developed such that fires involving different fuels can be recognized.[10]

Infrared emissions from hydrocarbon fuels (with the exception of acetylene and other highly unsaturated hydrocarbons) are particularly strong in the 4.4 μm region due to CO_2 and in the 2.7 μm region due to water vapor.[11] Infrared detectors employ sensors designed to respond to infrared over narrow ranges associated with these frequencies.

Radiant energy sensing devices are generally limited to line-of-sight applications with a field of vision generally represented by a cone.* The size of fire that can be detected is a function of the distance between the detector and the radiant energy source. Because radiation intensity decreases as the square of the distance from the source, detectors generally need to be placed relatively close to the area being protected.

Convective Energy Release Signatures. Convective energy from a fire rises toward the ceiling, resulting in increased air temperature at ceiling-mounted heat detectors. The response time for heat detectors depends on the heat release rate of the fire, the distance between the fire and the ceiling, and the thermal response characteristics and exact location of the detector. The thermal response characteristics relate to the time that it takes for the detector to reach the temperature of the surround-

*Infrared sensors, however, may respond to surfaces that are heated by fires not in the direct line of sight.

ing hot gases. This time is called *thermal lag*. Detectors having low mass and high surface area respond to a given fire more quickly than detectors with high mass and low surface area.

Detectors designed to respond to convected thermal energy may activate at a fixed temperature or a specified rate of rise in temperature. If such detectors are located too far below the ceiling, they will be outside of the ceiling jet and will not respond.

Gas Signatures

A fire may produce several different gases. The type and production rate of gases produced in fires depends on the fuel composition, fire size, ventilation conditions, and burning mode.

Carbon-containing fuels produce CO and CO_2. Well-ventilated, flaming fires involving such fuels generally yield 100 to 1000 times more CO_2 than CO. Conversely, for underventilated or smoldering fires of carbonaceous fuels, the amount of CO_2 and CO produced may be similar. In addition to CO_2 and CO, hydrocarbon fuels also produce a variety of gases containing carbon, hydrogen, and oxygen, such as formaldehyde (HCHO) and acrolein (CH_2CHCHO).

Other gases produced by carbonaceous fuels depend on the presence of other elements in the fuel. For example, fuels that contain chlorine, such as polyvinyl chloride (PVC), produce hydrogen chloride (HCl) and chlorine gas (Cl_2). Fuels that contain nitrogen, such as wool and polyurethane, produce hydrogen cyanide (HCN), ammonia (NH_3), and nitrogen oxide compounds (NO_x). Sulfur-containing fuels produce sulfur dioxide (SO_2) and hydrogen sulfide (H_2S).

Estimating the concentration of selected gases from fires requires knowledge of the yield of each gas of interest and the total mass loss from the fuel involved in the fire. The yield is defined as the ratio of the mass of each gas generated per unit of fuel mass consumed. Yield factors for CO and CO_2 are most available for flaming, well-ventilated fires.[12] The availability of yield factors for other gases, nonflaming fires and underventilated fires are relatively sparse.

In addition to the ventilation and burning mode, the rate of production of any particular gas in a fire is affected by the size of the fire, expressed in terms of the heat release rate of the fire. In general, the rate of production of a particular gas from a well-ventilated, flaming, 500 kW fire is five times that from a well-ventilated, flaming, 100 kW fire.

Currently, gas sensors are used primarily for industrial safety applications, that is, to detect the release of a particular chemical. Some manufacturers have considered incorporating CO and CO_2 sensors in fire detectors.

Other Fire Signatures

Although the human body is well designed to feel heat and smell smoke, some evidence suggests that sounds associated with a burning fire can be the first cues received. Sounds caused by fire arise from a variety of causes such as nonuniform expansion of heated materials, boiling of trapped moisture, and bursting of gas bubbles. Experiments have been conducted to demonstrate the feasibility of using acoustic signatures of fire as the bases for fire detection.[13,14]

The human nose recognizes an odor of smoke by detecting a group of airborne gases and particles and associating that array of gases with a particular source. Some individuals are able to distinguish between different fuels producing the smoke, for example, burning leaves versus burning electrical insulation. Currently, artificial noses are used in some industrial process control applications, such as to determine when coffee beans have been sufficiently roasted or to detect spoiled food. However, current efforts to develop an artificial nose for fire detection are limited to research activities.[15]

Multiple Signature Detection

An emerging technology addresses the problem of unwanted alarms and improving response time to unwanted fires. Chemical sensors, for example, are being investigated to detect fire precursors.[16] Considerable research has been conducted on using combined gas/fire signatures for fire detection. Combining CO and CO_2 sensors and evaluating the CO/CO_2 ratio has been shown to be an effective means for detection of fire.[17] Additionally, CO/CO_2 concentrations have been used to discriminate between smoldering and nuisance fires.[18] Experiments have also been conducted using light obscuration; temperature; CO, CO_2, and O_2 concentrations; and signals from metal oxide sensors. By employing neural network and statistical methods, a system was developed to distinguish between fire and nonfire sources. Flaming and nonflaming fires could also be differentiated.[19,20]

Data on the response of individual sensors in full-scale fire tests has been analyzed to explore the benefits of multi-sensor detectors. This includes residential applications with commercial smoke detectors and CO[21] and combined optical, thermal, and CO sensors.[22] Analysis of the data from the Home Smoke Alarm Project[23] resulted in suggested algorithms involving the magnitude and rate of rise of several combinations of temperature, CO_2, and commercial smoke alarms. Similarly, data from experiments involving shipboard fire scenarios was analyzed to explore the benefits of the response of combinations in the signal and rate of rise of CO, CO_2, and commercial smoke alarms.[24,25]

SUMMARY

A variety of technologies exist for detecting the products of combustion generated at different stages of fire growth and spread. These technologies are based on detecting one or more unique fire signatures and have been growing in sophistication as the fire community becomes more adept at measuring fire and its effects.

Chapter 7

Theory of Fire Extinguishment

Revised by

Hong-Zeng Yu ❏ Jeffrey S. Newman

Chapter Contents

Mechanisms for Affecting the Combustion Process
Extinguishment with Water
Extinguishment with Aqueous Foams
Extinguishment with Water Mist
Extinguishment with Inert Gases
Extinguishment with Halocarbon Agents
Extinguishment with Dry Chemical Agents
Special Cases of Extinguishment

Key Terms

actual delivered density (ADD), aqueous foam, automatic sprinkler system, carbon dioxide, chain reaction, combustion, dry chemical agent, dry ice, flame, flammable liquid, halocarbon agent, inert gas, premixed combustion, pre-wetting density (PWD), pyrolysis, required delivered density (RDD), water mist

One or more of the following mechanisms—more often, several of them simultaneously—can be used to extinguish a fire:

- Physically separating the combustible substance from the flame
- Removing or diluting the oxygen supply
- Reducing the temperature of the combustible or of the flame
- Introducing compounds that modify the combustion chemistry

For example, when water is applied to a fire of a solid combustible burning in air, several extinguishing mechanisms are involved simultaneously. The solid is cooled by contact with water, causing its rate of pyrolysis, or gasification, to decrease. The gaseous flame is cooled, causing a reduction in heat feedback to the combustible solid and a corresponding reduction in the endothermic pyrolysis rate. Steam is generated, which, under some confined conditions, may prevent oxygen from reaching the fire. Water in the form of fog may also block radiative heat transfer.

As another example, consider the application of a blanket of aqueous foam to a burning pool of flammable liquid. Several mechanisms may operate. The foam prevents the fire's radiant heat from reaching the surface and supplying the needed heat of vaporization. If the fire point of the flammable liquid is higher than the temperature of the foam, the liquid is cooled and its vapor pressure decreases. If the flammable liquid is water soluble, such as alcohol, then, by a third mechanism, it will become diluted by water from the foam, and the vapor pressure of the combustible will be reduced.

As yet another example, when dry chemical is applied to a fire, the following extinguishing mechanisms may be involved:

- Chemical interaction with the flame
- Coating of the combustible surface
- Cooling of the flame
- Blocking of radiative energy transfer

Ideally, any fully successful theory of fire extinguishment should be able to predict the quantity and rate of application of the extinguishing agent needed for a given fire. Such a theory would be better than empirical measurements that yield the same information, because the empirical data would be fully reliable only in circumstances identical to those employed in the empirical testing. Furthermore, the theory would provide guidance for improvement of extinguishment performance.

Unfortunately, the agents mentioned above—water, foam, and dry chemical—each work by a combination of several mechanisms and the relative importance of the various contributions varies with circumstances. The degree of complexity resulting from each situation, as well as other

Dr. Hong-Zeng (Bert) Yu is a principal scientist and a technical team leader in fire suppression at FM Global. His primary work focus is research and development in water-based fire protection.

Jeffrey S. Newman is an assistant vice-president and principal engineer for the FM Global Research Campus. He is currently responsible for oversight of the campus infrastructure, including development, operation, and maintenance of technology systems.

problems, has up to now prevented completion of a quantitative fundamental theory of extinguishment action. However, much is known about the various extinguishment modes, and this knowledge is outlined herein. A more detailed treatment can be found in Friedman.[1]

MECHANISMS FOR AFFECTING THE COMBUSTION PROCESS

Much scientific information has been developed about the combustion process, the understanding of which is central to the understanding of fire extinguishment. For details, one may refer to Section 2, Chapter 1, "Physics and Chemistry of Fire," and the texts by Friedman,[1] which is rather elementary; Drysdale[2] and Glassman,[3] which are more advanced; or Strehlow,[4] which is the most advanced. Only combustion concepts especially relevant to fire extinguishment are presented in this chapter. These relevant concepts include combustion, flaming, pyrolysis, and chain reactions.

Combustion, Flaming, and Pyrolysis

The term *combustion* usually refers to an exothermic, or heat-producing, chemical reaction between some substance and oxygen. The concern in fire protection is generally with the type of combustion reactions between various materials and the oxygen of the air that involves a flame. A *flame* is a gaseous oxidation reaction that (1) occurs in a region of space much hotter than its surroundings and (2) generally emits light. Familiar examples include the yellow flame of a candle and the blue flame of a gas burner. When a solid such as a match or candle burns, a portion of the heat of the gaseous flame is transferred to the solid, causing the solid to vaporize (Figure 2.7.1). This vaporization can occur with or without chemical decomposition of the molecules. If chemical decomposition occurs, the process is called *pyrolysis.*

Flaming combustion requires a high temperature, and the chemical reactions must proceed fast enough at this high temperature to generate heat as fast as it is dissipated, so that the reaction zone will not cool down. If anything is done to upset this heat balance, such as introducing a coolant, it is possible that the combustion will be extinguished. It is not necessary for the coolant to remove heat as fast as it is being generated, because the combustion zone in a fire is already losing some heat to the cooler surroundings. In some cases, only a modest additional loss of heat is needed to tip the balance toward extinguishment (see Figure 7.3 in Friedman[1]).

Extinguishment can be accomplished by cooling either (1) the gaseous combustion zone or (2) the solid or liquid combustible. In the latter case, the cooling prevents the production of combustible vapors. This is probably the primary mode of action when a wood fire is extinguished by applying water.

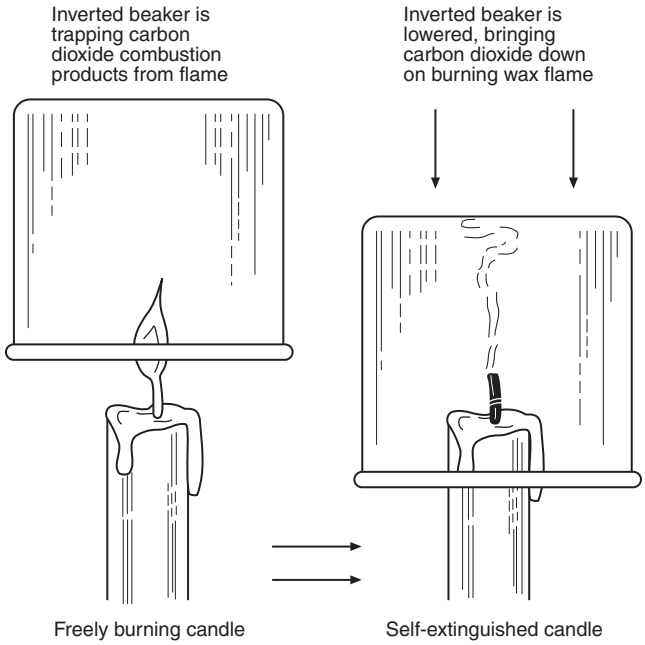

FIGURE 2.7.1 Flaming Combustion (Left) and Extinguishment by Its Own Combustion Products (Right) of a Wax Candle

As an alternative to removing heat from the combustion zone to slow the reactions, it is also possible to reduce the temperature of the flame by modifying the air that supplies the oxygen that feeds the flame. Air is 21 percent oxygen by volume, the remainder being almost entirely the inert gas nitrogen. The nitrogen, which is drawn into the flame along with the oxygen, absorbs heat, with the result that the flame temperature is much lower than it would be in a fire burning in pure oxygen. If additional nitrogen or some other chemically unreactive gas, such as steam, carbon dioxide, or a mixture of combustion products, were to be added to the air entering the flame, the heat absorbed by these inert molecules would cause the flame temperature to be even lower.

The flame temperature is so important because the rate of a key combustion reaction ($H + O_2 \rightarrow OH + O$) is very sensitive to temperature. A small decrease in temperature causes a disproportionately large decrease in the rate of this reaction, according to Arrhenius' law, which states that chemical reaction rates vary exponentially with temperature.

Chain Reaction

The symbol H denotes a free hydrogen atom, as contrasted with the ordinary stable form of hydrogen, H_2. Combustion consists of rapid *chain reactions* involving these hydrogen atoms and other active species, hydroxyl free radicals OH, and free oxygen atoms O. The sequence of reactions occurring in a hydrogen-oxygen flame is illustrated in Figure 2.7.2.

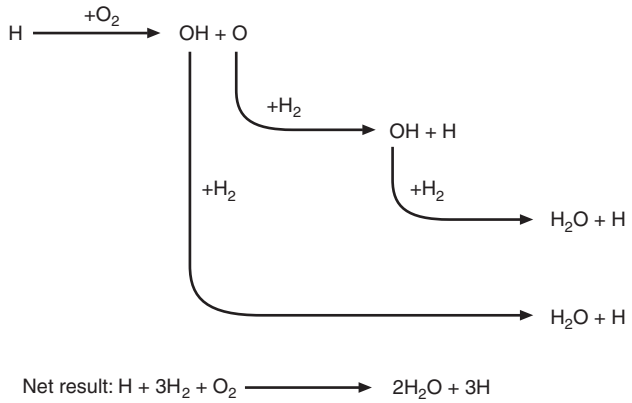

FIGURE 2.7.2 Chain Reaction Mechanism in a Hydrogen-Oxygen Flame

Figure 2.7.2 shows that a single H atom, when introduced into an H_2-O_2 mixture at an elevated temperature, will be transformed in a fraction of a millisecond to form two molecules of H_2O and three new H atoms. Each of these new H atoms can immediately initiate the same sequence, resulting in a branching chain reaction, which continues until the reactants are consumed. Then, the remaining H, O, and OH species recombine according to the reactions

$$H + O \rightarrow OH$$

and

$$H + OH \rightarrow H_2O$$

Similar chain reactions occur in flames of any hydrogen-containing species. Hydrogen is present in the vast majority of combustibles, except for metals and pure carbon.

The ability of hydrogen atoms to multiply rapidly in a flame depends, then, on the prevailing temperature in the flame, which is modified by heat loss or by inert gases, thus leading to extinguishment.

Hydrogen atoms or other active species may also be removed from the flame by purely chemical means—that is, by introducing a species capable of chemical inhibition, which will be discussed later in this chapter.

Accordingly, the following are two fundamental ways of reducing combustion intensity in a flame and ultimately causing extinguishment:

1. Reducing the flame temperature
2. Adding a chemical inhibitor to interfere with the chain reaction

Consider the effect of adding additional nitrogen to a fuel vapor-air mixture. Suppose the fuel vapor is methane, CH_4. Figure 2.7.3 shows that if more than about 35 percent additional nitrogen is added to a 9.5 percent methane-air mixture at 77°F (25°C), the resulting mixture is nonflammable. This nonflammability is caused by the reduction of flame temperature from about 3452°F (1900°C) to about 2192°F (1200°C), since the added nitrogen absorbs heat.

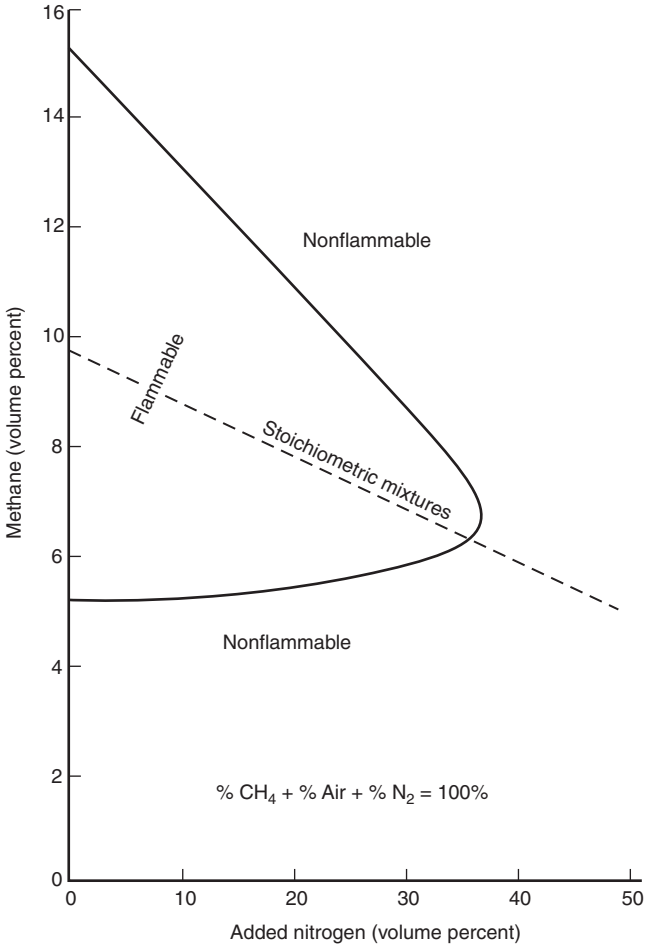

FIGURE 2.7.3 Limits of Flammability of Various Methane-Air-Nitrogen Mixtures at 77°F (25°C) and 1 atm (Source: M. G. Zabetakis, "Flammability Characteristics of Combustible Gases and Vapors," 1965[5])

But why is the flame unable to burn when its temperature is below 1200°C? This is not fully understood. If we had an ideal flame, burning in a place with no gravitational field (e.g., a space station), and also with negligible radiative heat loss, it is believed that there would still be a flammability limit, caused by the competition between chain-branching and chain-breaking chemical reactions. Chain-branching reactions are known to be much more temperature-sensitive than chain-breaking reactions; therefore, below a critical temperature, chain-breaking reactions will dominate and the flame can no longer burn.

However, a real flame, on earth, will be in a gravitational field, and when the dilution of the flame reduces the burning velocity to a value lower than the free-convective motions (buoyancy) of the burning region surrounded by colder gases, then the burning surface will be "strained" and disrupted, and extinguishment will result. Another effect is the radiative heat loss from the flame to the surroundings, which can cause instability when the rate of heat loss becomes a sufficient fraction of the rate of heat generation. The relative importance of the various effects for various flames has not been fully established yet.

For practical purposes, the measured flammability limits can be relied on.

Notice also from Figure 2.7.3 that a 9.5 percent methane-air-nitrogen mixture can be made nonflammable by adding not only nitrogen but also additional air or additional methane. Such additions would produce an excess of one of the reactants and, therefore, a dilution and reduction of flame temperature.

The foregoing discussion of flammability limits applies to *premixed combustion,* or combustion of a uniform mixture of fuel and air and possibly a third component. This is often the case for explosions, but fires are generally diffusion flames with buoyancy-induced large-scale turbulence rather than premixed flames. That is, a solid or liquid combustible is vaporizing, and air approaches the vapor cloud from the sides. The flame burns at the interface of the interdiffusing, turbulent combustible vapors and air. The hot turbulent combustion products then rise in a fire plume because of buoyancy.

A turbulent diffusion flame is clearly more complex than a premixed flame, but much the same principles apply to its extinguishment. If more inert gas is added to the air feeding a diffusion flame, extinguishment will occur when the temperature of the individual flamelets within the turbulent diffusion flame is reduced to about 2192°F (1200°C) or 2372°F (1300°C). However, another important way of extinguishing a diffusion flame over a solid or liquid is to cool the solid or liquid enough to interrupt the gasification process. If the gasification rate can be reduced to less than a few grams per square meter per second, the flame becomes unstable and can no longer sustain itself.

EXTINGUISHMENT WITH WATER

One might suppose that water is the most widely used extinguishing agent because of its low cost and ready availability, relative to other liquids. However, quite aside from cost and availability, water is superior to any other known liquid for fighting the majority of fires.

Characteristics of Water

Water has a very high heat of vaporization per unit mass, at least four times higher than that of any other nonflammable liquid. It is also outstandingly nontoxic; even a chemically inert liquid, such as liquid nitrogen, can cause asphyxiation. Water can be stored at atmospheric pressure and normal temperatures. Its boiling point—212°F (100°C)—is well below the 482°F (250°C) to 842°F (450°C) range of pyrolysis temperatures for most solid combustibles, and therefore evaporative cooling of the pyrolyzing surface is efficient. No other liquid, regardless of cost, can match these properties. However, water is not an absolutely perfect extinguishing agent. It does freeze below 32°F (0°C). It does conduct electricity. It can irreversibly damage some items, although, in many cases, it is practical to salvage water-damaged items. When applied in bulk or in sprays consisting of large droplets, water may not be effective for flammable liquid fires, especially flammable liquids that are insoluble in water and float on water, such as hydrocarbons. Water is not compatible with certain hot metals or certain chemicals. With fires in these materials, other agents, for example, aqueous foam, inert gases, environmentally-friendly halocarbons, and dry chemicals, are preferred.

Water may extinguish a fire by a combination of mechanisms—cooling the solid or liquid combustible; diluting water-soluble flammable liquids; cooling the flame itself; generating steam that prevents oxygen access; and as fog, blocking radiative transfer. Although all these mechanisms may contribute to extinguishment, probably the most important is cooling a gasifying combustible.

For a solid to burn, a portion of the solid must be at a high enough temperature so that pyrolysis occurs at a sufficient rate to maintain the flame. For most solids, this temperature is 572°F (300°C) to 752°F (400°C), and the pyrolysis rate must be a few grams per square meter per second. If even a small amount of liquid water, with its high heat of vaporization, can reach this region, the solid can be cooled sufficiently to reduce or stop the pyrolysis, and the flame will be extinguished. Even deep-seated fires can be suppressed in this way. Accordingly, water is the obvious agent of choice for burning solids.

Water as an Extinguishing Agent

The two most common means of applying water are by (1) a solid stream or spray from a hose and (2) spray from automatic sprinklers. The practical aspect of manual fire fighting and the use of sprinklers are discussed elsewhere in this handbook. From a scientific viewpoint, studies reviewed by Heskestad[6] and Rasbash[7] have investigated the minimum rate of water application to a burning solid surface that will cause extinguishment.

In an important paper by Magee and Reitz,[8] burning slabs of various plastics, horizontal and vertical, were simultaneously heated with radiant heaters and cooled with controlled water sprays. Extinguishment conditions were then determined. Figure 2.7.4 shows a linear relationship between the radiative heating rate and the water application rate required for extinguishment. The reciprocal of the slope of the line is found to be approximately the heat of vaporization of water, as theory would predict.

To extinguish burning polymethyl methacrylate (acrylic sheet), enough water must be applied to reduce the burning rate to less than about 4 g/m^2·sec. Depending on the intensity of the externally imposed radiative flux—up to 18 kW/m^2—a water application rate of 1.5 g/m^2·sec to 8 g/m^2·sec was required. This is a very small application rate of water. For extinguishment with no external radiative flux, it was only necessary to spray enough water so that the heat absorbed by its vaporization was 3 percent of the heat of combustion.

Experiments with other plastics and with wood cribs have given similar results; only a few grams per square meter per second of water must be applied to the burning surface to cause extinguishment, and the rate of heat absorption by the water is only a few percent of the rate of heat generation by the fire before water application.

The reason for this high efficiency is well understood. Consider a horizontal slab of polymethyl methacrylate, 0.3 m × 0.3 m, which is burning steadily on its top surface. Measurements[1] have shown that only about 12 percent of the energy

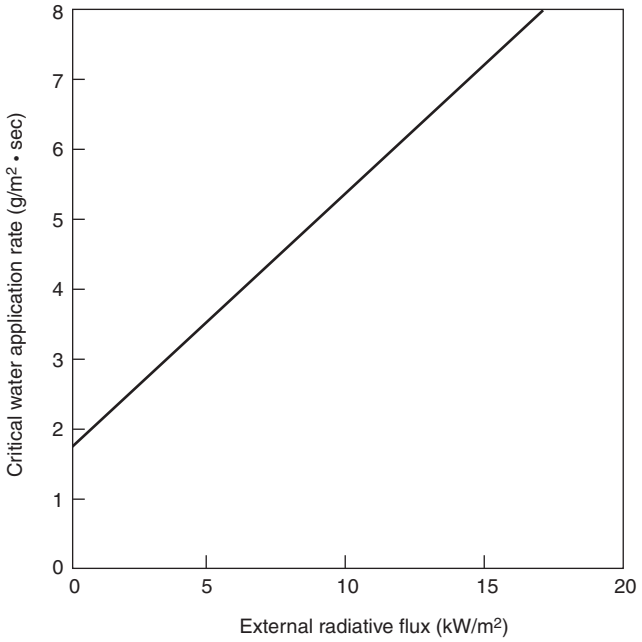

FIGURE 2.7.4 Water Application Rate Needed to Extinguish a Fire on a Vertical Polymethyl Methacrylate Sheet

released by combustion is transferred back to the surface. Of this energy arriving at the surface, primarily by radiation from the flame above, about 40 percent is reradiated from the hot surface to the surroundings, and only 60 percent of 12 percent, or 7 percent of the available combustion energy, is used to decompose and gasify the plastic. It is only necessary to apply enough water to the surface to drain off a substantial portion of this 7 percent of the combustion energy, and the rate of burning is then reduced to a point at which the flame can no longer sustain itself.

For combustibles arranged in warehouse rack-storage configurations, Yu et al.[9] found that the required water fluxes for fire extinguishment were greater than those obtained from the small-scale experiments described above. Fire suppression experiments were conducted by applying uniform water fluxes to the top of the entire storage array at different fire development stages. The experiments examined the fire suppression requirements for different storage heights. One of the combustibles investigated was corrugated paper cartons, for which the critical water flux for fire extinguishment per unit carton surface area exposed to water application was found to be 6 g/(m^2·sec). This is greater than the 2.7 to 5.5 g/(m^2·sec) reported by Heskestad for wood cribs.[6] Heskestad also reported that the critical water flux for wood crib fires and wood pallet fires is higher than that for wood slab fires. It appears that a combustible's morphology, configuration, and storage arrangement all affect the critical water flux for fire extinguishment due to the influence of heat feedback from the fire, even though the combustible in each case is made of the same base material. Note that the Magee and Reitz[8] experiments showed that a higher water flux was needed when there was a higher imposed radiant flux on the burning surface. In large-scale storage arrangements, burning fuel surfaces are exposed to elevated radiant flux levels from flames on nearby burning surfaces, which leads to a greater water flux requirement.

Of course, the evaporation of the water produces steam that dilutes the flame and reduces the flame temperature, causing some reduction in the rate of burning, but this effect is generally small (except when water is applied in mist form, as discussed in the section "Extinguishment with Water Mist") and need not be considered in a first-approximation model of the extinguishment process. It is interesting to note that in ignition experiments, a solid surface is progressively heated, with a gradual increase in the rate of pyrolysis, or gaseous decomposition, but it is not possible to ignite the vapors to obtain a self-sustaining flame until the pyrolysis rate reaches a certain minimum value. This is roughly the same value to which the pyrolysis rate must be reduced when water is applied to a burning surface to accomplish extinguishment.

In practical fire fighting, water must be applied at 10 to 100 times the rates used in the research described above because of the difficulty of delivering the water directly to the burning surface.

Water and Automatic Sprinklers

In the case of fire suppression by use of sprinklers at the ceiling, it is possible to calculate the fraction of the water droplets able to penetrate the fire plume and arrive at the burning surface beneath. Such a calculation is complex.[10] It is necessary to know the distribution of heat release rate relative to the location of nearby ceiling sprinklers and several different water-spray distribution functions. These include the angular distributions of droplet size, water flux, and droplet velocity at or near the sprinkler deflector, which are usually unknown and have to be determined indirectly by matching the calculated results with spray data further downstream where measurements are feasible. As a result, such calculations to date always have an uncertainty regarding the actual starting condition of the sprinkler spray. Some information on droplet size distribution is available from previous specialized studies.[11] The droplet size distribution of the water depends not only on the sprinkler design but also on the pressure drop across the sprinkler. For geometrically similar sprinklers, the mean droplet size varies inversely with the cube root of the pressure drop and is proportional to the two-thirds power of the orifice diameter. The droplet size also depends on the surface tension of the water, which could be modified with additives. Once accurate starting conditions are available, the calculation will then take into account the aerodynamic drag on the downward-moving droplets encountering the upward-moving fire gases, and calculate the change in motion of the fire gases because of the downward momentum of the water spray. Droplet evaporation and cooling of the fire gases are included in the calculation.

The effectiveness of sprinkler sprays penetrating the fire plume can be quantified by measurements as a practical alternative to the preceding calculation. For instance, Figure 2.7.5 shows an apparatus developed to measure the water fluxes generated by sprinkler sprays under a fire plume which reproduces

FIGURE 2.7.5 An ADD-PWD Apparatus for Measuring the Effectiveness of Sprinkler Spray Penetration Through the Fire Plume (Source: Copyright © 2008 FM Global. Reprinted with permission. All rights reserved.)

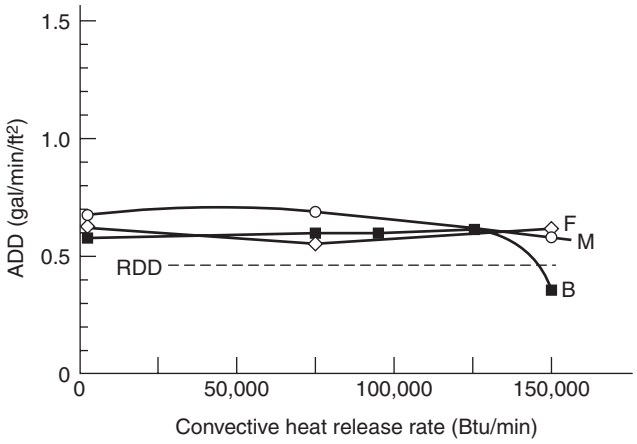

FIGURE 2.7.6 ADD-RDD Concept (Source: *ESFR Update,* Vol. 2, No. 2. Copyright © 1985 FM Global. Reprinted with permission. All rights reserved.)

the thermal flow environment of a realistic fire of interest.[12] Measured water fluxes include *actual delivered density* (ADD), defined as the average water flux that has penetrated the fire plume in the fire area and the *pre-wetting density* (PWD), defined as the average flux just outside the fire area. Basically, the apparatus consists of a movable ceiling whose height can be adjusted easily, a fire plume generator, and a set of instrumented water collection pans arranged at the desired locations. Such apparatus have been used by fire sprinkler developers and approval laboratories.

Suppression of fires in certain arrays of solid combustibles by overhead water sprays has been investigated by measuring the water flux that must be delivered to the top surface of the array in order to achieve a lasting decay in the fire heat release rate. This measured fire suppression water flux is defined as the *required delivered density* (RDD).[13] The RDD is related to the critical water flux for fire extinguishment per unit combustible surface and the total combustible surface area for water exposure.[9] Suppression in this case can be achieved if the ADD is always greater than the RDD associated with a particular heat release rate growth and decay history. Figure 2.7.6 illustrates the ADD-RDD concept.[14] Prototype sprinklers F and M achieve fire suppression when the sprinkler is located directly over the fire source at about 2.7 m clearance, but prototype B does not. In this particular illustration, Sprinkler B's ADD drops below the RDD when the fire grows to 150,000 Btu/min (2640 kW). As a result, Sprinkler B cannot suppress the fire. The other two sprinklers suppress the fire because the corresponding ADD is always greater than the RDD before the fire intensity decreases.

When ADD is less than RDD, the fire will spread beyond its origin if the water flux applied to its surrounding area is not enough to sufficiently wet the combustibles outside the fire area. To control fire spread, an adequate PWD has to be applied. The lower the ADD, the greater is the fire intensity, so a higher PWD is required to stop or minimize fire spread beyond the fire origin.

For a fire hazard, a comparable fire damage area could result from different combinations of ADDs and PWDs. However, the higher ADD combination tends to provide a better overall fire control result, in terms of total amount of combustibles burned, building structure damage, smoke damage, and water damage.

In some cases—for example, a purely gaseous fire—water may extinguish the fire by cooling the flame rather than the source of the fuel vapor. The theory of this action has been discussed previously.

For a pool fire of a flammable liquid with a high flashpoint (e.g., diesel oil), water can be effective by reducing the temperature of the liquid below its flashpoint. However, water impinging on the flammable liquid with high velocity can cause burning liquid to be scattered, increasing the fire intensity. Water applied as a foam or as a fine mist avoids this situation.

EXTINGUISHMENT WITH AQUEOUS FOAMS

Also see Section 17, Chapter 4, "Foam Extinguishing Agents and Systems."

Aqueous Foams and Flammable Liquid Fires

Aqueous foam agents are principally used for fighting flammable liquid fires. If the flammable liquid is lighter than water and is insoluble in water, then application of water would simply result in the flammable liquid floating on it and continuing to burn. If the flammable liquid is an oil or fat, the temperature of which is substantially above the boiling point of water, then the water will penetrate the hot oil, turn into steam below the surface, and cause an eruption of oil that will accelerate the burning rate and possibly spread the fire. Foams are the primary tools for fighting fires that involve substantial quantities of petroleum products, such as those found at refineries, tankers, and storage areas.

If the flammable liquid is water soluble, such as alcohols, then the addition of sufficient water will dilute the liquid to the

point where it is no longer flammable. If there is a deep pool of water-soluble flammable liquid rather than a shallow spill, however, the time required to obtain sufficient dilution might be so great that an aqueous foam would be a better extinguishing agent. If the nature of a liquid is unknown, aqueous foam might be chosen instead of the direct application of water.

Another important application of aqueous foam agents is on liquids or solids that are burning in difficult-to-access spaces, such as a room in a basement or the hold of a ship. The foam is used to flood the compartment completely.

Characteristics of Fire-Fighting Foam

Fire-fighting foam is a mass of bubbles formed by various methods from aqueous solutions of specially formulated foaming agents. Because foam is much lighter than any flammable liquid, it floats on the liquid, producing an air-excluding, cooling, continuous layer of vapor-sealing, water-bearing material that can halt or prevent combustion.

Fire-fighting foams are formulated in several ways for fire-extinguishing action. Some foams are thick and viscous, forming tough heat-resistant blankets over burning liquid surfaces and vertical areas. Other foams are thinner and spread more rapidly. Some foams are capable of producing a vapor-sealing film of surface-active water solution on a liquid surface, and some are meant to be used as large volumes of wet gas cells for inundating surfaces and filling cavities. There are various methods for applying foams, which are fully described in Section 17.

The use of foam for fire protection requires attention to its general characteristics. Foam breaks down and vaporizes its water content when under attack by heat and flame. Therefore, it must be applied to a burning surface in sufficient volume and rate to compensate for this loss and to provide an additional amount to guarantee a residual foam layer over the extinguished portion of the burning liquid. Before starting to apply foam to a large fire, a sufficient amount of foam concentrate to do the job must be accumulated. Nothing will be accomplished by putting out only part of a fire and then running out of foam, because the fire will build back to its original intensity.

Foam is an unstable air-water emulsion and can be broken down easily by physical or mechanical forces. Certain chemical vapors or fluids can destroy foam quickly. When certain other extinguishing agents are used in conjunction with foam, severe breakdown of the foam can occur. Turbulent air or violently uprising combustion gases can divert light foam from the burning area.

There is no theoretical basis available to serve as a guide to the needed rates of application of the various types of foams in different situations. The guidelines come from experience or from empirical tests. One useful laboratory measure of foam effectiveness is to fill a graduated cylinder with foam and observe the time required for a certain fraction of the water in the cylinder to drain to the bottom. The more stable the foam, the slower it will drain.

Clearly, the time for collapse of a foam layer should be greater than the time required to coat the entire surface of a large spill with foam. Thus, a basis is available for calculating the necessary rate of application. Of course, fire causes foam to break down at a greater rate than indicated by the drain test in a cylinder; therefore, empirical information is still needed.

Another laboratory tool useful for formulating film-forming foams is the measurement of surface tension of the foam solution, F, the flammable liquid, L, and the interfacial tension between the two liquids, FL. The film will spread over the surface only if F plus L is greater than FL.

EXTINGUISHMENT WITH WATER MIST

There has been recent interest in developing equipment for applying a fine mist of water to a fire as an alternative to halogenated agents. The following three methods can be used to distribute water mist:

1. Fixed installation, in which a fine mist is used to inert a compartment in which a fire may occur, perhaps in a concealed and unpredictable location
2. Fixed spray nozzles positioned around or above the site of an anticipated fire
3. A portable extinguisher using a fine spray or mist

Application Mechanisms

Four mechanisms by which water mist application might extinguish a flame are as follows:

1. The mist droplets, while evaporating, remove heat, either at the surface of the combustible or within the gaseous flame. This cooling can cause extinguishment, as discussed previously.
2. The fine droplets evaporate in the hot environment even before reaching the flame, generating steam that dilutes the oxygen percentage in the air approaching the flame, thus causing extinguishment by a mechanism similar to that of an inert gas—for example, carbon dioxide.
3. The mist blocks radiative heat transfer between the fire and the combustible.
4. The induced gas current helps overall cooling and dilution and even blows off the flame from the burning surface.

In those tests in which mists have successfully extinguished fires, some combination of the above effects appears to have occurred in each case.

In regard to the first mechanism, it is much easier for a large drop to reach a burning surface than for a very fine drop (mist), which would tend to be blown away from the surface by the pyrolysis gases, if indeed fine droplets could get through the upward velocity of the fire plume to the vicinity of the underlying surface in the first place. This difficulty disappears when the fine mist is directed at the burning surface with high momentum.

It has been shown experimentally that as the droplet size decreases, less water flux is required to extinguish a flammable liquid pool fire, following the typical trend shown in Figure 2.7.7.[7,15] Qualitatively, the trend may be explained as follows. The smaller the droplets, the more readily they are vaporized to cool the fire gases and pool surface. As droplets become smaller, they more nearly follow the gas current. Therefore, when nozzles are pointed toward a flammable liquid pool, the propensity

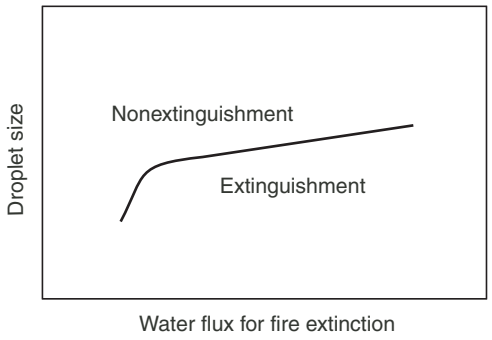

FIGURE 2.7.7 Typical Relationship Between Droplet Size and Required Water Flux for Fire Extinguishment for Non-Water-Soluble Flammable Liquids (Sources: D. J. Rasbash, "The Extinction of Fire with Plain Water: A Review," 1986[7]; M. M. Braidech, J. A. Neale, A. F. Matson, and R. E. Dufour, "The Mechanism of Extinguishment of Fire by Finely Divided Water," 1955.[15]

of droplets to splatter on or penetrate into the pool surface decreases as the drop size decreases. As a result, finer droplets have a lower tendency to cause sputtering on the pool surface and emulsification in a non-water-soluble pool. The pool surface sputtering, in turn, tends to produce flammable liquid droplets above the pool and thus makes the pool fire more difficult to extinguish. For a hot non-water-soluble flammable liquid pool whose temperature is much higher than 212°F (100°C), emulsification may also make fires more difficult to extinguish. The large temperature difference between the immersed droplets and the flammable liquid could initiate bubbling nucleation in the immersed water droplets; the burst of the bubbles as they rise in the pool releases fine flammable liquid droplets above the pool and results in more challenging fires. Consequently, higher water fluxes are required for larger droplets to compensate for the fire intensification.

In regard to cooling the flame gases rather than the burning surface, a sufficiently high concentration of water mist in the approaching air must be achieved. This is estimated to be at least 15 percent water mist by weight in air. This can be achieved if the mist is sprayed directly at the flame, but if the mist is sprayed in some random direction into a compartment, the buildup to a high concentration is hampered by the settling of some mist droplets to the floor of the compartment. Table 2.7.1 shows settling times of water droplets of various sizes.

The settling rate is negligible (assuming the goal is extinguishment in a few tens of seconds) for droplets finer than about 10 microns diameter. It is very difficult to produce droplets this fine with conventional atomization methods.[17] However, it is possible to produce mist in the 5 to 10 micron range with gas-assist nozzles by substituting steam for the air or inert gas conventionally used in this type of nozzle. Mawhinney et al.[18] classify mists as Class 1 sprays (at least 10 percent of the spray less than 100 microns) or Class 2 sprays (at least 10 percent of the spray less than 200 microns). The bulk of the droplets in sprays just meeting the Class 1 requirement settle out in a very few seconds, according to Table 2.7.1; thus, it is very difficult

TABLE 2.7.1 Settling Velocities of Water Droplets

to build up an adequate concentration in the compartment for droplets in this range. Such mist spray classifications were adopted in the 1996 edition of NFPA 750, entitled *Standard for the Installation of Water Mist Fire Protection Systems.* However, the classifications were dropped in its 2000 edition.

The blockage of radiation by a mist will often be effective in reducing the intensity or spread rate of a fire, but will rarely be sufficient in itself to extinguish a fire.

Water mist sprays induce gas currents by transferring the droplet momentum to the surrounding gases. The gas currents help extinguishment by cooling the burning surfaces and diluting fuel vapor. The gas currents may be so strong that flames are displaced or even blown off from the burning surface. This mechanism is more pronounced for mist sprays produced with gas-assist atomizers than with single-fluid nozzles.

Water Mist Effectiveness

In summary, the effectiveness of a fine mist depends on (1) the momentum and direction of the spray relative to the fire, (2) droplet size, and (3) the compartment geometry and size and the size and location of openings. In general, for enclosure fires protected with total flooding water mist systems, the effectiveness of the water mist protection increases with increasing fire size and decreases with increasing enclosure and opening size. On the other hand, a fire in an open space becomes more difficult to extinguish as the fire becomes larger. Further discussion of water mists can be found in Mawhinney et al.[18] and the International Conference on Water Mist Fire Suppression Systems.[19]

See also Section 16, Chapter 8, "Water Mist Fire Suppression Systems."

EXTINGUISHMENT WITH INERT GASES

Extinguishment Mechanism of Inert Gases

Water acts to extinguish fires primarily by cooling, although the formation of steam helps to dilute the concentration of oxygen. On the other hand, inert gases act to extinguish a fire primarily by dilution. Carbon dioxide is the most commonly used inert gas, although nitrogen or steam could be used. Theoretically, helium, neon, or argon could be used, but they are expensive, and there is no reason to use them except in certain special cases, such as magnesium fires.

TABLE 2.7.2 Minimum Required Volume Ratios of Carbon Dioxide or Nitrogen to Air That Will Prevent Burning of Various Vapors at 77°F (25°C)

	Carbon Dioxide		Nitrogen	
Vapor	CO_2/Air	$\%\ O_2$	*Extra* N_2/Air	$\%\ O_2$
Carbon disulfide	1.59	8.1	3.00	5.2
Hydrogen	1.54	8.2	3.10	5.1

Methane	0.33	15.7	0.63	12.9

Source: R. Friedman, *Principles of Fire Protection and Physics,* 3rd ed., 1998.[1]

Table 2.7.2 presents the minimum proportions of carbon dioxide or nitrogen gas that if added to air will form an atmosphere in which various vapors will not burn. On a volume basis, carbon dioxide is substantially more effective than nitrogen. Note, however, that a given volume of carbon dioxide is 1.57 times as heavy as nitrogen (44 to 28 molecular weight ratio), so the two gases have nearly equal effectiveness on a weight basis. Either gas in sufficient quantity will prevent the combustion of anything except certain metals or unstable chemicals such as pyrotechnics, solid rocket propellants, hydrazine, and so on.

If available, steam also can be used as an inert extinguishing agent. The percentage by volume required is intermediate between that required for carbon dioxide and for nitrogen.

Table 2.7.2 shows that the required addition of either carbon dioxide or nitrogen reduces the oxygen level to a point at which exposed humans will suffer undesirable effects. In the case of carbon dioxide, an additional serious physiological effect will occur at the concentrations required to extinguish a fire.

Table 2.7.2 refers only to vapors, but the data are relevant to liquids or solids because they burn only by vaporizing or pyrolyzing. Accordingly, application of an inert gas can extinguish the flame over a liquid or solid. However, if the inert gas dissipates after several minutes, because, for example, the enclosure is not airtight, it is possible that a glowing ember or hot metal could reignite the fire. Reignition is common for a deep-seated fire, such as what might occur in upholstered furniture or in a carton of documents.

Forms of Carbon Dioxide

Some explanation of the physical forms of carbon dioxide is appropriate. Carbon dioxide is unusual in that it can exist only as a gas or solid at normal atmospheric pressure, but not as a liquid. Figure 2.7.8 shows the phase diagram of carbon dioxide.

The solid form of carbon dioxide, commonly known as *dry ice,* at atmospheric pressure, exists only below –110°F (–79°C),

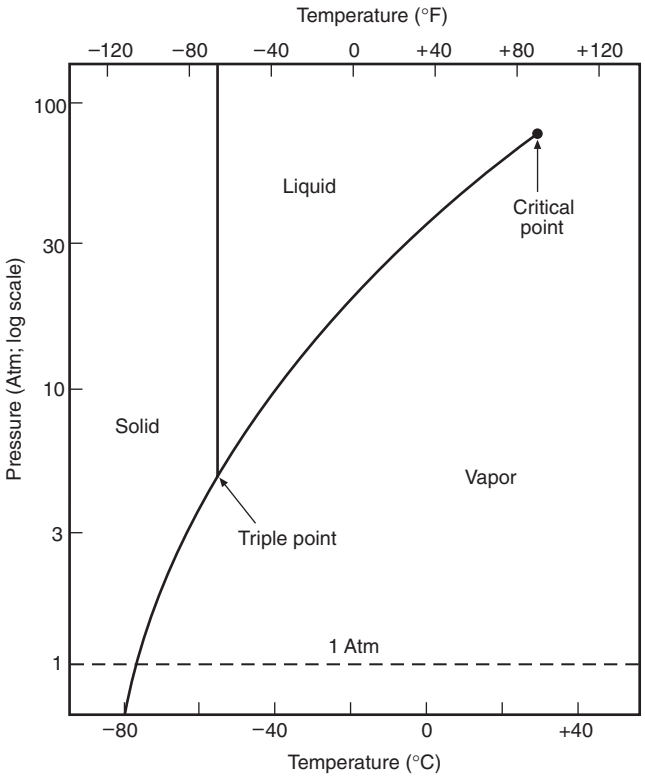

FIGURE 2.7.8 Phase Diagram of Carbon Dioxide

at which temperature it undergoes sublimation directly to vapor, without melting. However, liquid carbon dioxide can exist at elevated pressures, as long as the temperature is above –71°F (–57°C) and the pressure is above 5.2 atm. This temperature and pressure condition is known as the triple point of carbon dioxide because it is the only condition at which solid, liquid, and vapor can coexist.

Liquid carbon dioxide can be kept in a pressure vessel at any temperature between –71°F (–57°C) and 88°F (31°C) (the critical temperature). Above the critical temperature, there will no longer be a liquid-gas interface in the pressure vessel; therefore, the fluid in the vessel would be a gas. A pressure vessel at 70°F (21°C) containing liquid carbon dioxide would be at a pressure of 58 atm, which is the vapor pressure of carbon dioxide at that temperature. This pressure is used to expel liquid carbon dioxide from a cylinder in fire fighting. The cylinder normally would contain an internal dip tube reaching to the bottom so that liquid rather than vapor would be discharged. As the liquid droplets emerge from a nozzle into the lower-pressure environment, instantaneous evaporation occurs, with evaporative cooling of the residual liquid in each drop. This process causes solidification of the residual portion into dry ice particles at –110°F (–79°C). If the liquid was originally at 70°F (21°C), about 75 percent of the discharged liquid would have evaporated and about 25 percent would have been converted to dry ice particles.

Some of the dry ice particles might impinge on a combustible surface and have a cooling effect. However, because the heat of sublimation of carbon dioxide is only about one-fourth the heat

of vaporization of water and because only about one-fourth of the carbon dioxide discharged is converted to dry ice, the cooling effect on a hot surface is only about one-sixteenth that produced by water discharged at an equal rate (on a mass basis).

In comparing carbon dioxide and nitrogen, carbon dioxide has the advantage that it can be stored in a cylinder as a liquid at a relatively moderate pressure of 58 atm at 70°F (21°C), whereas nitrogen at the same temperature must be stored as a gas, usually at about 140 atm. A given size of cylinder at 70°F (21°C) and these pressures could hold about three times as large a volume of carbon dioxide as nitrogen (measured after expansion, at atmospheric conditions). Nitrogen also could be stored for short periods more compactly as a cryogenic liquid at –321°F (–196°C) and 1 atm. However, long-term storage results in continuous loss of nitrogen. As a result of these factors, carbon dioxide is used more commonly than nitrogen as an inerting gas.

Semipermeable membranes have been developed that can inexpensively separate the oxygen and nitrogen of the air. Such systems make it practical in certain cases to provide permanent nitrogen-inerting of hazardous spaces that do not require human presence. A reduction of the oxygen percentage in the air from 21 percent to 10 percent by volume would make fires and explosions impossible, except for a few special gases—for example, hydrogen, acetylene, or carbon disulfide, which would require greater dilution.

EXTINGUISHMENT WITH HALOCARBON AGENTS

Halocarbon agent extinguishing systems are a relatively recent innovation in fire protection, but despite this, the first generation of these agents no longer can be produced as of January 1, 1994, by international agreement due to the effect of these first-generation agents on depletion of the earth's ozone layer. As a result, a new generation of halocarbon agents has been developed that not only is compatible with the ozone layer but also less likely to be involved in global warming. For additional details on this topic, see Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems," and Section 17, Chapter 7, "Application of Gaseous Agents to Special Hazards Fire Protection."

Halocarbons are chemical derivatives of methane (CH_4) or ethane (CH_3-CH_3), in which some or all of the hydrogen atoms have been replaced with fluorine, chlorine, bromine, or iodine atoms, or by some combination of these halogen elements. These agents are liquids when stored in pressurized tanks at normal temperatures, but most of them are gases at atmospheric pressure and normal temperatures.

Halocarbon agents can be used for fire applications such as those discussed previously for carbon dioxide and other inert gases. For example, they can be used on electrical fires, in cases where water or dry chemicals would cause damage, or for inert-gas flooding of compartments.

Halogenated agents have the following two principal advantages over carbon dioxide:

1. Certain halogenated agents are effective in low volumetric concentrations such that sufficient oxygen remains in the air after compartment flooding for comfortable breathing.
2. For several halogenated agents, only partial vaporization occurs initially during flow from a nozzle, allowing the liquid to be projected farther than carbon dioxide.

The drawbacks of using even the new generation of halocarbon agents relate to agent toxicity and the toxicity and corrosivity of agent decomposition products during a fire.

Of the first-generation halocarbons, Halon 1301 (bromotrifluoromethane) was by far the most commonly used in fire protection because it has the lowest toxicity as well as the highest effectiveness on a weight basis, including the highest volatility, which is desirable for flooding applications. If a halocarbon liquid was needed for direct application to a burning surface to accomplish cooling as well as inerting of the nearby region, however, a less volatile compound, such as Halon 1211 (bromochloro-difluoromethane) or Halon 2402 (dibromotetrafluoroethane), was the first-generation agent preferred.

Physical Properties and Inerting Capabilities

Table 2.7.3 gives the physical properties of these three halocarbons. They are all liquids at normal temperatures when stored in pressurized tanks. They can be stored under high-pressure nitrogen if the liquid must be expelled from the tank more rapidly than under the vapor pressure of the halon alone. The use of nitrogen for pressurization is especially important for outdoor storage in the winter.

The inerting capabilities of Halon 1301 and Halon 1211 are shown in Table 2.7.4. If methane in any proportion is combined with a mixture containing 5.4 volumes of Halon 1301 and 100 volumes of air, at 77°F (25°C), then no combustion can result. By contrast, a mixture containing 33 volumes of carbon dioxide and 100 volumes of air is required to obtain the same result. This suggests that a molecule of Halon 1301 is 6.1 (33/5.4) times as effective as a molecule of carbon dioxide. Note, however, that the molecular weight of Halon 1301 is 149, whereas that of carbon dioxide is 44, so the ratio of molecular weights is 3.39 (149/44). Accordingly, on a weight basis, Halon 1301 is only 1.8 (6.1/3.39) times as effective as carbon dioxide for methane fires.

TABLE 2.7.3 Physical Properties and Chemical Formulas of Three Halon Extinguishing Agents

Property	*Halon 1301 (CF_3Br)*	*Halon 1211 (CF_2ClBr)*	*Halon 2402 (C_2F4Br_2)*

Source: Calculated from tabulations in J. M. Kuchta, "Investigation of Fire and Explosion Accidents in the Chemical, Mining, and Fuel-Related Industries—A Manual," 1985.[20]

Table 2.7.4 shows that the inerting proportion of halon needed varies somewhat, depending on the nature of the combustible, and substantially more halon is needed for hydrogen, carbon disulfide, or ethylene fires than for most other combustibles. Table 2.7.4 also shows that Halon 1301 and Halon 1211 have similar effectiveness on a volume basis for most combustibles.

Table 2.7.4 is based on experiments in which a strong ignition source is applied to a uniform combustible-air-halocarbon mixture, and the occurrence or nonoccurrence of a propagating flame is noted. A somewhat smaller quantity of halocarbon would be needed to cause an existing flame on a burner to become unstable and then extinguish itself; the quantity needed will depend on the details of the burner. A flame burning on a solid is even more easily extinguished. Grant[21] found that flames on most solids could be extinguished with 4 to 6 percent by volume of Halon 1301 in the surrounding atmosphere. Still, the discussion in the previous section about problems with extinguishment of deep-seated fires by carbon dioxide or nitrogen is equally valid when a halocarbon agent is used. Unless a sufficient quantity of the halocarbon in liquid form can reach the seat of the fire and cool all the solid sufficiently, reignition can occur after the agent has dissipated. If the halocarbon reaches the combustible as a gas by compartment flooding, then no such cooling can occur, and the effect of the gaseous agent is to extinguish the flame without affecting the pyrolysis or smoldering.

Table 2.7.4 also shows that the addition of Halon 1301 or 1211 needed in the air will only reduce the oxygen percentage from 21 percent to about 19 percent for most combustibles, whereas the required amount of carbon dioxide would have reduced the oxygen level to 14 percent or 15 percent. Furthermore, the physiological effects of carbon dioxide on humans at the concentrations needed for inerting are greater than those of Halon 1301.

Effectiveness of CF_3Br and CF_2ClBr

It would, of course, be highly desirable if chemists discovered a perfect, environmentally benign substitute for Halon 1301 or Halon 1211 that provided both fire protection and breathability qualities. Such a perfect substitute has not yet been found, but many second-generation agents have been developed with substantial fire protection effectiveness. In considering the possibility of discovering even more efficient chemical agents, a review follows of what is known about why the CF_3Br and CF_2C1Br molecules are so effective.

Figure 2.7.9 shows a methane-air flammability limit diagram as modified by various volumetric proportions of bromotrifluoromethane or carbon dioxide. The enormous difference is obvious. It has been established that carbon dioxide acts by absorbing heat and reducing the flame temperature from about 3452°F (1900°C) for a stoichiometric fuel-air mixture to about 2192 to 2372°F (1200 to 1300°C). Below these temperatures, most flames can no longer burn.

If nitrogen were added to a stoichiometric fuel-air mixture instead of carbon dioxide, a somewhat larger volume of inert agent would be needed because the heat capacity of the nitrogen molecule is less than that of the carbon dioxide molecule. Similarly, if argon were added—argon has an even lower heat capacity per molecule—an even larger volume of argon would be needed for inerting. In each case, the flame would go out when the temperature dropped below 2192 to 2372°F (1200 to 1300°C). However, if a small volume of bromotrifluoromethane were added to a flame, so that the temperature dropped to only about 2732°F (1500°C), the flame would be extinguished. Clearly, the mechanism is different.

The important chemical reactions in flames involve the free atoms H and O and the free radical OH, which undergo chain reactions with the fuel and oxygen. In particular, the branching chain reaction $H + O_2 \rightarrow OH + O$ is very important. It is believed that the CF_3Br molecule decomposes in the flame to form HBr, and HBr then acts to remove H atoms and OH radicals by the following two combustion reactions:

$$HBr + H \rightarrow H_2 + Br$$

and

$$HBr + OH \rightarrow H_2O + Br$$

HF and HCl cannot react as rapidly with H or OH as can HBr, so bromine appears to be essential to the inerting molecule. It has been found that hydrogen iodide, HI, is about as effective as HBr, but iodine is more expensive and heavier than bromine as well as quite toxic, and so iodine offers no advantage over bromine for flame extinguishment. In addition to the destruction of chain carriers, it has been speculated that a secondary contribution of halons to flame extinguishment comes from the extreme sootiness of halogen-containing flames. The more sooty or luminous the flame, the greater the radiative heat loss and the lower the temperature.

The role of fluorine in halocarbon agents is twofold. First, fluorine atoms replace hydrogen atoms in methane or ethane, thereby reducing the flammability of the inerting agent itself. Second, the toxicity of the agent is reduced. For example,

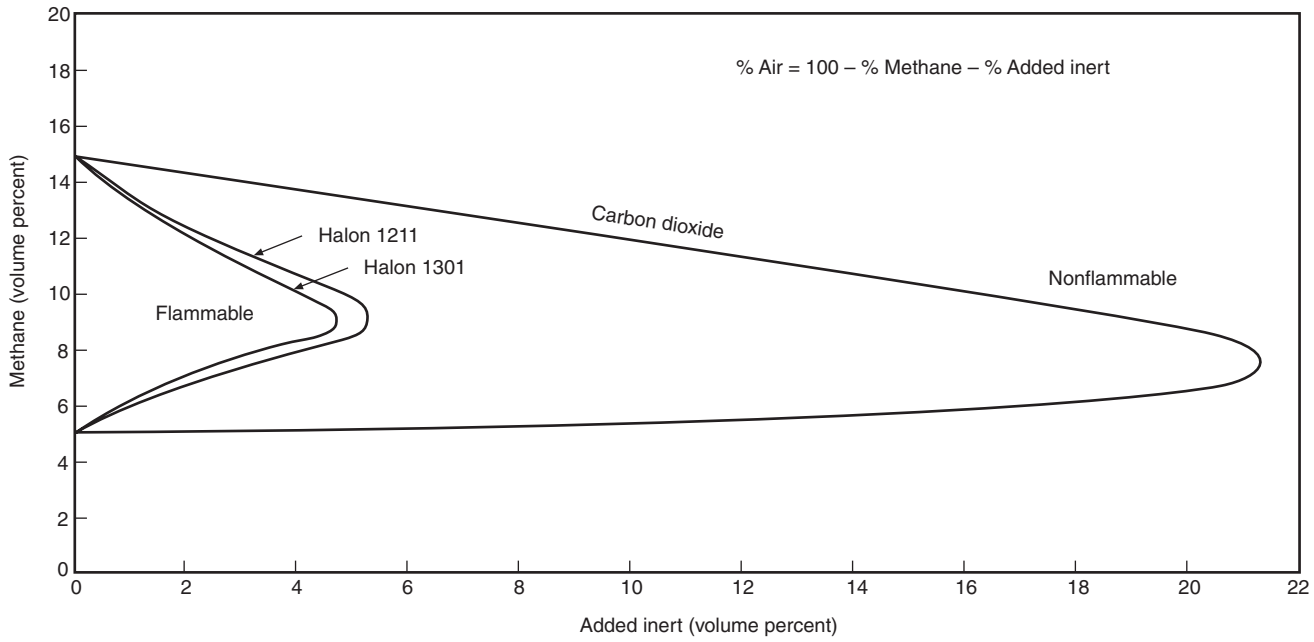

FIGURE 2.7.9 Flammability Limits for Methane-Air Mixtures with Added Inerting Agents (Source: J. M. Kuchta, "Investigation of Fire and Explosion Accidents in the Chemical, Mining, and Fuel-Related Industries—A Manual," *Bulletin 680,* 1985[20])

CH_3Br is much more toxic than CF_3Br, and, again, CH_2C1Br is much more toxic than CF_2C1Br.

EXTINGUISHMENT WITH DRY CHEMICAL AGENTS

See also Section 17, Chapter 2, "Chemical Extinguishing Agents and Application Systems."

Dry chemicals provide an alternative to carbon dioxide or the halons for extinguishing a fire without the use of water. These powders, which are 10 to 75 microns in size, are projected by an inert gas. Of the five types of dry chemicals in use, only one, monoammonium phosphate, is effective against deep-seated fires because of a glassy phosphoric acid coating that forms over the combustible surface. All forms of dry chemical act to suppress the flame of a fire. One reason that dry chemical agents other than monoammonium phosphate are popular is corrosion. Any chemical powder can produce some degree of corrosion or other damage, but monoammonium phosphate is acidic and corrodes more readily than other dry chemical agents, which are neutral or mildly alkaline. Furthermore, corrosion by other dry chemicals is stopped by a moderately dry atmosphere, whereas phosphoric acid, a product of decomposed monoammonium phosphate, has such a strong affinity for water that an exceedingly dry atmosphere would be needed to stop corrosion.

Application of any dry chemical agent on electrical fires is safe, from the viewpoint of electric shock, for fire fighters. However, these agents, especially monoammonium phosphate, can damage delicate electrical equipment. For the special case of kitchen fires involving hot cooking oil, monoammonium phosphate is not recommended because it does not create a foam layer (saponification) on the surface of the oil. An alkaline dry chemical, such as sodium bicarbonate, is preferred.

Table 2.7.5 lists the chemical names, formulas, and popular or commercial names of various dry chemical agents. In each case, the particles of powder are coated with an agent, such as zinc stearate or a silicone, to prevent caking and to promote free flowing. The effectiveness of any of these agents depends on the particle size: the smaller the particles, the less agent is needed, as long as particles are larger than a critical size.[22] The reason for this is believed to be that the agent must vaporize rapidly in the flame to be effective.[23] However, if an extremely fine agent were used, it would be difficult to disperse and apply to the fire.

It is difficult to compare precisely the effectiveness of one dry chemical with another because a comparison to reveal chemical differences would require that each agent have iden-

TABLE 2.7.5 Dry Chemical Agents

Chemical Name	*Formula*	*Popular Name(s)*
Sodium bicarbonate	$NaHCO_3$	Baking soda
Sodium chloride	NaCl	Common salt
Potassium bicarbonate	$KHCO_3$	"Purple K"
Potassium chloride	KCl	"Super K"
Potassium sulfide	K_2SO_4	"Karate Massiv"
Monoammonium phosphate	$(NH_4)H_2PO_4$	"ABC" or Multipurpose
Urea + potassium bicarbonate	$NH_2CONH_2 + KHCO_3$	"Monnex"

tical particle size, which is difficult to achieve. Furthermore, gaseous agents can be compared by studying the flammability limits of uniform mixtures at rest. If particles were present, however, they would settle out unless the mixtures were agitated, thus modifying the combustion behavior.

It seems clear that the effective powders act on a flame by some chemical mechanism, presumably forming volatile species that react with hydrogen atoms or hydroxyl radicals. However, the precise reactions have not been firmly established. Although the primary action is probably removal of active species, the powders also discourage combustion by absorbing heat; by blocking radiative energy transfer; and, in the case of monoammonium phosphate, by forming a surface coating. The potassium-bicarbonate-based agent, often referred to as "Purple K," is about twice as effective on a pound-per-pound basis as ordinary sodium-bicarbonate-based dry chemical.

SPECIAL CASES OF EXTINGUISHMENT

Metal Fires

Water is usually the wrong agent for fires involving metals because a number of metals can react exothermically with water to form hydrogen, which, of course, burns rapidly. Furthermore, violent steam explosions can result if water enters molten metal.[24] As an exception, extinguishment has been accomplished when large quantities of water were applied to small quantities of burning magnesium, in the absence of pools of molten magnesium.

Table 2.7.6 lists extinguishing agents used for various metal fires. In general, metal fires are difficult to extinguish because of the very high temperatures involved and the correspondingly long cooling times required. Note that certain metals react exothermically with nitrogen; therefore, the only acceptable inert gases for these metals are helium and argon. Halocarbons should not be used on metal fires.

TABLE 2.7.6 Extinguishing Agents for Metal Fires

Agent	*Main Ingredients*	*Used On*
Powders		
"Pyrene" G-1 or "MetalGuard"	Graphitized coke + organic phosphate	Mg, Al, U, Na, K
"Met-L-X"	$NaCl + Ca_3(PO_4)_2$	Na
Foundry flux	Mixed chlorides + fluorides	Mg
"Lith-X"	Graphite + additives	Li, Mg, Zr, Na
"Pyromet"	$(NH_4)_2H(PO_4)$ + NaCl	Na, Ca, Zr, Ti, Mg, Al
"T.E.C."	$KCl + NaCl + BaCl_2$	Mg, Na, K
Dry sand	SiO_2	Various
Sodium chloride	NaCl	Na, K
Soda ash	Na_2CO_3	Na, K
Lithium chloride	LiCl	Li
Zirconium silicate	$ZrSiO_4$	Li
Liquids		
"TMB"	Trimethoxyboroxine	Mg, Zr, Ti
Gases		
Boron trifluoride	BF_3	Mg
Boron trichloride	BCl_3	Mg
Helium	He	Any metal
Argon	Ar	Any metal
Nitrogen	N_2	Na, K

Chemical Fires

In addition to metals, certain inorganic chemicals are not compatible with water. For example, alkali and alkaline earth carbides, of which the best known is calcium carbide, react with water to form acetylene, which is highly flammable. Lithium hydride, sodium hydride, or lithium aluminum hydride react with water to produce hydrogen. Peroxides of sodium, potassium, barium, and strontium react exothermically with water. Cyanide salts react with acidified water to form a highly toxic gas, hydrogen cyanide. Even if these chemicals are not combustible themselves, they could be packed in combustible cartons and thus become involved in a fire or they could be stored in racks above combustible items.

Certain organic peroxides used as polymerization catalysts in plastics manufacturing are so unstable that they are stored under refrigeration to avoid exothermic heating. If water at normal room temperature were to be applied, it would provide heat to the peroxide and promote its exothermic decomposition.

A problem in applying water to fires involving toxic chemicals, such as pesticides, is associated with the runoff of contaminated water, which could cause groundwater pollution. In cases where no other agent but water is available or practical, the only alternatives might be to use the minimum quantity of water possible or to allow a building to burn, thus producing downwind air pollution if the fire does not completely destroy the toxic chemicals.

SUMMARY

The fundamentals of combustion science, which relate to fire extinguishment, are briefly reviewed and references are provided to more detailed treatments. Limits of flammability are discussed. Chemical chain reactions and the possibility of inhibiting these reactions are reviewed.

Details of how water extinguishes a fire or a burning solid are presented. The role of aqueous foams in fighting flammable liquid fires is discussed in terms of extinguishment mechanism. Discussion is provided of extinguishment by mists, by inert gases, by halocarbon agents, and by dry chemical agents. Metal fires and chemical fires are mentioned as examples of special extinguishment situations.

Chapter 8

Explosions

Robert Zalosh

Chapter Contents

Fundamental Explosion Principles
Types of Explosions

Key Terms

blast mitigation, blast wave, chemical reaction explosion, deflagration, detonation, dust explosion, energy release duration, explosion, peak pressure, projectile fragment, steam explosion, vapor cloud explosion, vapor explosion

The *Random House Dictionary of the English Language* defines *explosion* as a violent expansion or bursting with noise. The violent expansion is due to a sudden release of energy or an energy transformation that causes a region of high pressure and/or temperature, which propagates away from the source as a blast wave. Therefore, a more scientific definition for *explosion* would be *a sudden, rapid release of energy that produces potentially damaging pressures.*

One way to categorize various types of explosions is in terms of the energy source. Fire protection professionals are familiar with combustion energy sources that cause gas explosions and dust explosions when the fuel and air are premixed and confined before being ignited. Other energy sources that can be released or transformed rapidly enough to produce explosions include condensed phase explosives, chemical reactions other than combustion, nuclear energy, potential energy due to compression, and extremely rapid vaporization. This chapter discusses the fundamental nature of various types of explosions, beginning with a brief overview of the energies released and the associated peak pressures produced. A general discussion of blast waves and primary and secondary fragments is also provided.

See also Section 6, Chapter 15, "Explosives and Blasting Agents"; Section 6, Chapter 17, "Tables and Charts"; and Section 18, Chapter 6, "Deflagration (Explosion) Venting."

FUNDAMENTAL EXPLOSION PRINCIPLES

The amount of energy released determines the strength of the blast wave—that is, the pressure disturbance—at a given distance far away from the energy release site. The peak pressure (i.e., the maximum pressure) at the explosion site itself depends on the energy released per unit volume. However, a more complete understanding of both the damage potential and various explosion protection alternatives also requires knowledge of the approximate time duration of the energy release. Therefore, it is helpful to characterize the various types of explosions in terms of their peak pressures, energies, and energy release durations.

Peak Pressure, Energy, and Energy Release Duration

Figure 2.8.1 shows a very rough plot of the peak pressures and energy release durations in various types of explosions. Nuclear explosions release by far the greatest amount of energy per unit volume, and therefore generate the highest peak pressures, which are of the order of many millions of pounds per square inch (psi). This pressure is generated within a millionth of a second (microsecond) as the fission or fusion products and expanding bomb debris compress and heat the air at the release site.[1]

Condensed Phase Explosives. Commercial and military condensed phase explosives are usually divided into two categories: high explosives and low explosives. High explosives tend to detonate, that is, to have a reaction propagation speed greater than the speed of sound in the reacting material. High explosives can generate peak pressures in the range 10^4 to 10^6 psi (700 to 70,000 bar).

Dr. Robert Zalosh is professor emeritus of fire protection engineering at Worcester Polytechnic Institute in Worcester, Massachusetts, and a consultant with expertise in industrial fire and explosion issues and incident investigations.

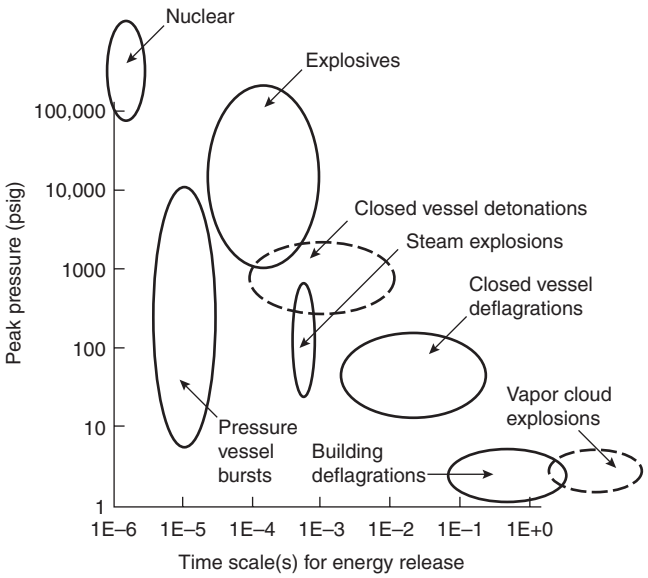

FIGURE 2.8.1 Peak Pressures and Energy Release Time Scales in Various Types of Explosions

The energy release time-scale for a high explosive is equal to the length of the explosive material divided by its detonation speed. For example, the detonation propagation speed of dynamite is approximately 16,000 ft/sec (4900 m/sec), so that a 1 ft (0.3 m) long stick would release its energy in 1/16th of a millisecond (ms). Detonation speeds for other high explosives are in the range of 2000 to 8200 m/sec.[2]

Low explosives tend to deflagrate, that is, to have a reaction propagation speed that is less than the speed of sound in the reacting material. The actual speeds can vary from hundreds of meters per second down to millimeters per hour.[3] Peak pressures produced by low explosives are orders of magnitude lower than those of high explosives.

The current UN/U.S. DOT classification system for explosives consists of six categories, depending on their propensity to detonate in their entirety, their susceptibility to accidental initiation, and whether they present projectile hazards, blast wave hazards, and/or fire hazards (NFPA 495, *Explosive Materials Code*). Standardized testing and classification procedures are described in 49 *CFR,* Parts 173.57 and 173.58. NFPA 495 also has tables of recommended separation distances of condensed phase explosive storage from inhabited buildings and roadways.

Energies released by condensed phase explosives and military weapons are often quoted in terms of the TNT (trinitrotoluene) equivalent weight. One kilogram of TNT has an explosive energy of 4.2×10^6 joules (J), so that one kiloton of TNT is equivalent to 4.2×10^6 kJ. Most condensed phase high explosives have an explosive energy per unit mass that is similar to that of TNT. For example, the explosive energy of pentolite (50/50) is 5.1×10^6 J/kg, and that of RDX is 5.4×10^6 J/kg. The corresponding TNT equivalent of pentolite is 5.1/4.2 = 1.2 kg-pentolite/kg-TNT, and that of RDX is 5.4/4.2 = 1.3 kg-RDX/kg-TNT.[2,4]

A burst pressure vessel releases its energy of compression in the time it takes for a crack to propagate sufficiently far to allow the metal shell to split open. This is typically on the order of 10 μsec. The peak pressure is approximately equal to the vessel pressure at the time of bursting, P_b. The isentropic expansion energy, E_{burst}, for an ideal gas released during the vessel burst is[4]

$$E_{burst} = \frac{(P_b - P_a)V}{\gamma - 1} \quad (1)$$

where

P_b = Vessel pressure at the time of bursting

P_a = Pressure of ambient air (1 atmosphere = 14.7 psia = 101 kPa at sea level)

V = Vessel volume

γ = Ratio of specific heats for the gas in the vessel ($\gamma = 1.4$ for air)

Using Equation 1, one can calculate the burst energy for a 10 m^3 vessel that ruptures when it is filled with air at a pressure of 1000 psia (6890 kPa). At sea level, $(P_b - P_a) = 6890 - 101 = 6789$ kPa. For a vessel filled with air, $(\gamma - 1) = 1.4 - 1 = 0.4$. Therefore, $E_{burst} = (6789 \times 10^3 \text{ Pa})(10^3)/0.4 = 172 \times 10^6$ J, which is equivalent to 172/4.2 = 41 kg (90 lb) of TNT.

Gas Explosions. Gas explosions can be either deflagrations or detonations, depending on whether the flame speed is less than or greater than sound speed in the unburned fuel-air mixture. (Sound speed is approximately equal to 335 m/sec if the fuel concentration is small compared to the air concentration.) Peak pressures and the form of the pressure-time loading are fundamentally different for deflagrations and detonations. Separate discussions of deflagrations and detonations are provided later in the chapter. For now, it is sufficient to say that the peak pressures generated in detonations are at least twice as large as those in deflagrations, and the time scale is often at least an order of magnitude smaller, as indicated in Figure 2.8.1.

Pressures generated in gas or dust deflagrations in buildings are often of the order of 1 psig because most building structures will fail at pressures of that order of magnitude. The structural failure, either planned (deflagration venting) or unplanned, releases the confined burned and unburned gases and usually prevents further pressure rise even though the fuel continues to burn. Deflagrations in process equipment often lead to higher pressures than in buildings because the equipment can withstand higher pressures prior to failure and because there is more likely to be a flammable mixture throughout the enclosure volume. The energy release time-scale is shown smaller for equipment than for buildings because the smaller volumes allow for more rapid rates of pressure rise.

Vapor Cloud Explosions. Vapor cloud explosions refer to external deflagrations of very large clouds of flammable gas or vapor in a highly obstructed or partially confined area. Peak pressures in vapor cloud explosions are of the same order of magnitude as those in building deflagrations, but the energy re-

lease times are usually longer because the flammable clouds are usually much larger than those that form inside buildings.

Blast Waves

Pressure disturbances propagating into the atmosphere away from the energy release region are called *blast waves.* The propagation of a blast wave that started as a detonation wave is shown in Figure 2.8.2 as a series of pressure versus distance profiles at six different times. In all six profiles, a shock wave (sudden discontinuous increase in pressure) occurs as the leading edge of the pressure wave, and the pressure decays behind the shock wave. As the blast wave propagates away from the energy release site, the amplitude of the shock wave decreases, and the time duration of the pressure disturbance increases. It eventually develops a characteristic N wave shape at time t_6, that is, in the far field at distances far from the explosion site.

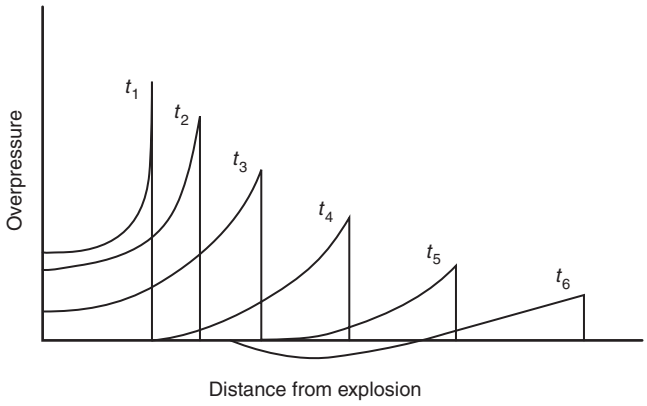

FIGURE 2.8.2 Blast Wave Propagation Away from Detonation Site

The parameters used to characterize far-field blast waves are identified in Figure 2.8.3. The shock wave amplitude is denoted as P_{s0}, and the area between the pressure curve and the ambient pressure, P_0, is called the specific impulse, i_s. Because there is a portion of the blast wave in which pressures are smaller than P_0, there is a positive specific impulse and a negative specific impulse. The blast wave damage and injury potential depends on the magnitudes of the shock pressure, P_{s0}, and the positive i_s. Various correlations and theoretical models of ideal blast waves (produced from instantaneous, point source releases of energy) have shown that P_{s0} can be correlated with an energy-scaled distance of the following form:

$$\frac{z}{E^{1/3}} \text{ or } \frac{z}{W_{\text{TNT}}^{1/3}}$$

where

z = Distance from the explosion site

E = Blast wave energy

W_{TNT} = The TNT equivalent weight for the same blast wave energy

Figure 2.8.4 shows the correlations between P_{s0} and $\frac{z}{W_{\text{TNT}}^{1/3}}$ and between i_s and $\frac{z}{W_{\text{TNT}}^{1/3}}$ (in ft/lb$^{1/3}$ or m/kg$^{1/3}$) for a condensed phase explosion at ground level.

Criteria for blast wave damage and injuries generally involve considerations of both pressure (P_{s0}) and impulse (i_s). However, at large distances from the explosion site, the impulse is usually large enough that structural damage depends primarily on P_{s0}. Table 2.8.1 shows the consequences of representative values for overpressure and the associated TNT equivalent-scaled distance.

The scaled distances in Table 2.8.1 were developed from correlations of explosions at various altitudes and from the incident blast wave pressures at the various types of targets listed

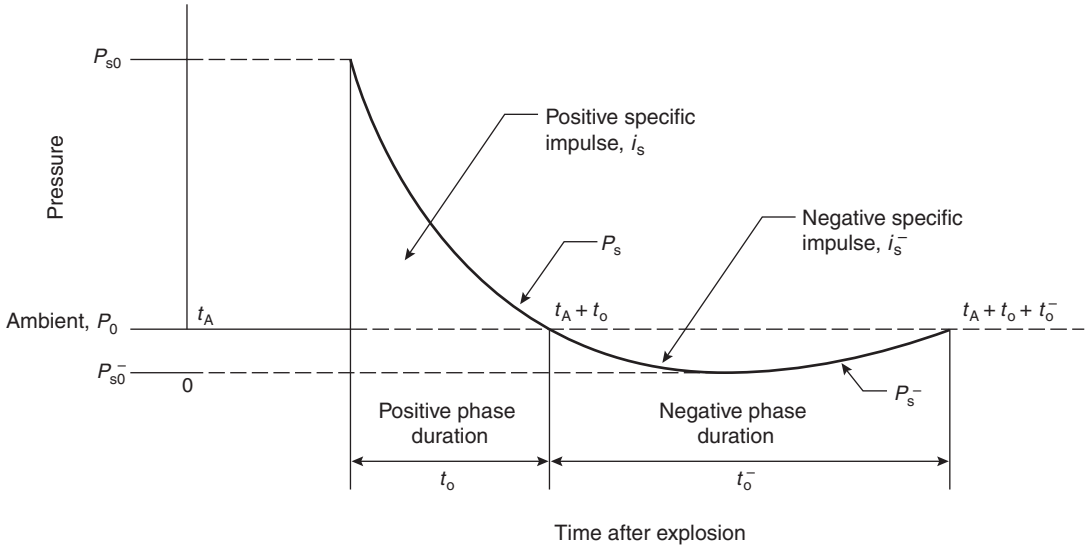

FIGURE 2.8.3 Pressure-Time Variation for a Far-Field Blast Wave (Source: U.S. Department of Defense[5])

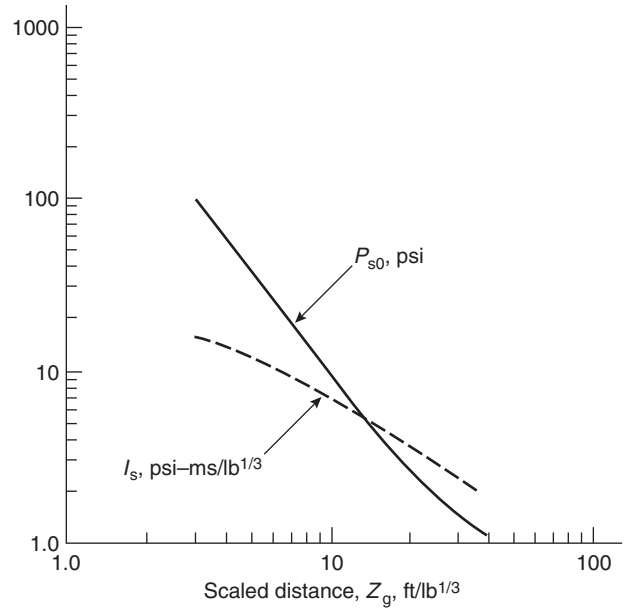

FIGURE 2.8.4 Decay of Blast Wave Pressure and Specific Impulse with Distance from Explosion Site (Source: U.S. Department of Defense[5])

in the table. One complication in using this data is that explosions at ground level produce hemispherically expanding blast waves, whereas elevated explosions produce spherically expanding blast waves that are reflected off the ground. The usual way of accounting for the reflection effect is to use double the blast wave energy when applying the correlations for spherically expanding blast waves to ground level explosions. This doubling of the blast wave energy would be needed in using the scaled distances in Table 2.8.1, whereas the correlations in Figure 2.8.4 do not need any corrections because they come directly from ground level explosions.

Consider the previous example of the 10 m^3 pressure vessel burst as an example of the how to use Table 2.8.1 and Figure 2.8.4. Suppose we want to find the distance from the vessel to the location at which P_{s0} would be 1 psig (6.9 kPa), in other words, to the blast wave distance at which personnel would be knocked down, windows shattered, and thin sheet metal panels buckled, according to Table 2.8.1. If we use the scaled distance in Table 2.8.1 of 44 ft/kg$^{1/3}$ (13.4 m/kg$^{1/3}$), the blast wave distance is calculated as follows:

$$(44 \text{ ft/kg}^{1/3})(2 \cdot 41 \text{ kg})^{1/3} = 191 \text{ ft}$$

If we use the correlation for P_{s0} in Figure 2.8.4 extrapolated slightly to 1 psig, the calculated distance is

$$(45 \text{ ft/lb}^{1/3})(90 \text{ lb})^{1/3} = 202 \text{ ft}$$

Thus, the distance would be approximately 200 ft (61 m) in both cases. However, if we are evaluating blast damage potential for a structural surface that directly faces the explosion, we would have to account for the reflected blast wave pressures. The ratio of reflected blast wave pressure to incident pressure is approximately 2 for values of P_{s0} less than about 2 psig. Thus, if the exposed persons and structures are facing the pressure vessel at the time of rupture, the corresponding effects could be experienced

TABLE 2.8.1 High Explosives Overpressure Consequences

Scaled Distance Z (ft/kg$^{1/3}$)	*Overpressure (psi)*	*Consequences*
3000–890	0.01–0.04	Minimum damage to glass panels
420–200	0.1–0.2	Typical window glass breakage
200–100	0.2–0.4	Minimum overpressure for debris and missile damage
82–41	0.5–1.1	Windows shattered, plaster cracked, minor damage to some buildings
44–32	1.0–1.5	Personnel knocked down
44–28	1.0–1.8	Panels of sheet metal buckled
44–24	1.0–2.2	Failure of wooden siding for conventional homes
28–20	1.8–2.9	Failure of walls constructed of concrete blocks or cinder blocks
20–16	2.9–4.4	Self-framing paneled buildings collapse
20–16	2.9–4.4	Oil storage tanks ruptured
16–12	4.4–7.3	Utility poles broken off
16–12	4.4–7.3	Serious damage to buildings with structural steel framework
11–10	10.2–11.6	Probable total destruction of most buildings
15–9	5.1–14.5	Eardrum rupture
14–11	5.8–8.7	Reinforced concrete structures severely damaged
14–11	5.8–8.7	Railroad cars overturned
6.7–4.5	29.0–72.5	Lung damage
3.8–2.7	102–218	Lethality
2.4–1.9	290–435	Crater formation in average soil

Note: 1 psi = 6.9 kPa.
Source: Kinney and Graham.[6]

at a value of P_{s0} as low as 0.5 psig, corresponding to a TNT-equivalent scaled distance of 82 ft/kg$^{1/3}$, as per Table 2.8.1.

Blast wave vulnerability assessments and incident investigation analyses often need to account for complications such as multiple and oblique shock wave reflections associated with building features, adjacent structures, and other effects of either a congested urban environment or uneven natural terrain. A wide variety of blast wave computer codes has been developed for these effects and for convenience in using even the simplified blast wave correlations. Although many of these computer codes have restricted distributions, some can be obtained commercially, and others can be accessed through the original code developers. For example, Luccioni et al. (2006) have described the use of one commercially available Computational Fluid Dynamics (CFD) code called AUTODYN-3D to conduct simulations of the blast wave generated in a blast attack in Buenos Aires. Clutter and Stahl (2004) describe the use of their special CFD code called Computational Explosion and Blast Assessment Model. Many other types of codes are listed on the U.S. Army Corps of Engineers software website: https://pdc.usace.army.mil/software. Code distribution restrictions, where applicable, are also described on this website. The National Academies 1995 report on Blast-Effects Mitigation Technology has an older compilation of computer codes used for blast assessment evaluations.

Primary and Secondary Fragments

Casualties from explosions are often caused by projectile fragments, either from the exploding container (primary fragments) or from structures damaged by the explosion blast wave (secondary fragments). Fragmentation of the exploding container depends on the type of container or explosive case, and is usually approached via statistical analysis of test and accident data. High explosives and weapons usually produce a large number of casing fragments, whereas burst pressure vessels produce relatively few, but larger, fragments.

Primary fragment statistical correlations for condensed phase explosives are described by Baker et al.[7] Calculations for burst pressure vessels involve first estimating the number and size of fragments and then using the results of projectile calculations to determine how far the fragments can fly. This procedure is explained in Baker et al.[7] and CCPS.[8]

Primary fragment projectile distances often determine the safe standoff distance for a pressure vessel exposed to a fire. Correlations shown in the *Guidelines for Consequence Analysis* and *Guidelines for Chemical Process Quantitative Risk Analysis* (1999) show approximately 80 percent of the fragments from LP-gas BLEVEs land within about 1000 ft (305 m) from the vessel; however, one fragment in a Mexico City incident traveled about 3000 ft (915 m). In the case of horizontal cylindrical vessels, more fragments are projected in the axial direction than in the lateral direction, but emergency responders need to be wary of the danger of fragments in all directions. Two volunteer firefighters in Iowa were killed in 1998 when they were about 100 ft (30.5 m) from the side of an LP-gas vessel that eventually failed as a BLEVE and projected fragments in all directions.[9]

Secondary fragment hazards have been documented and generalized through analyses of damage and casualties at major explosions. Oswald et al.[10] conducted such an analysis for five buildings damaged in the 1995 Oklahoma City bombing. The 4000 lb (1800 kg) ammonium nitrate fuel oil explosion in that incident had an estimated TNT equivalence of 3400 lb (1540 kg). Using data from that and other incidents, Oswald et al. developed a correlation for the percentage of building occupants that are expected to experience life-threatening injuries due to glass shard projectiles, building roof damage, and wall damage. Implementation of the Oswald et al. model requires calculations of blast wave impulse at the location of the exposed building as well as specifications of the type of building wall and roof construction. Hu and Chen (2006) have recently developed a new computer model to simulate the synergistic effects of blast and fragment loadings, but they acknowledge that additional experimental, analytical, and computational effort is needed before this type of model can be used for general blast load applications.

Blast Mitigation Technology

In 1997, the U.S. Department of Defense (DOD) initiated a Blast Mitigation for Structures Program aimed at improving the technology for protecting people within civilian and military buildings from bomb blast attacks. Similar efforts are underway in several other countries. These programs have led to an assortment of blast mitigation technology that has been tested and commercialized recently. Although many of the new products involve blast-resistant construction for new buildings, some of the new products are intended as retrofits for existing buildings and structures. A database for the various products is available at the following DOD website: https://bmag.usace.army.mil/index.php.

Examples of the new blast-resistant construction products include shock absorbing walls, blast-resistant cladding panels, and spray-on polymers for interior wall surfaces, blast-resistant wraps, and blast-resistant fences. One example of a blast-resistant foam cladding is honeycombed layered sacrificial metallic foam that can absorb large amounts of blast energy via plastic deformation. Ma and Ye (2006) have recently developed an analytical model to assess the ability of the cladding and protected structure to withstand the combined blast peak pressure and impulse loads. One example of a blast-resistant wrap is a sandwich of blast-resistant filler material such as glass beads between two laminated films. The wraps are intended to be used either as wall or ceiling linings, as a suspended free-standing barrier, or as a wrap for containers. The spray-on polymers for interior wall surfaces can contain or mitigate wall fragments resulting from blast loadings. An analogous product is shatter-resistant-window-film to contain glass window fragments. Both the spray-on polymers and the shatter-resistant-window-films can be applied in varying thicknesses to achieve varying levels of blast resistance.

DOD test facilities have been used to evaluate the effectiveness of these and other new blast mitigation products. Their effectiveness is sometimes expressed in terms of a reduced standoff distance between the target structure and an explosive with specified blast energy. For example, recent tests with one readily available type of spray-on polymer have shown that the standoff distance to achieve either no damage or only slight

damage can be reduced in half over a wide range of blast energies. A recent National Academy of Science panel report (2003) on implementation of the new blast mitigation technology has provided seven recommendations for improved transfer of the new technology to the civilian sector. One recommendation is to gear the technology transfer effort toward products and methods that can achieve protection against multiple hazards such as fire and extreme winds, as well as blast effects.

TYPES OF EXPLOSIONS

Flammable Gas and Vapor Deflagrations

Ignition of a gas-air mixture usually results in a deflagration; that is, a flame propagation at subsonic speed away from the ignition site. The pressure developed in the enclosure depends on the extent of flame propagation, the temperature and composition of the burned gas, and the size and location of any vent area. If the flame has propagated throughout an unvented enclosure, the ratio of the deflagration pressure to the initial pressure in the enclosure can be obtained from the ideal gas equation as it applies to the postdeflagration and predeflagration gas-air mixtures, both of which occupy the same enclosure volume. Thus,

$$\frac{P_m}{P_0} = \frac{n_b T_b}{n_0 T_0} \tag{2}$$

where

P_m = Pressure developed at the completion of a closed vessel deflagration

P_0 = Initial pressure in the enclosure

n_b = Number of moles of burned gas at the completion of the deflagration

n_0 = Number of moles of gas-air mixture initially in the enclosure

T_b = Temperature of the burned gas at the completion of the deflagration

T_0 = Initial temperature of the gas-air mixture

Conservative estimates of burned gas temperature and composition can be obtained using the assumption that there is no heat loss from the flame to the enclosure walls. Assuming there is no heat loss or venting, various computer codes are available to calculate the burned gas temperature, composition, and pressure at the completion of the deflagration. Calculations obtained with the STANJAN code are shown in Figure 2.8.5 for the closed vessel deflagration pressures for methane-air, propane-air, and hydrogen-air mixtures of varying concentration. The fuel concentration used in Figure 2.8.5 is the equivalence ratio, defined as the fuel-to-air ratio divided by the stoichiometric fuel-to-air ratio. In terms of the fuel volume fraction, x, the equivalence ratio is equal to $\frac{x(1-x_{st})}{x_{st}(1-x)}$ where x_{st} is the stoichiometric volume fraction of fuel. The stoichiometric fuel volume fraction for methane-air is 0.095, for propane-air 0.040, and for hydrogen-air 0.296. The maximum pressures for each flammable gas occur at fuel equivalence ratios in the range 1.1 to 1.2, that is, at slightly richer than stoichiometric concentrations. These worst-case deflagration pressures are in the range of 8 to 9.6 atm absolute (118 to 140 psia) for an initial pressure of 1 atm, that is, the ratio P_m/P_0 is 8 to 9.6. Experimental measurements of closed vessel deflagration pressures agree well with the theoretical values of P_m at near-stoichiometric concentrations, but are significantly less than the theoretical values at concentrations near the lower and upper flammable limits because of incomplete flame propagation and heat losses for marginally flammable mixtures.

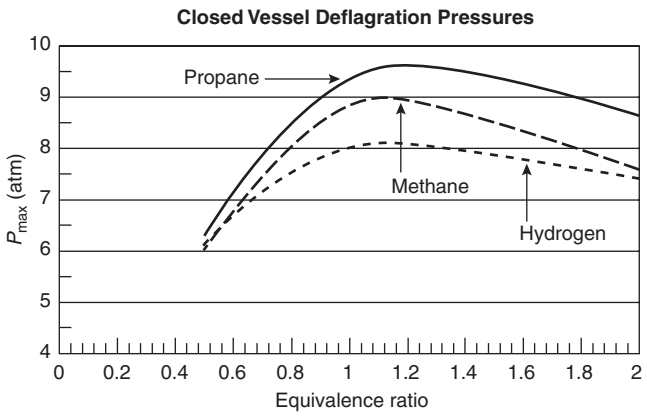

FIGURE 2.8.5 Calculated Adiabatic, Constant Volume Pressures as a Function of Equivalence Ratio

Similar P_m/P_0 pressure ratios occur for closed-vessel deflagrations initiated at other initial pressures. One example of a deflagration initiated at a lower initial pressure is the Center Wing Tank explosion that occurred during the TWA 800 flight on July 17, 1996. The flammable vapor in the Center Wing Tank of the Boeing 747 on that flight came from a small quantity of Jet A fuel in the tank. Although the composition of Jet A is complicated, many of the volatile constituents have flame temperatures and deflagration pressures similar to those of methane and propane. As the fuel was heated from air conditioning equipment under the Center Wing Tank, and the partial pressure of tank air was reduced as the Boeing 747 climbed after takeoff, the fuel-air equivalence ratio increased well into the flammable range. Ignition occurred at an altitude of 14,000 ft (4300 m), at which the ambient pressure is 0.585 bar (8.6 psia). A deflagration pressure ratio of 6 at that initial pressure would correspond to a P_m of 6 (8.6 psia) = 52 psia, and $P_m - P_0 = 43$ psi (3.0 bar). This pressure difference was significantly higher than the strength of the Center Wing Tank structures, leading to a massive breakup of the Boeing 747.

The rate of pressure rise in a gas or vapor deflagration is a crucial factor in determining the effectiveness of protection measures such as deflagration venting and suppression. Flame speeds, enclosure volume, and the value of P_m are the primary parameters governing the rate of pressure rise. Theoretical models described in the chapter on explosion protection of the *SFPE Handbook of Fire Protection Engineering*[11] allow the transient pressure rise to be calculated for any gas-air mixture with a known burning velocity (rate of flame propagation rela-

tive to the unburned gas velocity). Calculated pressure histories for three different sets of conditions are shown in Figure 2.8.6. During the early stages of the deflagration, the pressure rise varies as $(S_u t/a)^3$ where S_u is the mixture burning velocity and a is the radius of a sphere with the same volume as the enclosure. The burning velocities of 45 cm/sec and 300 cm/sec used for the calculations represent laminar burning velocities for near-stoichiometric propane-air mixtures and hydrogen-air mixtures, respectively. Flame speeds are often significantly higher than the burning velocities because they include the velocity of the unburned gas as it is compressed by the expanding burned gases behind the flame front.

The curve in Figure 2.8.6 for a 1-m-radius enclosure containing a gas-air mixture with a burning velocity of 45 cm/sec shows the pressure rising to 2 psig (0.14 bar) in about 0.2 second. If the damage threshold for the enclosure is 2 psig (0.14 bar), deflagration venting or suppression would have to be actuated within 0.2 second of ignition to prevent damage in this case. The pressure developed in a vented or suppressed deflagration is denoted by P_{red}. Methods and guidelines for determining P_{red} are discussed elsewhere in this Handbook, and in NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* and NFPA 69, *Standard on Explosion Prevention Systems.*

If the deflagration pressure causes the enclosure to open (because of either deflagration venting or structural failure), a blast wave will exert pressure loads on adjacent structures. Blast waves emitted from vented deflagrations are very different than those discussed earlier from condensed phase explosives and burst pressure vessels. The blast wave energy is difficult to define and locate because the combustion energy is released both inside and outside the enclosure. Correlations discussed by Forcier and Zalosh[12] indicate that the blast wave pressure is proportional to P_{red}/d where d is the line-of-sight distance from the enclosure vent.

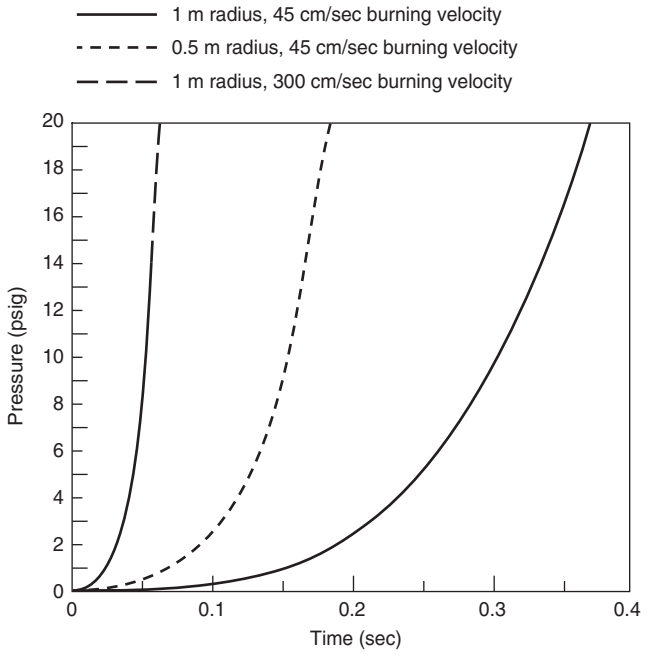

FIGURE 2.8.6 Calculated Pressure Versus Time During the Early Stages of Three Different Deflagrations

Flammable gas or vapor deflagrations that may occur within irregular or obstructed enclosures produce more highly accelerated and distorted flame propagation patterns. Calculations of transient pressure loadings in these complicated applications are often conducted with special CFD codes containing algorithms to simulate the turbulent combustion chemistry that is coupled to the flow field. FLACS is an example of a computer code that was developed precisely for this type of application.

Gas Detonations

A detonation is an explosion in which the flame propagates at supersonic speeds through the unburned fuel. Detonations are fundamentally different from the closed vessel deflagrations described in the previous section of this chapter. As flames in a deflagration propagate at speeds well below the speed of sound, whereas pressure disturbances propagate at sound speed, the pressure increase during a deflagration occurs virtually uniformly throughout the enclosure as the explosion evolves. In contrast, the pressure rise during a detonation is highly nonuniform and occurs virtually instantaneously as the shock wave propagates through the gas-air mixture. If the flame speed is slightly less than the speed of sound, such that the pressure rise is nonuniform but shock waves do not occur, the explosion is called a quasi-detonation.

The practical significance of this fundamental difference between detonations and deflagrations is that they require different approaches to explosion protection. The sudden, spatially nonuniform pressure rise during a detonation or quasi-detonation precludes the use of explosion venting or explosion suppression systems. Furthermore, the high-peak, short-duration detonative pressure loads warrant special considerations in the evaluation of structural resistance. Methods for designing and analyzing detonation resistant structures are discussed in *Structures to Resist the Effects of Accidental Explosions.*[5]

Peak pressure during a detonation can be calculated from the classical Chapman-Jouguet theory, which is a combination of thermochemical equilibrium and gas dynamic conservation equations across the detonation front. Figure 2.8.7 shows calculated detonation pressures as a function of fuel concentration for seven different flammable gases. A good approximation to the Chapman-Jouguet detonation pressure, P_{CJ}, is $P_{CJ} = 2P_m$, that is, twice the closed vessel deflagration pressure. This approximation represents a much simpler alternative to the Chapman-Jouguet theory of calculating detonation pressures. As indicated in Figure 2.8.7, P_{CJ} for a near-stoichiometric gas-air mixture initially at atmospheric pressure is in the range 16 to 20 atmospheres.

The different pressure loads during deflagrations and detonations produce characteristically different structural failure modes on equipment and structures. The slower pressure loadings in deflagrations usually cause ductile metals to fail by bulging out and stretching. The rapid impulsive loads in detonations often cause sharp fractures of metal, plastic, and wood structures. Photographs of the detonation fracture patterns on

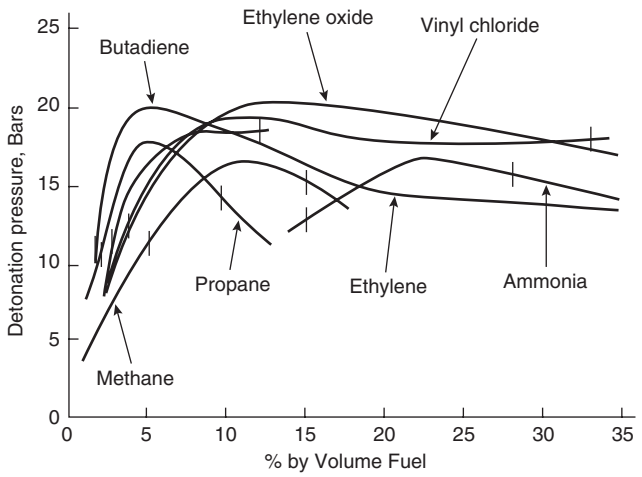

FIGURE 2.8.7 Calculated Chapman-Jouguet Detonation Pressures

the fragments of a large reactor vessel are included in the Jacobs et al. paper describing the detonation that destroyed a large petroleum refining unit in Indiana.[13]

What is the likelihood of a detonation occurring rather than a deflagration? Most accidental explosions are deflagrations. However, detonations can occur in very flammable gas mixtures if there is an exceptionally strong or large ignition source (flame jet ignition, for example), a highly elongated or obstructed geometry, or an exceptionally high level of turbulence to promote flame acceleration.

In the case of a weak (typical accidental) ignition source in a pipe or some other elongated enclosure, the deflagration-to-detonation transition (DDT) distance depends on the following parameters:

- *Mixture reactivity (burning velocity).* The more reactive the mixture, the more rapid the flame acceleration to DDT.
- *Enclosure or pipe wall roughness and the presence of obstruction.* The rougher the pipe interior surface or the more obstructions present, the shorter the transition length to DDT.
- *Enclosure or pipe diameter.* The larger the enclosure or pipe diameter, the shorter the transition to DDT.
- *Initial pressure and temperature.* The higher the initial temperature and pressure, the shorter the transition length to DDT.
- *Initial turbulence level.* The more turbulence or initial gas velocity in the enclosure, the shorter the DDT transition length.

In the absence of any obstructions and initial turbulence, data reviewed in Zalosh[11] indicate that length-to-diameter ratios greater than 100 are needed for DDT in most hydrocarbon-air mixtures. Thus, detonations are much more likely to occur in large piping systems rather than in building explosions or process vessel explosions. This demonstrates the importance of preventing long propagation lengths by using the various deflagration isolation systems described in NFPA 69.

Combustible Dust Deflagrations

Clouds of combustible dust in an enclosure also produce deflagrations when they are ignited while the dust concentration is greater than the minimum explosive concentration (MEC) for a particular material. The MEC depends on dust particle size as well as material composition, with smaller particles having smaller MECs than larger particles have. Typical lower explosive limits for dusts with characteristic particle sizes less than about are in the 30–60 g/m^3 range. Some examples for representative dusts and particle sizes are shown in Table 2.8.2.[14]

The other parameters shown in Table 2.8.2 are the maximum deflagration pressure in a closed vessel, P_{max}, and the K_{st} parameter defined as follows:

$$K_{st} = \left(\frac{dP}{dt}\right)_{max} V^{1/3} \tag{3}$$

where

$(dP/dt)_{max}$ = Maximum rate-of-pressure rise measured in a test vessel of volume V

Laboratory tests are usually conducted in a 20 L spherical vessel per the ASTM E1226 standard. The magnitude of K_{st} depends on the dust reactivity, the particle size, and the level of turbulence used to generate the dust cloud. Higher turbulence levels produce higher rates of pressure rise. The larger the K_{st} value, the more difficult it is to achieve effective deflagration venting or suppression. Thus, K_{st} for dusts plays a similar role as the burning velocity, S_u does for flammable gases.

Dust cloud concentrations above the MEC values are experienced routinely in process equipment such as dust collectors, blenders, dryers, pulverizers/grinders, conveying systems, and silos/bunkers. Tabulations of dust explosions in Germany from 1965 to 1985 indicate that 78 percent of all dust explosions originate in this equipment. Ignition sources that have occurred in dust explosions in Germany and in U.S. grain elevator explosions are shown in Table 2.8.3. The most frequent ignition source reported in the German dust explosions is mechanical sparks—presumably impact or friction sparks. Impact sparks are often attributable to tramp metal in either conveying systems or pulverizers/grinders. The most frequent ignition source in U.S. grain elevator explosions investigated by Kauffman[15] is mechanical heating/friction of belt drives in bucket elevators. Electrostatic discharges have been responsible for initiating explosions of dusts and powders, such as tantalum, with high resistivities and low ignition energies.[16] Guidance on eliminating these dust explosion ignition sources is provided in NFPA 654, *Standard for the Prevention of Fire and Dust Explosions from the Manufacturing, Processing, and Handling of Combustible Particulate Solids.*

Most of the damage and casualties in destructive dust explosions occurs as a result of secondary explosions. A secondary dust explosion is caused by dust layers on floors, equipment, and structures being dispersed by the blast wave of the primary explosion, and then being ignited by the flame emitted from the primary explosion. This process, illustrated in Figure 2.8.8, is particularly destructive when it occurs in confined and occupied areas. Accounts of 14 grain dust explosions investigated in Kauffman[15] indicate that 17 of 20 fatalities, 58 of 65 injuries,

TABLE 2.8.2 Explosibility Data for Representative Powders and Dusts

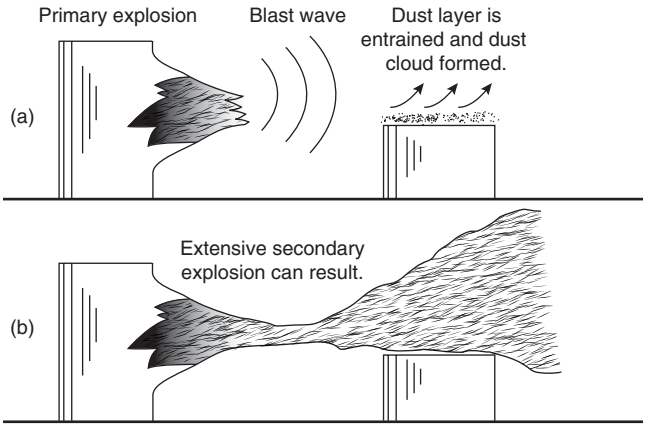

FIGURE 2.8.8 Secondary Dust Explosion Schematic (Source: Eckhoff[14])

and $36 million of the $37 million in property damage were due to the secondary explosions in these incidents. Prevention of these secondary explosions requires using effective protection measures for the primary explosion *and* minimizing dust accumulations in surrounding areas. However, this is a major challenge because dust layers as thin as 1 mm can generate an average dust cloud concentration of 100 g/m^3 (above the MEC for most combustible dusts) when dispersed throughout a 5-m-high room.[14] Partial dispersal over a lesser height can generate a still larger concentration, with correspondingly increased damage potential.

Chemical Reaction Explosions

Uncontrolled chemical reactions can cause explosions in two ways. First, they can produce gaseous reaction products that can overpressurize vessels that are not equipped with an adequate relief vent area. Second, runaway exothermic reactions can generate sufficient heat to increase rapidly the pressure of the existing gases and vapors in the vessel and possibly vaporize other materials.

Fire protection personnel are familiar with hydrocarbon combustion reactions, which produce carbon dioxide and water vapor as complete reaction products. There are also several other types of generic chemical reactions that can occur as fast as or faster than hydrocarbon combustion reactions at elevated temperatures, and can also produce multiple gaseous reaction products. These reactions include decompositions and polymerizations of inherently unstable compounds, rapid oxidation-reductions, nitrations, diazotizations (formation of a salt containing two nitrogen atoms and an aromatic hydrocarbon group), and hydration of water-reactive materials. Several of these reactions are autocatalytic in the sense that reaction products catalyze the reaction of the remaining reactants.

Examples of chemical reaction explosions are shown in Table 2.8.4.

The last two incidents in Table 2.8.4 have some remarkable similarities. They were both multiple fatality incidents caused by the detonative decomposition of hydroxylamine (NH_2OH). In both cases, the aqueous solution hydroxylamine concentration was significantly higher than the normal recommended practice (< 50% HA). Laboratory tests have shown that these high concentrations, together with trace contaminants, can lead to particularly violent decomposition reactions, often in the form of a detonation.

How can chemists and regulatory authorities recognize the potential for chemical reaction explosions and take appropriate actions to prevent them? The AIChE Center for Chemical Process Safety has published guidelines[23,24] to answer this question. These guidelines call for a combination of the following:

1. Reviewing lists of unstable materials[25] and potentially dangerous reactive combinations of materials
2. Using software to help identify incompatible chemicals[26] and to characterize the reaction energy associated with unstable chemicals[27]
3. Conducting reactivity laboratory screening tests to determine reaction onset temperatures, concentrations, and sensitivities
4. Having experts review the material storage/handling/processing conditions and results of screening tests, literature review, and software calculations

Additional guidelines are being developed by the Reactivity Management Roundtable under the aegis of the Center for Chemical Process Safety.

The design of process controls and emergency vents to accommodate these hazardous reactions requires scale-up calculations based on the reaction chemistry, material thermodynamic properties, expected heat transfer rates, and the possible presence of two-phase vent flow regimes.[28] After the design is completed, on-site audits are necessary in view of the reported poor record of many facilities in properly installing and maintaining pressure relief devices.[29]

TABLE 2.8.4 Examples of Chemical Reaction Explosions

Date	*Location*	*Chemicals*	*Cause of Accident*	*Casualties*	*Reference*
March 11, 1997	Tokai, Japan	Asphalt, sodium nitrate, sodium nitrite, sodium carbonate, and sodium bicarbonate	Excessive concentration of sodium bicarbonate lowered the reaction onset temperature	37 people received some radioactive contamination	Hasegawa and Li[17]
March 26, 1997	Haskell, Oklahoma	Printing ink solvents and oxidizers	Mixing of incompatible chemicals	1 fatality, 2 injuries	EPA[18]

Steam Explosions: Melt-Water Explosive Interactions

A steam explosion is a physical explosion caused by the extremely rapid vaporization of water due to heat transfer from a second liquid that is at a temperature far in excess of the water boiling point and in direct contact with the water. As the second liquid is usually either molten metal or some other melt, a steam explosion is a violent melt-water interaction. If the water is replaced with some other liquid that has a much lower boiling point than the hot liquid, the more general term is *vapor explosion.*

Steam explosions occur only if certain thermodynamic and hydrodynamic conditions are satisfied. The thermodynamic condition is that the liquid–liquid contact surface temperature, T_{con}, must be greater than the spontaneous nucleation temperature, T_{sn}, for water, that is, the temperature at which vapor bubbles first appear in the absence of any heated surfaces. The equation for T_{con} follows:[30]

$$T_{con} = \frac{T_H + T_C \sqrt{(k\rho c)_c/(k\rho c)_H}}{1 + \sqrt{(k\rho c)_c/(k\rho c)_H}} \qquad (4)$$

where

T_H = Hot liquid temperature

T_C = Cold liquid temperature

$k\rho c$ = Product of thermal conductivity, density, and specific heat for either the hot liquid or cold liquid, depending on the subscript

For example, if molten copper at a temperature of 1400°C is immersed in 20°C water, the interfacial contact temperature as per Equation 4 is 1341°C. If molten cuprous oxide at a temperature of 1330°C is immersed in 20°C water, the calculated interfacial contact temperature is 954°C.[31] In both cases, the contact temperature is substantially higher than the spontaneous nucleation temperature for water, which is very sensitive to surface tension changes due to additives or contaminants, but can be as high as 270°C. Thus, molten copper interactions with water can indeed be explosive. Similar results are observed with many other molten metals and with kraft smelt immersions into water. The latter have been associated with black liquor recovery boiler accidents at paper mills.

The liquid temperature criterion is a necessary, but not sufficient, condition for the occurrence of steam explosions. For the vaporization to occur rapidly enough and in sufficient volume to generate potentially damaging pressures, it is necessary to have ample liquid–liquid interfacial contact area. The consensus among steam explosion researchers[32] is that a large-scale steam explosion also requires premixing of the liquids, triggering of vapor film collapse, and rapid propagation of vapor zone collapse subsequent to triggering, as illustrated in Figure 2.8.9.

The upper left diagram in Figure 2.8.9 shows numerous drops of melt falling through water, which is the required premixing. The upper right sketch shows that each melt drop is surrounded by a water vapor film associated with film boiling of water around the perimeter of the drop. The lower right-hand diagram shows the vapor film being penetrated by a small jet of

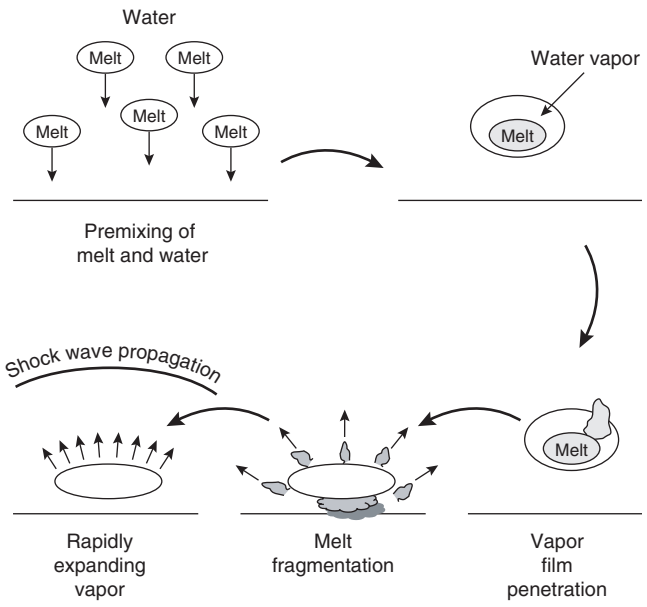

FIGURE 2.8.9 Steam Explosion Phenomena

melt, thus triggering film collapse. The lower middle diagram shows the interaction continuing via the fragmentation of the original drop into numerous jet fragments. As the jet fragments are propelled into the surrounding water, they explosively vaporize the water in a rapidly expanding region shown in the lower left-hand corner of Figure 2.8.9. This rapid vaporization/expansion provides the energy needed to drive a shock wave through the liquid and the adjacent area.

Our current limited understanding of the phenomena illustrated in Figure 2.8.9 does not allow a priori predictions of all the conditions that may result in steam explosions as opposed to less violent vaporization interactions. On the other hand, there have been several interesting empirical studies to help us anticipate the kinds of melts, containers, and mixing conditions that are more likely to lead to steam explosions. For example, Nelson[33] reports that smelt-water explosions do not occur when the water temperature is greater than 187°F (86°C), and Zyskowski[31] reports that molten tin-water explosions do not occur at water temperatures above 60°C. Long[34] did some pioneering experiments that showed how the bottom surface of the water container influences the likelihood of an explosion when molten aluminum was poured into the container. A rusty container base would promote steam explosions, whereas a greased or oil-coated or painted container base would prevent such explosions. These surface treatments change the wettability of the surface and the probability of a water film being trapped beneath a molten aluminum puddle. Later experiments have confirmed that molten aluminum-water explosions will not occur without either a wetted solid wall or high-velocity injection of one liquid into the other.[30] Other experiments have shown how water additives can change the likelihood of molten metal-water or smelt-water explosions by altering the water viscosity or surface tension.

When a steam explosion does occur, it often produces peak pressures in the range of 30 to 1000 psig (2 to 70 bar), with

pressure rise times of the order of a millisecond. Significantly lower pressures have also been observed under marginal conditions that produce rapid vaporization in the absence of shock waves. Vapor explosions have also been observed during at least some mixing conditions with the following pairs of liquids: Freon-22 and heated mineral oil, water and liquid nitrogen, liquid ethane and water,[30] molten nuclear reactor fuel and water, and molten zirconium oxide and water.[32]

Vapor Cloud Explosions

A vapor cloud explosion is a combustion explosion that follows the release of a large quantity of flammable gas or vapor in an outdoor area with conditions that promote rapid flame speeds and associated pressure increases. The following conditions promote rapid flame speed:

- Turbulent jet releases
- Partial confinement due to large structures or buildings in the release area
- Repeated obstructions usually due to congested process equipment and piping
- Ignition delays that allow the formation of large clouds with vapor-gas concentrations above the lower flammable limit

Flame speeds needed to generate potentially damaging overpressures in a virtually unconfined area are of the order of 100 m/sec. As the level of confinement increases, the required flame speeds decrease.

The levels of turbulence or obstructions and the size of the cloud needed to generate such flame speeds depend on the reactivity of the flammable gas or vapor. Highly reactive gases or vapors with large laminar burning velocities and those more prone to flame accelerations are more likely to be involved in vapor cloud explosions. Some of the vapors that have been involved in large numbers of vapor cloud explosions include propane, propylene, ethylene, and various aromatic hydrocarbons.

Table 2.8.5 lists the vapor cloud explosion incidents described in the CCPS guidelines.[35] The gas or vapor, quantity released, and the numbers of reported casualties are shown in the table. The large number of fatalities in the 1948 Ludwigshafen incident was due to the release occurring in a populated area. The large number of fatalities in the 1989 Ufa incident was due to the cloud being ignited as two passenger trains were passing each other. These incidents, and the Flixborough and Pasadena incidents, demonstrate that vapor cloud explosions can be the most catastrophic of all accidental explosions. The same conclusion can be drawn from considerations of property damage. Lenoir and Davenport[36] have provided a much more extensive compilation of vapor cloud explosion incidents.

A better understanding of how vapor cloud explosions differ from nonexplosive ignitions of large vapor clouds can be obtained from a review of the flame acceleration factors in these incidents. The Ludwigshafen, Raunheim, Flixborough, Pasadena, and Kuwait incidents all occurred in petrochemical processing facilities with highly obstructed processing areas containing pipe racks, process columns, tanks, and so on. The Kuwait incident is particularly interesting because there were eight separate processing areas, each one corresponding to a blast center with damage caused by relatively high pressures. According to *Guidelines for Evaluating the Characteristics of Vapor Cloud Explosions, Flash Fires, and BLEVE,*[35] the Port Hudson explosion was ignited inside a concrete block warehouse, and then propagated outside into a rural area. The Ufa explosion was ignited by one of two passing trains. Trees in a heavily forested area around the tracks may have also contributed to the flame acceleration in the Ufa explosion.

Predictions of pressure damage from vapor cloud explosions consist of two parts. In the vicinity of the cloud, pressures depend on estimated flame speed and level of confinement. Theoretical calculations performed by Strehlow et al.[37] and described in the CCPS guidelines show how the pressure generated in the cloud varies with flame speed. Guidance on estimating flame speeds and confinement for vapor cloud explosion predictions have been developed by Baker et al.,[7] and the resulting method is called the Baker-Strehlow method.

TABLE 2.8.5 Noteworthy Vapor Cloud Explosion Incidents

Predictions of blast wave pressures outside the cloud entail using curves of shock pressure, P_{s0}, versus an energy-scaled dimensionless distance, defined as follows:

$$\bar{R} = \frac{rP_0^{1/3}}{E^{1/3}} \quad [5]$$

where

r = Distance from the blast epicenter

P_0 = Atmospheric pressure

E = Combustion energy that contributes to the blast wave

The computation of E involves estimating the amount of flammable vapor released and the yield; that is, the fraction of the theoretical combustion energy contributing to the blast wave. An essential part of the Baker-Strehlow method is the choice of an appropriate yield value for gases or vapors of various reactivity classes. Another important step in the method is the selection of the appropriate flame speed or Mach number curve to use, again based on the gas/vapor reactivity category. The effect of using the Baker-Strehlow curves, or similar curves generated by other researchers, is that the blast wave pressure at a given energy-scaled distance is higher than what would be predicted using the curve shown in Figure 2.8.3, which was based on correlations for blast pressures produced by condensed phase explosives. Thus, vapor cloud explosions represent a more extensive damage and injury potential for a given blast wave energy. This is consistent with the observed areas of destruction in many of the large vapor cloud explosion incidents.

SUMMARY

An overview of explosion fundamentals is provided in terms of the relationship between peak pressure and energy release magnitude and duration for various types of explosions. Ideal blast wave propagation and scaling relations are also discussed, along with a brief summary of primary and secondary fragmentation effects. The following specific types of explosions are briefly described: flammable gas and vapor deflagrations, gas detonations, combustible dust deflagrations, chemical reaction explosions, steam explosions, and vapor cloud explosions.

Information and Analysis for Fire Protection

Richard L. P. Custer ❑ **John R. Hall, Jr.**

3.1 An Overview of the Fire Problem and Fire Protection
3.2 Fire Loss Investigation
3.3 Fire Data Collection and Databases
3.4 Use of Fire Incident Data and Statistics
3.5 Introduction to Fire Modeling
3.6 Applying Models to Fire Protection Engineering Problems and Fire Investigations
3.7 Fire Hazard Analysis Techniques
3.8 Fire Risk Analysis
3.9 Closed Form Enclosure Fire Calculations
3.10 Performance-Based Codes and Standards for Fire Safety
3.11 Overview of Performance-Based Fire Protection Design

The practice of fire protection revolves around decision making: deciding how to best meet a code requirement or a client objective. The principal tools of decision making are information (whether in the form of statistics or investigative findings), analysis, (through, for example, calculations or modeling), and the application of codes and design techniques. Section 3 of the *Fire Protection Handbook*® focuses on these decision-making tools of fire protection. Because this section describes a more explicitly engineered approach to fire protection, its chapters include extensive references to the guides and works published by the Society of Fire Protection Engineers. Anyone who is interested in pursuing the kinds of analysis described in this section is strongly encouraged to seek out the SFPE materials and members for further guidance.

Chapter 1, "An Overview of the Fire Problem and Fire Protection," provides a statistical perspective on the size, trends, and patterns of the U.S. and global fire problems. Chapter 2, "Fire Loss Investigation," concentrates on the more detailed information available from an individual fire incident and includes a discussion of the role of NFPA 921, *Guide for Fire and Explosion Investigations.* Chapter 3, "Fire Data Collection and Databases," and Chapter 4, "Use of Fire Incident Data and Statistics," describe the sources (particularly the U.S. National Fire Incident Reporting System) used for statistical analysis of fire experienced in the real world and how data source issues affect the analysis process.

The section next addresses fire modeling through two chapters. Chapter 5, "Introduction to Fire Modeling," explores the principal types of models (zone, computational fluid dynamics, and probabilistic) used to predict the growth of fire and the spread of fire effects. Chapter 6, "Applying Models to Fire Protection Engineering Problems and Fire Investigations," addresses model applications and considerations for selecting and using fire models.

Chapter 7, "Fire Hazard Analysis Techniques," introduces techniques to determine the expected outcome of a specific set of conditions, called a fire *scenario.* Topics covered include hazard identification, developing and quantifying design fire scenarios, and other steps in fire hazard analysis. Chapter 8, "Fire Risk Analysis," describes a comprehensive form of analysis that can be applied to any fire safety choice when fire hazard analysis of scenarios is expanded to include issues of scenario likelihood, identifying a comprehensive set of representative fire scenarios, and risk evaluation.

Chapter 9, "Closed Form Enclosure Fire Calculations," presents equations that can be solved using calculators to estimate conditions during the preflashover fire growth phase of a compartment fire.

In its final two chapters, the section considers performance-based approaches to fire safety. Chapter 10, "Performance-Based Codes and Standards for Fire Safety," contrasts performance-based

Richard L. P. Custer, M.Sc., FSPE, is associate principal and technical director at ARUP Fire in Westborough, Massachusetts, and a fellow of the Society of Fire Protection Engineers.

John R. Hall, Jr., Ph.D., is NFPA's assistant vice-president for fire analysis and research.

and prescriptive-based regulations and describes the role of codes and standards in performance-based design. Chapter 11, "Overview of Performance-Based Fire Protection Design," summarizes the performance-based design process, compares deterministic hazard assessment and probabilistic risk assessment in the context of performance-based design, and presents a new case study in the use of performance-based design.

Fire Loss Trends
Fire Prevention
Fire Protection
Materials, Products, and Environments
Detection and Alarm
Suppression
Confining Fires
Evacuation of Occupants
Systems Approaches for Property Classes
Organizing for Fire Protection

Key Terms

automatic sprinkler system, conflagration, evacuation, explosion, fire confinement, fire detection and alarm, fire fighter safety, fire loss, fire prevention, smoke alarm, systems approach

When the first *Fire Protection Handbook* was published in 1896, it contained no information on the size, trends, or patterns of the U.S. fire problem. Like most scientific and engineering handbooks, especially in years gone by, the first *Fire Protection Handbook* merely compiled a series of rules, tables, and formulas, which the knowledgeable fire safety professional of that time would find useful. One had to read between the lines to realize that the information provided in that handbook said nothing about hazards to life and limb and little about fire prevention as a strategy to reduce fire loss. (One also saw very little about such related hazards as electrical shock, hazardous materials, and environmental risks, topics that later editions have steadily expanded.)

In the century since that first edition appeared, the field of fire protection has grown tremendously. This edition of the *Fire Protection Handbook* is more than an order of magnitude larger than the original edition. With that growth of information has come an increasing need for context, perspective, and systematic approaches to organizing knowledge.

This chapter has two goals. One is to provide a perspective on the size, trends, and patterns of the U.S. fire problem and the global fire problem as well. Special attention has been paid to the incidents that led to changes in codes and standards—and the changes in fire experience that followed those code and standard changes. The other goal is to provide a basic structure for the elements of fire protection—a structure that can be tied to particular measures of the fire problem and that is carried forward in the first-level organization of this handbook. In the handbook, Sections 2–4 cover basic information and methods. Sections 5–11 cover prevention through education or engineering and other safety measures defined by materials, equipment, other products, processes, services, or facilities. Sections 12–13 cover the fire service; Section 14 covers detection and alarm; Sections 15–17 cover suppression; and Sections 18–19 cover confinement and structural protection. Sections 20 and 21 cover occupancy type. Accordingly, this chapter begins with basic information on the U.S. and world fire problem, follows with material organized by stage of fire protection, and concludes with information on different occupancies and information on the fire service.

To understand the sequencing of the sections, think of fire protection as a series of opportunities to intervene against a hostile fire, arrayed along a timeline of potential growth in fire severity. First, there are the opportunities to prevent the fire entirely, by education or by changes to products, whether heat sources or combustible materials (addressed in Sections 5–11). Second, there are opportunities to slow the initial growth and spread of fire or to reduce the severity of fires through the design, selection, and handling of materials and products (also addressed in Sections 5–11). Third, there are opportunities to detect fire early, permitting effective intervention before damage becomes too severe (addressed in Section 14). Fourth, there are opportunities for automatic or manual suppression (addressed in Sections 15–17). Fifth, there are opportunities to confine the fire in space through compartmentation and other passive fire protection methods (addressed in Sections 18–19). Sixth, there are opportunities to move occupants to safe locations, taking advantage of the extra time provided by the earlier steps to move people from hazardous locations to safety or to defend them where they are (addressed primarily in Sections 20–21, along with occupancy-specific aspects of the topics covered in Sections 5–11 and

John R. Hall, Jr., Ph.D., is NFPA's assistant vice-president for fire analysis and research.

Arthur E. Cote, P.E., FSPE, is NFPA's executive vice-president and chief engineer (retired).

14–19). Before examining each of these fire protection strategies, it is useful to assess the size of the fire problem that faces us and the success achieved in reducing it over the past decades.

See also Section 1, Chapter 1, "Challenges to Safety in the Built Environment"; Section 1, Chapter 3, "Codes and Standards for the Built Environment"; Section 3, Chapter 4, "Use of Fire Incident Data and Statistics"; and Section 20, Chapter 1, "Assessing Life Safety in Buildings."

FIRE LOSS TRENDS

Fire in the United States

Table 3.1.1 and Figures 3.1.1 through 3.1.4 show that the number of fires has declined over the past quarter century. Civilian fire deaths were stuck at around 6000 annually during 1982 to 1988, but have declined by roughly half during the past quarter century. Civilian fire injuries showed no consistent trend up or down, until the mid-1990s, when they began to decline consistently. Direct property damage has risen dramatically, but most of that is due to inflation, although there have been years when individual fires of historic size have driven the total, adjusted for inflation, to new heights.

Table 3.1.2 and Figure 3.1.5 provide a longer perspective on U.S. fire deaths by switching to trends in the death certificate database. (NFPA uses this database only for long-term trend analysis, where there is no alternative database with as much consistency in methodology. Fires involving postcrash vehicle fires or arson are often excluded or missed from the fire totals in the death certificate database.)

Fire deaths have fallen by roughly two-thirds in the past nine decades since their peak levels around World War I. Fire death *rates* have fallen by a factor of 9. The decline in fire deaths was fairly irregular until the mid-1960s, in part because indi-

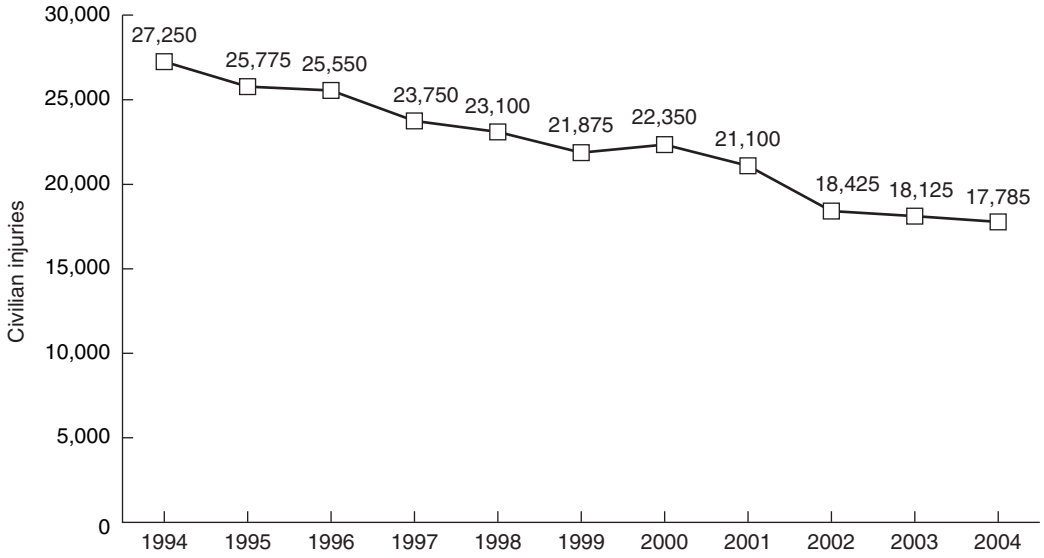

FIGURE 3.1.3 U.S. Civilian Fire Injury Trend, 1994–2004 (Source: NFPA National Fire Experience Survey)

vidual incidents with death tolls in the hundreds used to occur with some regularity. A few such incidents could significantly affect the total U.S. fire death toll in a given year. From 1955 to the present, there have been only five U.S. incidents with a death toll of 100 or more—the Lexington, Kentucky, restaurant fire in 1977; the Oklahoma City, Oklahoma, office building bombing of 1995; the Florida inflight fire of 1996; the terrorist attack on the World Trade Center in 2001; and the 2003 Station nightclub fire in Rhode Island. By contrast, the previous 55 years (1900 through 1954) produced 44 incidents involving death tolls of 100 or more, a decline from nearly one fire per year of that severity to less than one per decade.[1]

America Burning,[2] the report of the National Commission on Fire Prevention and Control (NCFPC), set a goal in 1973 of reducing the U.S. fire death toll by one-half in a generation, which is usually understood to mean 25 years. With that generation now gone, fire deaths measured by death certificates did fall by roughly one-half.

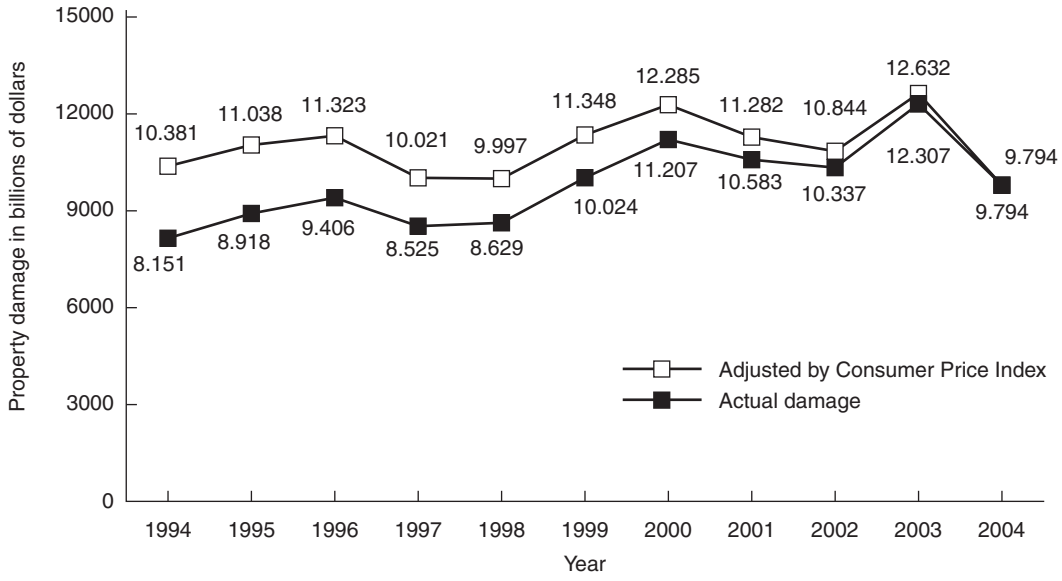

FIGURE 3.1.4 U.S. Direct Property Damage Trend, 1994–2004. Note: 2001 figures exclude the $33.44 billion loss at the World Trade Center. (Source: NFPA National Fire Experience Survey)

TABLE 3.1.2 History of U.S. Fire and Burn Fatalities

Year	*Fire Deaths**	*Fire Deaths per 100,000 Population*
1913	8,900	9.1
1918	10,200	9.9
1923	9,100	8.1
1928	8,400	7.0
1933	6,800	5.4
1938	6,500	5.0
1943	8,700	6.5
1948 (old)	7,700	5.3
1948 (new)	6,800	4.7
1953	6,600	4.2
1958	7,300	4.2
1963	8,200	4.3
1968	7,300	3.7
1973	6,500	3.1
1978	6,200	2.8
1983	5,000	2.2
1988	5,000	2.0
1993	3,900	1.5
1998	3,300	1.2
2003	3,400	1.5

*Fire deaths are calculated on the basis of death certificates and are given to the nearest hundred. Fire deaths involving arson or postcollision vehicle fires may be omitted. Classification changes in 1968, 1958, and especially 1948 limit comparability of figures.

Source: *Injury Facts,* 2005–2006 ed., National Safety Council, Itasca, IL.

Table 3.1.3 provides a longer perspective on property damage in fire, using estimates from the Insurance Services Office (ISO). (NFPA uses this database only for long-term trend analysis, where there is no alternative database with as much consistency in methodology. The database has considerable uncertainty due to its adjustments for uninsured and unreported losses.) Fire losses have grown more than 250 times in the past 124 years, but this reflects a factor of five decline in the purchasing power of the dollar and a more than 60-fold increase in the nation's economy measured by gross national product (GNP) after adjustment for those changes in purchasing power. As a fraction of GNP, fire loss has declined by a factor of five since the turn of the century, a large decline though not as large as the decline in the fire death rate relative to population.

Fire Around the World

Figure 3.1.6 shows fire death rates in many countries of the world, especially Europe. It is possible that the completeness of reporting varies from country to country. As an example, fire statistics jumped in the Russian Federation after the society became more open at the urging of President Boris Yeltsin. The highest fire death rates tend to be in parts of the former Soviet Union.

Figure 3.1.7 looks at a quarter century of trend data on fire death rates for three countries where comparable data have been consistently available for this long period. The United States and Canada have tracked together throughout this period, and both have narrowed the gap in fire death rates with the United Kingdom and Japan, passing the latter in the 1997. The U.S. and Canadian rates were twice as high in the late 1970s, roughly 50 percent higher in the late 1980s, and nearly the same in the late 1990s. The gap is closing because the United States and Canada

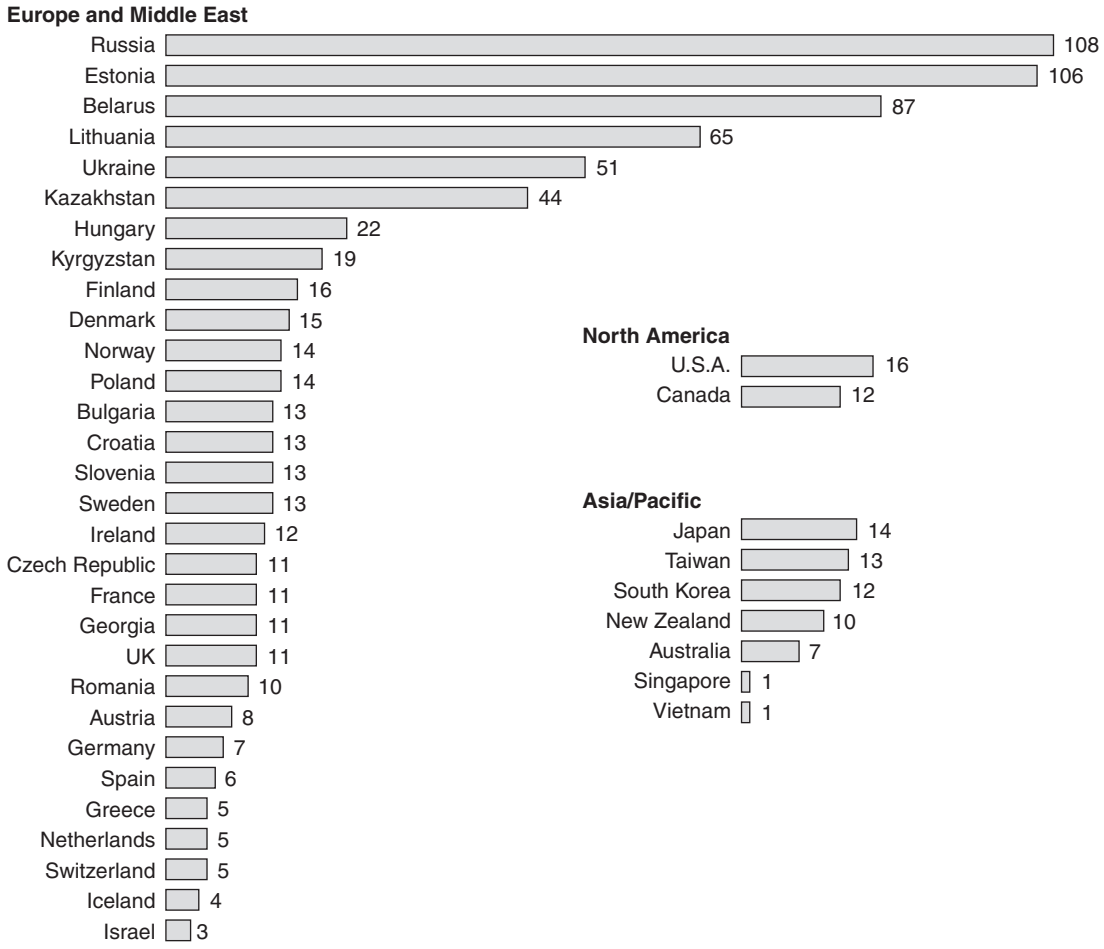

FIGURE 3.1.6 Fire Deaths Around the World, per Million Population, 1993–2002. Note: Countries were included only if they had rates for at least 7 of the 10 years. (Source: CTIF Center of Fire Statistics, *Fire Statistics,* No. 10, 2004, Table 5)

have been improving fire safety faster than other countries. Throughout, analysis has shown that the United States does well in holding down the average severity of fire (i.e., deaths per fire) but fares poorly in holding down the fire incident rate (i.e., preventing fires).

Figure 3.1.8 shows 2000–2002 property loss to fire as a fraction of gross domestic product, based on the estimates of the World Fire Statistics Centre (WFSC). The WFSC analysts make a number of adjustments to nationally reported loss data, in order to improve comparability. Comparable data on fire loss are not readily available outside North America, Europe, and Japan.

Most of the visibility of the fire problem and a large share of the public's fear and concern centers on very large fires. Table 3.1.4 lists the 10 deadliest U.S. fires and explosions through 2004. Except for the World Trade Center attacks of September 11, 2001, the most recent incident on the list is a 1947 incident involving shipping and industrial port facilities. Table 3.1.5 lists the 10 deadliest U.S. fires and explosions of the decade 1995–2004. The list is led by two terrorist attacks on office buildings. There are two aircraft fires, two nursing home fires, a nightclub fire, two industrial fires not involving buildings, and a wildland fire. Note that there are three wildland fires on the list of all-time deadliest fires.

Table 3.1.6 lists the 10 deadliest fires and explosions of all time in the world. The death tolls in two Japanese earthquake fires dwarf every other incident on the list. The other incidents are major conflagrations, industrial explosions, and the World Trade Center attacks.

Table 3.1.7 lists the 10 deadliest fires and explosions of all time in Central and South America and the Caribbean. This list shows more recent fires than any of the other all-time lists.

Table 3.1.8 lists the 10 costliest U.S. fires and explosions of all time adjusted for inflation, and Table 3.1.9 lists the 10 costliest U.S. fires and explosions of the decade 1995–2004. The all-time list includes four long-ago citywide conflagrations (one triggered by an earthquake), four recent wildland fires, one recent industrial explosion and fire incident, and the World Trade Center attacks. The top 10 for the decade 1995–2004 includes four wildland fires, four industrial incidents, one inflight airline fire, and the World Trade Center attacks. Except for the wildland/urban interface, the risk of

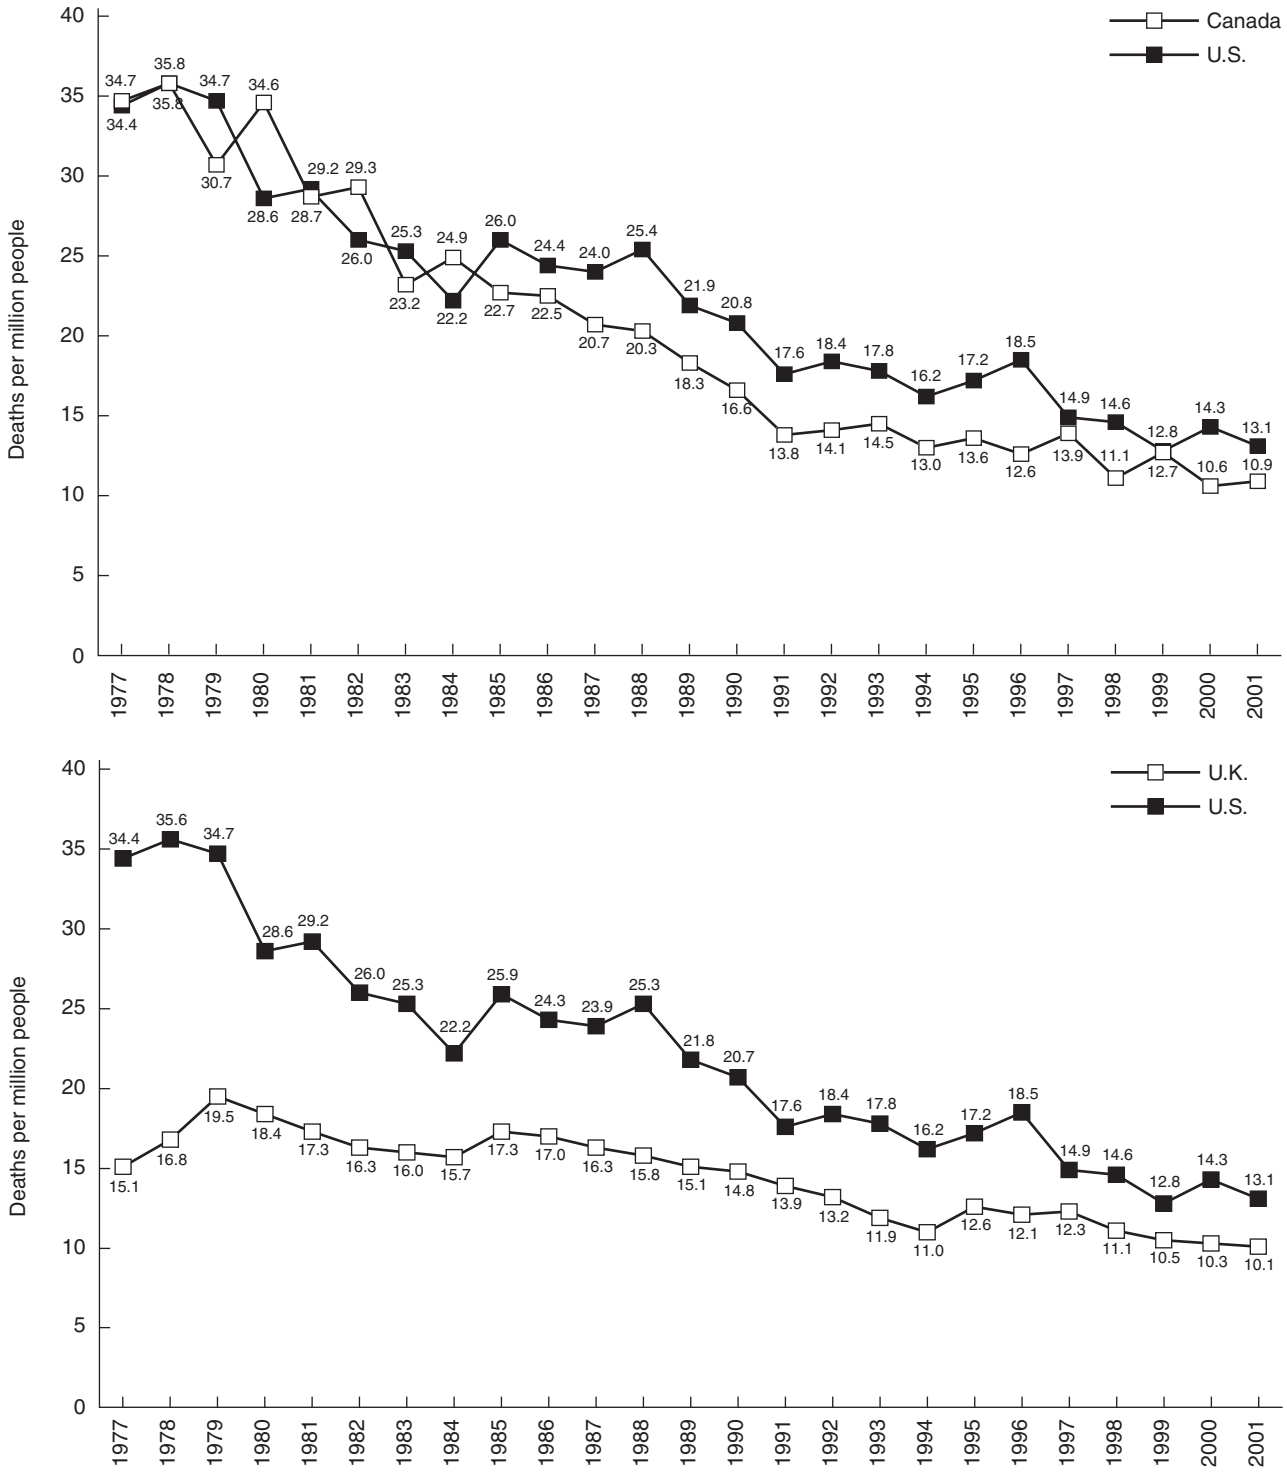

FIGURE 3.1.7 Fire Death Rates for Four Countries, 1977–2001. Note: 2001 U.S. rate excludes events of September 11, 2001. (Sources: Data from NFPA Survey, U.S. Census Bureau, annual reports from Canadian Fire Marshals and Fire Commissioners, UK Home Office, Japan's *White Book* [Dr. Ai Sekizawa])

conflagration has declined significantly from the pattern of a century ago.

Conflagration lacks a fully standardized definition. The definitions used to code death certificates use the term *conflagration* to mean any building fire. More often, conflagration is used colloquially to mean any large fire with significant flame showing outside. NFPA generally uses the term *conflagration* to describe a fire with major

large postearthquake fires have occurred, the term *city fire* is often used for a conflagration.

Table 3.1.10 describes different types of conflagrations, or group fires, and gives recent examples of each. The first type listed is also the most common conflagration scenario in recent years, which is the forest fire or brush fire that spreads to nearby buildings in what is called the urban/wildland interface. The classic conflagration scenario of the last century, involving narrow streets and closely packed buildings, is now comparatively rare. The 1973 Chelsea, Massachusetts, conflagration is the premier example in recent decades. The construction and density conditions for such fires are largely confined to the old manufacturing areas of some older cities, particularly in the Northeast. A more common problem, particularly in the Southwest, is the phenomenon of conflagrations driven by strong, hot, dry winds and untreated wood shingles. This problem has been around for as long as NFPA has been collecting information on major fires.

FIRE PREVENTION

Every hostile fire requires an initial heat source, an initial fuel source, and something to bring them together. That something

TABLE 3.1.6 Deadliest Fires or Explosions in the World of All Time Excluding Bombings and Wartime Attacks

1.	Tokyo to Yokohama, Japan September 1, 1923 Most of 142,807 total deaths	Earthquakes resulted in fires that caused most deaths
2.	Tokyo, Japan March 21, 1857 Most of 107,000 total deaths	Earthquake resulted in fires that caused most deaths
3.	Kiev, U.S.S.R. April 26, 1986 31 immediate deaths plus 7,000–8,000 deaths of exposed clean-up workers.	Nuclear power plant chemical explosion led to release of nuclear radiation
4A.	Constantinople (now Istanbul), Turkey 1729 7,000 deaths	Urban conflagration
4B.	Chiang-king, China September 3, 1949 7,000 deaths	Fire
6.	Bhopal, India December 3, 1984 3,849 deaths by chemical fumes	Pesticide plant explosion released deadly chemical fumes
7.	Johanngeorgendstadt, East Germany November 29, 1949 3,700 deaths	Uranium mine explosions
8.	Brescia, Italy 1769 3,000+ deaths	Gunpowder explosion in arsenal
9.	New York, New York, USA September 11, 2001 2,749 civilian and fire fighter deaths	Office buildings collapsed due to fire started when airliners were flown into upper floors
10.	Chungking, China September 2, 1949 1,700 deaths	Riverfront conflagration; reported separately from 4B, which occurred the next day

Note: These are incidents known to NFPA and deemed to fit within the eligibility parameters, based on best available information. Terrorist incidents using explosives are excluded, but other terrorist incidents are not treated as wartime incidents and are not excluded. Incidents involving warships but not arising from conflict are not excluded.

TABLE 3.1.7 Deadliest Fires or Explosions of All Time in Latin America and the Caribbean Excluding Bombings and Wartime Attacks

	Number of Deaths
1. Santiago, Chile, church fire December 8, 1863	1488–2500
2. Cali, Colombia, explosion of seven dynamite trucks August 7, 1956	1100–1200
3. Cubatão, Brazil, oil pipeline explosion February 25, 1984	508
4. Lagunillas, Venezuela, conflagration November 14, 1939	500
5. Suburb of Asuncion, Paraguay, supermarket fire August 1, 2004	426
6. Mexico City, Mexico, gas storage area explosion November 19, 1984	334
7. Niterói, Brazil, circus fire December 17, 1961	323
8. Lima, Peru, fireworks explosion at fireworks stand in crowded shopping area of stores and sidewalk stalls December 29, 2001	276
9. Guatemala City, Guatemala, mental hospital fire July 14, 1960	200–225
10. Guadalajara, Mexico, explosion of chemical released into sewers April 22, 1992	190–200

Note: These are incidents known to NFPA and deemed to fit within the eligibility parameters, based on best available information. Terrorist incidents using explosives are excluded, but other terrorist incidents are not treated as wartime incidents and are not excluded. Incidents involving warships but not arising from conflict are not excluded.

TABLE 3.1.8 Ten Costliest U.S. Fires and Explosions of All Time (in 2004 dollars)

	Loss in Year Fire Occurred (in Dollars)	*Adjusted Loss (in 2004 Dollars)*
1. The World Trade Center, New York City, New York September 11, 2001	33.4 billion	35.6 billion

nearly always has a human component, usually an immediate act or omission that brings heat and fuel together or sometimes the delayed effects of an error in design or installation. Fire also requires oxygen and sustainable chemical chain reactions, both of which can be useful points of attack for some suppression systems. Nevertheless, the three components of heat, fuel, and human error are central to nearly all fires and can be used as a framework for thinking about fire prevention, without much fear of oversimplification.

Fire Prevention Actions

It is important to remember that prevention can occur through successful action on the heat source, the fuel source, or the behavior that brings them together. No one line of attack is clearly preferable to the other, and success is most likely to come if all three components are treated as real options at all times.

Product redesign is the means by which a heat source or a fuel source is changed. Such a change can come about in several ways: (1) regulation, (2) design to a set of voluntary consensus codes and standards, (3) a voluntary industrywide program to change product designs, not driven by laws or codes, and (4) product redesign in response to consumer demand.

Changing behavior means education, which also may be done by targeting a variety of audiences. Schoolchildren are a group that can be reached when they are ready and able to learn substantial quantities of information. Manufacturers' labels and instructions reach consumers when they may be most disposed to learn rules for the fire-safe use of products. Product advertisements and public service announcements (PSAs) have the potential to reach large audiences. Brochures, educational kits, community meetings, and the like can reach small, motivated

TABLE 3.1.10 Illustrative Recent Conflagrations and Group Fires

1. Urban/wildland interface, Los Alamos, NM, 2000
   A fire that began as a prescribed burn under the control of the National Park Service ultimately spread over 48,000 acres (compared to the intended 900 acres), resulting in a total estimated loss of $1 billion.
   Four of the costliest U.S. fires and explosions of all time are wildland/urban interface fires.

2. Congested, combustible district, Chelsea, MA, 1973
   The fire began in a yard area of a congested district of combustible buildings, including multifamily housing and storage properties. The heavy fuel load inside and outside the buildings and the narrow separations between buildings created an ideal environment for rapid multibuilding fire growth. The wind was strong, gusting up to 48 mph (80 kph). The water supply was inadequate to support master streams, and some sprinklered properties had broken piping that depleted the water supply without fighting the fire. Eventually, hundreds of buildings over 17 blocks were destroyed. Damage was estimated at $4 million.
   More recently, a 2004 fire in Richmond, Virginia, spread over 20 city blocks and involved more than 25 properties. Wind gusting up to 23 mph (38 kph) caused flaming brands and embers to travel the short distances to neighboring buildings.

3. Untreated wood shingles, San Jose, CA, 2002
   A fire began in a two-to-seven-story residential and shopping complex under construction. Sprinklers were installed in about 20 percent of the complex at that point, but all were turned off because of ongoing work. Flying brands and embers spread fire up to a half mile (nearly a kilometer) downwind to an apartment and townhouse complex with wood shake roofs built in the 1970s. Total loss was estimated at $90 million.
   A 1982 Anaheim fire also involving wood shingles resulted in an estimated loss of $50 million. The fire, initially reported as a tree fire, spread over several blocks. Untreated wood shingles provided a ready source of secondary ignitions and firebrands, which were transported by high winds, gusting up to 60 mph (100 kph). These hot, dry Santa Ana winds spread damage to 53 structures, for total estimated damages of $50 million.

Source: NFPA Fire Incident Data Organization.

audiences who can act as change agents. And Fire Prevention Week, of which NFPA is the originator and a sponsor, provides heightened attention to fire safety each October.

People can be educated and motivated if approached in the right way. Addressing people effectively may involve nothing more than emphasizing what to do rather than what not to do. This is why an important milestone of the late 1970s was the introduction into the nation's schoolrooms of fire safety education based on sound behavioral principles and good learning techniques.[3]

Product design strategies need to be carefully examined and not treated as simple technological quick fixes. Many design improvements can be undone by product users if the users have not also been educated to the importance of fire-safe product usage. Some product design proposals have high costs relative to the problem they address, and some involve the loss of other significant product performance features, even nonfire safety features. And with any product design strategy, except one driven by consumer demand, there should be concern over the loss of freedom of choice.

Educational programs have concerns, too. Comprehensive, proven fire and life safety curricula are still in very limited use in U.S. schools. Although many schools have some fire safety education, there is a danger that brief exposure to fire safety slogans will be considered an adequate means of teaching fire-safe behavior. This is not the case.

Also, in any fire prevention program, the highest-risk groups tend to be the hardest to reach. The poor may not be able to afford safer products. Small rural communities are too

scattered to be reached efficiently by targeted means of communications. Preschool children are harder to reach with curriculum programs. Elderly people may resist changes in products and practices. This means that a program with less-than-national coverage is likely to miss a disproportionate number of those most in need. The challenge to fire prevention is to recognize this danger and design programs that reach everyone. It can be done. For example, universal fire safety education, particularly in the schools but also in neighborhoods, seems to be a crucial factor in the still lower fire death rates in western Europe and Japan.

Leading Causes of Fire

As noted, hostile fire requires an initial heat source, an initial fuel source, and usually a behavioral error. Therefore, causes can be defined and ranked in terms of any of these three components. Table 3.1.11 provides a consolidated list of leading causes for 1999–2002 U.S. structure fires, based on behaviors and on equipment and other heat sources.

Cause patterns can be quite different between different occupancy groups, as is illustrated in Tables 3.1.12 and 3.1.13, which provide similar leading-cause listings for homes and nonhome structures. Cause profiles for more detailed occupancy groups are updated annually by NFPA's One-Stop Data Shop.

Smoking materials are the number one cause of civilian fire deaths, accounting for more than a quarter of deaths, and most begin with ignition of upholstered furniture, mattresses, or bedding. The ignitability of these items by lighted tobacco products has been declining for some time, due to a federal law restricting mattress construction and a voluntary program by the upholstered furniture industry. The growing popularity of state requirements for fire-safe (reduced ignition strength) cigarettes offers the promise of improvements in the near future.

Intentional fires are the number one cause of property damage for structure fires, accounting for nearly one of every five

TABLE 3.1.11 Leading Causes of U.S. Structure Fires, 1999–2002 Annual Averages*

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Cooking equipment fire	126,800	(25%)	280	(9%)	4,570	(26%)	665	(8%)
Identified cooking equipment	90,200	(17%)	280	(9%)	4,050	(23%)	644	(7%)
Confined cooking fire	36,700	(7%)	0	(0%)	520	(3%)	21	(0%)
Heating equipment fire	65,000	(13%)	340	(11%)	1,470	(8%)	867	(10%)
Confined heating equipment fire	15,500	(3%)	0	(0%)	40	(0%)	11	(0%)
Identified heating equipment	49,500	(10%)	340	(11%)	1,440	(8%)	856	(10%)
Intentional	59,500	(12%)	600	(19%)	1,800	(10%)	1,592	(18%)
Electrical distribution or lighting equipment	45,700	(9%)	240	(8%)	1,210	(7%)	1,087	(13%)
Smoking materials	35,100	(7%)	890	(28%)	2,130	(12%)	627	(7%)
Candle	20,900	(4%)	170	(5%)	1,750	(10%)	468	(5%)
Exposure to other fire	25,500	(5%)	30	(1%)	120	(1%)	497	(6%)
Playing with heat source	17,800	(3%)	220	(7%)	1,430	(8%)	304	(4%)
Clothes dryer or washer	17,300	(3%)	10	(0%)	410	(2%)	118	(1%)
Contained trash or rubbish fire	13,600	(3%)	0	(0%)	40	(0%)	2	(0%)
Lightning	8,000	(2%)	10	(0%)	60	(0%)	295	(3%)

Note: These are the leading causes, obtained from the following list: intentional (from the NFIRS field "cause"); playing with fire (from factor contributing to ignition); confined heating (including confined chimney and confined fuel burner or boiler fires), confined cooking, and contained trash or rubbish (from incident type); identified heating, identified cooking, clothes dryer or washer, torch (including burner and soldering iron), electrical distribution and lighting equipment, medical equipment, and electronic office or entertainment equipment (from equipment involved in ignition); smoking materials, candles, lightning, and spontaneous combustion or chemical reaction (from heat source); and mobile property involved (from mobile property involved in ignition). The statistics on smoking materials and candles include a proportional share of fires in which the heat source was heat from an unclassified open flame or smoking material. Exposure fires include fires with an exposure number greater than zero, as well as fires identified by heat source or factor contributing to ignition when no equipment was involved in ignition and the fires were not intentionally set. Because contained trash or rubbish fires are a scenario without causal information, they are shown at the bottom of the table if they account for at least 2% of the fires. Causal information is not routinely collected for these incidents. The same fire can be listed under multiple causes, based on multiple data elements. Details on handling of unknowns, partial unknowns, and other underspecified codes may be found in the Appendix.

These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest ten, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation.

dollars lost. More than half of all the people arrested for arson are juveniles.

Cooking equipment is the leading cause of structure fires and structure fire injuries, and is involved in the majority of unreported home fires. Unattended cooking is the principal behavioral factor.

Heating equipment is the second leading cause of structure fire incidents. Most involve portable or other space heaters; however, the current size of the heating fire problem is much smaller than the peak it reached shortly after the rapid growth in usage of portable and other space heaters in the 1970s and early 1980s.

Child fire play, typically involving matches or lighters, accounts for only 1 of every 14 fire deaths.

Electrical distribution system equipment accounts for a much smaller share of the fire problem than many people realize, ranking no higher than fourth among the leading cause categories for any measure of loss, except for property damage, where it ranks second, reflecting the fact that many such fires are in concealed spaces and are hard to attack. The widespread use and enforcement of NFPA 70, *National Electrical Code*®, is probably the primary reason why electrical systems are not among the leading causes of fire. Moreover, even a fire cause such as this, which seems to be solely an equipment problem, usually involves human error. One benchmark study found that 61 percent of home electrical fires involved code violations, particularly the general workmanship provisions.[4] Exposed elements, such as cords, are even more subject to abuse by occupants.

FIRE PROTECTION

Recognizing that prevention will never be 100 percent successful, it is necessary to plan and design so as to mitigate damages when fire occurs. The various strategies to do this constitute what is usually called fire protection. It is important to remember that fire protection requires the development of an integrated system of balanced protection that uses many different design features and systems to reinforce one another and to cover for

TABLE 3.1.13 Leading Causes of U.S. Nonhome Structure Fires, 1999–2002 Annual Averages*

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Intentional	25,100	(18%)	40	(22%)	300	(12%)	872	(27%)

one another in case of the failure of any one. Defense in depth and engineered redundancy are concepts that are also relevant here. The process of achieving that integration, balance, and redundancy to attain fire safety objectives is the essence of fire protection engineering, including codes and standards.

This means that success is not measured by the extent of use of any one technology or system or code. Success is measured by the extent of use of effectively designed, integrated fire protection systems. No one system should be considered disposable, and no one system should be considered a panacea.

Once fire has started, the first opportunity to reduce its impact comes in the design of burnable items, that is, the choice of materials and products and their environments. Both the growth of the fire from small to large and its spread along vertical or horizontal surfaces may be slowed through such design.

Active fire protection systems provide the next opportunity. Automatic detection systems will tend to activate first, followed by automatic sprinklers or other automatic suppression systems, although this will vary depending on the design of the detection and suppression systems.

Passive fire protection provides the final opportunity to stop the fire and smoke but also plays an essential role in providing automatic systems with a manageable fire to act on. Passive protection is designed to confine fire and smoke in zones, a concept called compartmentation. Special attention is given to protection of the building's structural integrity and the spaces through which occupants will move to safety.

Occupant evacuation depends on effective detection and a system to alert occupants, along with a total fire safety design that will defend the occupants where they are or provide

protected routes to safe refuges, inside or outside the building. Evacuation also depends on the knowledge of the occupants.

MATERIALS, PRODUCTS, AND ENVIRONMENTS

If prevention fails, the first opportunity to reduce fire damage comes in the design of materials, products (including assemblies), and environments so as to slow down the growth and spread of fire. Tables 3.1.14 through 3.1.16 show that most structure fires never grow beyond the first involved room, but most deaths and property damage occur in the 29 percent of fires that do. This pattern holds for homes and for structures other than homes. Clearly, then, a fire that can be slowed in its growth so that it can be discovered and controlled before fire leaves the first room is likely to result in far less damage to people and property. (Injuries are something of an exception, as they are almost as likely to occur in small fires as in large ones.)

The following are some of the fire protection approaches that may be taken under this overall strategy:

1. Restrict materials used in contents and furnishings.
   - Reduce the heat release rate.
   - Reduce the smoke generation rate.
   - Prevent unusual toxic hazard relative to quantity of smoke generated.
2. Add fire retardant to materials.
   - Slow the growth of the heat release rate.
3. Use fire-resistive barriers.
   - Slow the spread of fire to large secondary items.
4. Restrict the total fuel load.
   - Limit contents based on total fuel potential.
5. Restrict linings of rooms to prevent rapid flame spread.
   - Restrict wall coverings.
   - Restrict ceiling coverings.
   - Restrict floor coverings.
6. Restrict materials in concealed spaces.
   - Restrict concealed combustibles.
   - Restrict concealed space linings.
7. Require safe handling of large quantities of potential fuel.

With regard to the last point, large quantities of combustible or flammable liquids or gases are the most obvious examples of materials that could make a small fire huge very quickly. It is important to handle and store these materials safely, following procedures such as those in NFPA 30, *Flammable and Combustible Liquids Code,* NFPA 54, *National Fuel Gas Code,* and NFPA 58, *Liquefied Petroleum Gas Code.* Unusually hazardous environments, such as oxygen-enriched atmospheres, also receive special attention.

DETECTION AND ALARM

The impact of automatic detection and alarm systems has been particularly great in homes. From less than 5 percent of homes

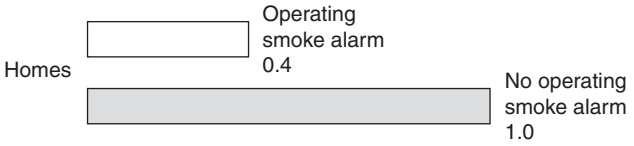

FIGURE 3.1.9 Death Rate per 100 Reported Fires by Smoke Alarm Status (Source: NFPA Fire Analysis and Research)

having smoke alarms in 1972, the United States has risen to a position where 96 percent of homes had at least one smoke alarm in 2004.[5] Smoke alarms cut the risk of dying in a home fire by more than half (Figure 3.1.9 and Table 3.1.17). Thousands of lives have been saved through the widespread use of home smoke alarms.

This success has been achieved in several stages. The initial surge in smoke alarm usage was driven primarily by manufacturer advertising of an attractive, affordable product and secondarily by public service announcements promoting home smoke alarms. Since then, state and local laws have come along to help complete the process of equipping U.S. homes with smoke alarms, which is important, because more than 40 percent of reported home fires occur in the tiny fraction of homes without smoke alarms. In 1977, most states had no home smoke alarm requirements of any kind. By 1983, most states had a home smoke alarm law, but most states still did not cover existing single-family homes, by far the largest segment of the population. By 1988, most states had laws that extended to all homes, new or existing, but most still did not mandate code-compliant, every-level coverage. The trend in state laws is clear—more complete and more thorough laws—but the process is still far from complete.

TABLE 3.1.17 Smoke Alarm Status in Homes, 1999–2002

Smoke Alarm Status	*Fires (%)*	*Civilian Deaths (%)*	*Death Rate per 100 Fires*
Smoke alarm operated in nonconfined fire	25	26	0.7
Smoke alarm alerted occupants in confined fire	18	0	0.0
Subtotal—operating smoke alarm	43	26	0.4
Smoke alarm present but failed to operate in nonconfined fire	9	19	1.5
No smoke alarm present in nonconfined fire	32	55	1.2
Smoke alarm did not alert occupants in confined fire	11	0	0.0
Subtotal—no operating smoke alarm	52	74	1.0
Fire too small to operate smoke alarm in nonconfined fire	5	0	0.0
Total	100	100	0.7

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire.

Source: NFIRS and NFPA survey.

Based on reported nonconfined fires, as shown in Table 3.1.17, about one in four smoke alarms does not operate when challenged by a fire large enough to operate it. Nonoperational smoke alarms typically are that way because of dead or missing batteries. Frustration over nuisance alarms, which typically outnumber real fire alarms by an order of magnitude, may be a factor in battery removal. Sensitivity drift, which is a gradual shift in the range of fire effects that will activate the smoke alarms, is an example of the problems that can affect older units. Smoke alarms more than 10 years old should be replaced, and this affects tens of millions of units now in use.

The success of smoke alarms in the home—and the importance of completing the job of providing complete coverage by operational smoke alarms in all homes—should not obscure the fact that automatic detection and alarm systems are an important part of an integrated system of fire protection in *any* property class. Major life-loss fires frequently cite problems with detection or alarm as significant contributing factors. Among the frequently cited problems in major fires with large loss of life are (1) the absence of needed systems, (2) misapplication, that is, using equipment or systems that were not appropriate for the property, (3) lack of maintenance, and (4) improper response by occupants to notification of the fire.

SUPPRESSION

Automatic sprinklers are highly effective elements of fire protection systems design for buildings. When sprinklers are present, the chances of dying in a fire and property loss per fire are cut by one-half to two-thirds, compared to fires reported to fire departments where sprinklers are not present.[6] Furthermore, this simple comparison understates the potential value of sprinklers, because it is based on data that combines not only all sprinklers, regardless of type, coverage, or operational status, but all types of automatic extinguishing systems. When new data coding is fully in place and complete, well-maintained, properly installed and designed systems can be isolated, sprinkler effectiveness would be seen as even more impressive.

The new coding is sufficiently well established to support estimates that sprinklers operate in 93 percent of fires that are in their coverage area and large enough to activate them. When they operate, they are deemed effective in 96 percent of cases. Therefore their operating reliability is estimated as 93 percent and their effective reliability is estimated as 89 percent (93% × 96%).[6] Figure 3.1.10 shows how operational reliability varies by property use. Note that the storage category extends to sheds, garages, silos, and other buildings quite different from warehouses.

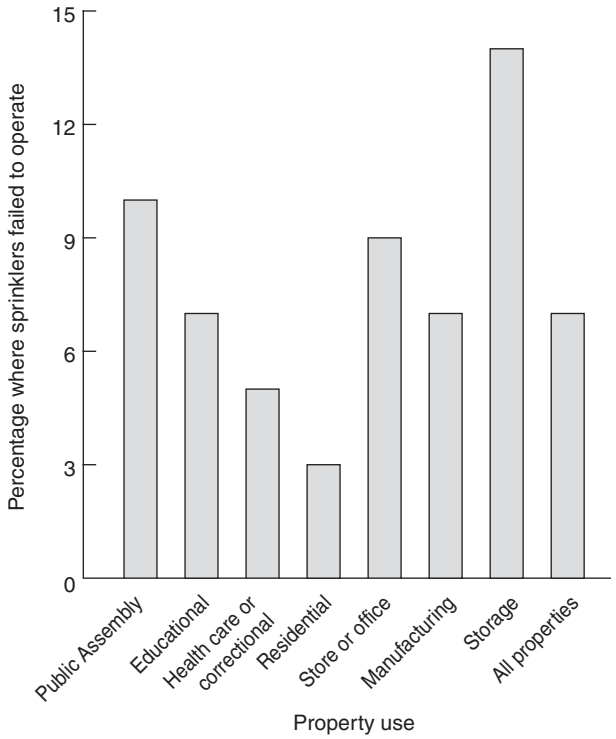

FIGURE 3.1.10 Estimated Operating Reliability of Sprinklers. Note: Figures exclude confined fires and fires coded as too small to test operationality. Data have been recoded when reported performance conflicted with reported reasons for unsatisfactory performance. (Source: 1999–2002 NFIRS and NFPA survey)

When sprinklers fail to operate, the reason given in 65 percent of the cases is that the system was shut off. Other reported reasons are defeating of the system by manual intervention (16%), lack of maintenance (11%), inappropriate system for type of fire (5%), and damage to system component (3%).

When operating sprinklers are not effective, the reason given in 55 percent of the cases is that agent did not reach the fire. Other reported reasons are not enough agent released (31%), inappropriate system for type of fire (7%), damage to system component (5%), and defeating of the system by manual intervention (2%).

In recent years, particular attention has gone to fast-response residential sprinklers for the home. The evidence of their potential for substantial reductions in loss of life and property is clear, but usage is still quite limited. Several communities have adopted requirements for these new sprinklers in new housing developments, and their experience provides the principal real-world proof to date of the tremendous fire protection value such systems deliver. The 2006 edition of NFPA *101*®, *Life Safety Code*®, for the first time mandates the installation of automatic sprinklers in all new one- and two-family dwellings.

The suppression strategy for fire protection involves much more than home sprinklers or even sprinklers in general. A 2002 survey found that 69 percent of U.S. households had at least one fire extinguisher.[7] A 2003 survey found a very similar 71 percent of U.S. households reported having at least one extinguisher, including 34 percent that reported having more than one extinguisher.[8] As with home smoke alarms beginning in the 1990s, it appears that many home fire extinguishers in use are past the age at which they need to be replaced

Non-water-based automatic extinguishing systems are important for some hazards. At eating and drinking establishment fires, for example, only 43 percent of reported automatic extinguishing systems are sprinklers, while another 43 percent are dry chemical systems, such as stovetop or duct protection systems.[6]

In the second half of the 1980s, the world became aware of and concerned about the potentially adverse environmental impacts of suppression systems using halogenated agents (the so-called halon/ozone problem). This development has led to research on alternative fire protection technologies and new agents for critical electronic facilities. It also serves to underline the importance of considering major nonfire factors in any fire protection design.

CONFINING FIRES

The design of building features to contain fires and their effects effectively is one of the most technically complex aspects of fire protection and is certainly the most difficult to evaluate statistically. In all the other phases—prevention, detection, suppression, evacuation—systems thinking also is essential, but it is at least possible to focus attention on one set of products or systems or occupants. But in fire confinement systems, thinking is both essential and unavoidable, because one must deal with every facet of building design and operation. One must consider not only the direct effects of wall assemblies, ceiling/floor assemblies, door assemblies, and the like on fire confinement but also their effectiveness in creating the design conditions assumed by every other part of the overall fire protection system.

The effectiveness of detectors and sprinklers can be demonstrated to some degree by comparisons of fire experience in buildings that have these systems to buildings that do not. Unfortunately, however, every building has walls, floors, ceilings, and doors, and the various types of assemblies have proved too diverse to be routinely documented in the national fire databases. The best analysis possible with existing statistics shows that, for many property classes, the proportion of fires confined to the room of origin rises as the type of construction becomes more fire protective, from unprotected wood frame to fire-resistive.

Problems with building in effective fire confinement tend to be more subtle, too. For detectors and sprinklers, the leading problem is turning off or disabling the equipment—a clearcut, yes/no change that is easy to document. For fire confinement features, the problems tend to be more a matter of degree—that is, barriers partially breached for utility networks, some but not all doors blocked open, and so forth.

Setting the context for this important strategy therefore must be approached in other ways. One is to point out the strong correlation between fire damage (i.e., to life and property), and fire spread, as was done in Tables 3.1.14 through 3.1.16. Also, the majority of fatal fire victims, including roughly one-third of the victims of fatal fires in structures other than homes, are

located away from the room of fire origin. What these figures indicate is that there are still many fatal victims of fire who might be saved by strategies that block or delay the passage of fire and smoke between rooms and floors—strategies of fire protection design for fire confinement.

Patterns are quite different in the United Kingdom. Whereas a majority of fatal U.S. fire victims are located outside the room of fire origin, a clear majority of fatal UK fire victims are located in the room of fire origin. Part of the reason may be that UK dwellings typically use a less open floor plan, with more separation of rooms by walls and doors. By keeping these doors closed to lower heating costs, UK households would also be expected to reduce the spread of fire and smoke beyond the room of origin, thereby reducing the number and share of fatal victims outside the room of fire origin as well. Some of the options available for fire confinement are the following:

1. Use construction barriers to block fire spread between zones.
   - Wall assemblies
   - Ceiling/floor assemblies
   - Barriers between occupied and concealed spaces
   - Firestopping in concealed spaces
   - Exterior barriers to vertical spread between floors
2. Design doors and windows to block fire spread between zones.
   - Fire door assemblies
   - Window restrictions to block spread between buildings
3. Separate buildings enough to prevent fire spread between buildings.
4. Regulate design and operations of ducts to permit shutoff of air movement in fires.
5. Regulate design and operation of systems for heating, venting, and air conditioning to prevent their serving as mechanisms to transfer smoke and gases into uncontaminated occupied areas.

Barriers around concealed spaces are of importance for two reasons. First, fires in concealed spaces cannot hurt people until smoke or flames break out into occupied spaces. Second, fires in occupied spaces may spread faster if they break into concealed spaces because many interior barriers do not extend into concealed spaces. For example, fire may spread vertically through concealed wall spaces if they are not firestopped at each floor or horizontally through concealed floor/ceiling spaces if the walls do not extend past the suspended ceilings that many buildings have below their main ceilings.

Exterior flame spread can occur in several ways, all of which must be addressed. Flying brands or heat from other fires can ignite exterior materials. Flames from one floor can "lap" up the exterior walls to ignite combustible materials on other floors by radiation from flame fronts.

Large losses of life or property are virtually unknown in buildings that comply with the fire protection requirements of modern codes. This is clear evidence of their effectiveness. Nevertheless, large losses continue to occur because so many buildings are not in compliance with modern codes. A major reason is the frequent exclusion of existing buildings from many requirements by "grandfathering" or a lack of retroactive application of codes. Even where good codes are on the books, enforcement may be hurt by a scarcity of resources in overburdened building and fire departments. And some communities do not routinely update their codes, which can create areas of vulnerability. Sustained, consistent attention to fire safety is key to the long-term success of an integrated system design for fire protection. Furthermore, universal application is essential to make a substantial impact on the fire problem.

Balanced fire protection really works, but there are no simple, one-time quick fixes. The installed system must be maintained every day. If this is done, however, such systems will virtually eliminate large losses of life or property. In fact, very large fires usually involve multiple major failures of fire protection design, but sometimes one or two deficiencies can be enough to produce disaster in a building with many excellent features. Remember that fire protection succeeds or fails as a system and is therefore only as sound as its weakest link.

Universality means, in simple terms, that any successful program must go where the fires are, including poor neighborhoods, rural communities, big-city neighborhoods, preschoolers, the elderly, and existing buildings. These are among the hardest groups to reach and the most frequently overlooked in the design of programs. But the fight for U.S. fire safety will largely be won or lost in these areas.

EVACUATION OF OCCUPANTS

Most fire protection strategies are designed to slow or divert the movement of smoke and fire, not stop it, so key questions are whether, where, and how to move the occupants. The occupant evacuation strategy, which includes defending in place and safe interior refuges as possibilities, involves both building design principles and behavioral/educational elements.

Building Design Principles

The building design principles include the following:

1. Two ways out from any location
2. Adequate numbers, sizes, and spacing of exits
3. Adequate capacity of all escape route parts
4. Protection for escape paths
   - Mark exit paths clearly and light them.
   - Restrict fuel loads and finishes in exit paths.
   - Enclose stairways.
   - Use construction barriers to keep fire out.
   - Use smoke control methods to protect atmosphere in exit paths.
   - Ensure structural integrity of exit path.
5. Escape to outside or to protected places, or adequate defense of places where occupants should remain
6. Avoidance of makeshift security systems

Protection of the exit paths begins with construction barriers to separate hallways from other rooms where fire may begin. Stairways need to be enclosed to separate them from all other spaces. Exits from any room or area must be adequate for the number of people those exits will serve. This dictates minimum

numbers and sizes of exits. Multiple exits from a room must be sufficiently separate to provide two distinct paths from the room to the outside so that escape will still be possible if one escape route is blocked. The paths themselves must not involve long distances, which dictates maximum distances from any occupied room to a stairway access or to access to some other protected area. Restrictions on the fuel loads and finishes in areas that serve as parts of exit paths also are needed to prevent rapid spread of fire into and through these paths.

Fire Escape Principles

Once the building is designed for safe evacuation, the occupants have to be educated about the principles of escape behavior:

1. Know whether to escape and where to go (e.g., stay in place, go to safe refuge, go outside).
2. Know two ways out.
3. Get out fast.
4. Practice escape.
5. Check paths for safety before proceeding (e.g., feel the door).
6. Crawl low under the smoke.

It is worth emphasizing the need for practice. Learning the rules of safe escape as slogans is not enough. (That is why it is a matter of concern that in 1999 three-fourths of U.S. households had not developed and rehearsed an escape plan.) If fire occurs, one does not have time to make the mistakes that typically occur during learning. To use an analogy, suppose one has read about driving a car and even passed the state's written test. One does not want the first time behind the wheel to be a drive to the hospital emergency room. The lack of learned confidence in the key behavior could cost time when it can be least afforded.

Most people have not seen a real hostile fire. They have no idea how fast fire can grow or how bad it can get. They are not familiar with the phenomenon of flashover. Therefore, they spend time they cannot afford confirming that there is a fire or gathering up valuables. They also may try to leave by their customary route, even in the face of serious fire hazard. Rehearsing safe behaviors is the only way to be sure that they will be used when necessary.

Special mention should be made of the problems posed by unusually vulnerable groups. Small children will need help to escape and are likely, on their own, to think hiding makes them safe. People who are elderly, handicapped, or impaired by substance abuse are likely to have physical or mental limitations that may present a need for help in escaping. Patients in health care facilities and inmates of confinement facilities present the largest problem, as they are large groups that cannot evacuate on their own. Specific plans need to be developed and rehearsed to address these situations.

SYSTEMS APPROACHES FOR PROPERTY CLASSES

In applying the general principles of fire protection, it usually becomes clear that particular property classes have special considerations that must be understood for an effective systems approach. Figures 3.1.11 to 3.1.14 show the relative importance of different broad property classes in U.S. fires and associated deaths, injuries, and property damage. Note that outdoor fires in trash, brush, and wildland account for half of all fires, but relatively little loss. Homes account for four out of five deaths, three out of four nonfatal injuries, and over half of all direct property damage. Vehicle fires account for nearly three times as many fires deaths as structures other than homes. Home fires account for roughly two-thirds more property damage than fires in all structures other than homes. Table 3.1.18 shows the relative importance of major occupancy groups within the larger category of nonresidential structures excluding dwelling garages.

Notable Fires

Historically, fires resulting in a major loss of life have resulted in important changes in building and fire codes and in standard fire protection or prevention practices. In the early 1900s, four building fires—the Iroquois Theatre in Chicago (1903), the Rhoades Opera House in Boyertown, Pennsylvania (1908), the Lakeview Grammar School in Collinwood, Ohio (1908), and the Triangle Shirtwaist Factory in New York City (1911)—were largely responsible for the appointment in 1913 of the NFPA Committee on Safety to Life. The opening summary of the "Origin and Development of *101*" in the current NFPA *101* states:

> For the first few years of its existence, the Committee devoted its attention to a study of the notable fires involving loss of life and in analyzing the causes of this loss of life. This work led to the preparation of standards for the construction of stairways, fire escapes, etc., for fire drills in various occupancies, and for the construction and arrangement of exit facilities for factories, schools, etc., which form the basis of the present *Code.*

The 1937 fire at the Consolidated School in New London, Texas, tragically pointed out the need for state laws to protect public buildings not subject to municipal ordinance and inspection. Then, in the 1940s, a series of multiple-death fires—including those at the Rhythm Club; the Cocoanut Grove; and the La Salle, Canfield, and Winecoff Hotels—focused national attention on the need for adequate exits and other fire safety features in hotels and public buildings. These fires resulted in major changes to the *Building Exits Code* (as NFPA *101* was then known) over a period of almost 2 decades. NFPA 102, *Standard for Grandstands, Folding and Telescopic Seating, Tents, and Membrane Structures* (included in NFPA *101* since 1994), was the result of still another multiple-death fire of the 1940s—the 1944 Hartford, Connecticut, circus tent fire in which 168 people were killed.

What follows are other examples of code changes following major fires in certain occupancy groups. NFPA has been a force for fire protection and fire safety for more than 100 years. In that time, most of NFPA's influence has come through its codes

TABLE 3.1.18 U.S. Nonresidential Fires and Losses by Major Occupancy Group

Occupancy	*Fires (%)*	*Civilian Deaths (%)*	*Civilian Injuries (%)*	*Direct Property Damage (%)*

and standards, which have changed the rules that guide building specifications and operations and, in that way, have changed the environments in which people live. As in past editions of the *Fire Protection Handbook,* this edition cites examples of major NFPA code changes that responded to needs demonstrated in major fire incidents.

This section describes several of the most dramatic examples of fire experience, organized by occupancy groups, which responded favorably to changes in codes or to changes in the extent of compliance with codes. Because most codes and standards focus on the risk of large fire losses outside the home, this section focuses on major incidents outside the home involving multiple loss of life. In particular, NFPA's fire incident record keeping is best for incidents in which 10 or more people died, and these incidents are used here as the principal tracking mechanism for the impact of codes, standards, and other fire protection requirements. In keeping with the normal approach used by NFPA's statisticians, most incidents are cited anonymously, to keep the emphasis on statistical patterns. In general, only incidents involving 50 or more deaths are given specific identifiers.

Schools

Since NFPA was founded in 1896, NFPA's fire incident records show a total of nine school fires in which at least 10 people died. Two of these are among the deadliest single-building fires in U.S. history. The first of the nine was also the only one not to involve grades K–12. It was a 1903 university building fire in which 11 people died. NFPA files indicate the building had no fire exits and escape was cut off. The second incident, in 1908, was also the second deadliest school fire in history. Inadequate fire escapes, inadequate fire drills, and a building layout that created bottleneck exit paths all contributed to the death toll of 176 at the Lakeview Grammar School in Collinwood, Ohio. A parochial school fire in 1915 was the third of the nine fires and cost 21 people their lives. After the fact, the exits were deemed inadequate, even though they complied with existing laws. Again, the failure to include all exits in fire drills made those drills inadequate and proved critical in this fire, as many exits were not used when they could have made a difference.

The first of three incidents in the 1920s was a 1923 fire that killed 77 people. Fleeing occupants jammed the only stairway serving the Cleveland School of Beulah, South Carolina, and it collapsed during the evacuation. A 1924 fire in a one-room schoolhouse spread rapidly from its origin in a Christmas tree. The fire department's report of the fire said, "the struggling crowd became wedged in the doorway, which was only 3 ft (0.9 m) wide." A total of 33 people died. Finally, a 1927 incident led to 46 deaths when a "crazed farmer" used dynamite to bomb a school.

The deadliest school incident in history stemmed from a gas explosion; 294 people died in the Consolidated School of New London, Texas, in 1937. The next school incident killing at least 10 people came in 1954, when a faulty heating system led to a gas buildup in the attic of a school. Ignition by an undetermined heat source produced a flash fire in an unoccupied area. Delayed discovery allowed the fire to spread into occupied areas, and 15 people died.

The last three incidents took place over 2½ decades, from 1927 to 1954, and all three involved rapidly developing situations—two explosions and a flash fire—that were unlike the earlier incidents. Officials might have been forgiven for believing that the older school fire problem, consisting of too many ordinary combustibles and insufficient or inadequate exits, was essentially under control. If so, that belief proved illusory when the 1958 Our Lady of the Angels School fire occurred in Chicago, Illinois, killing 95 people, 92 of them children.

The reaction to that fire was more rapid, more sweeping, and arguably more effective than the reaction to any other single fire in U.S. history. NFPA codes and standards were quickly revisited, and stricter requirements for interior finish and exiting were established. An April 1959 issue of the *Journal of American Insurance* caught the mood of the country at the enforcement end, noting in an article subhead: "U.S.A., aroused by Chicago lesson, is overhauling its school buildings as never before."

In the nearly four decades since the Our Lady of the Angels fire, there has *never* been another school fire killing 10 or more people. In recent years, no incident has even come close. In the period from 1994 through 1998, grades K–12 averaged one civilian fire death per year—a typical annual death toll for schools since at least 1980. Detailed examination of fatal school fires by NFPA analysts indicates that the few deaths that do occur are all or nearly all adults (e.g., maintenance workers) or juvenile firesetters fatally injured by the fires they set. Innocent children are no longer the victims in school fires. Few lessons have been learned as thoroughly as the ones from the Our Lady of the Angels incident appear to have been learned.

Hospitals

A similar story applies to U.S. hospitals. There were a similar number of incidents in which 10 or more people died, including a 1929 fire that killed 125 people in the Cleveland Clinic Hospital of Cleveland, Ohio, a 1949 fire that killed 74 people in St. Anthony's Hospital of Effingham, Illinois, and a 1950 fire at Mercy Hospital in Davenport, Iowa, that killed 41. The last hospital fire to kill 10 or more people was the Hartford Hospital fire of 1961, in which 16 people died in Hartford, Connecticut. Reports on the fire focused on combustible ceiling tile that led to rapid flame spread down a corridor, delayed reporting to the fire department, and the fact that all the deaths involved doors left open to the corridor. Closed doors meant survival in every case.

The NFPA *Building Exits Code* of 1961 already mandated complete sprinkler systems for hospitals for many combinations of height and construction. The next edition after the Hartford Hospital fire was the 1963 edition, which extended this requirement to even more combinations of height and construction. The 1966 edition changed the name of the document to a wordier version of today's NFPA *101,* signaling right from the cover that this code was not just about exits, as it had not been for some time.

By 1980, when NFPA first developed its nationally representative statistics on the use of sprinklers in buildings that had fires, nearly half (44%) of all fires in facilities that care for the sick were in properties with sprinklers. This undoubtedly meant that most hospitals were sprinklered by then, because it is known from occasional special studies on sprinkler usage that reported fires are more likely to occur in unsprinklered properties. By 1998, the latest year for which statistics are available, 71 percent of fires in facilities that care for the sick were in properties with sprinklers. Because hospitals and clinics are required to comply with NFPA *101* to receive reimbursement under Medicare and Medicaid, other provisions of NFPA *101* are undoubtedly also in nearly universal use. This helps explain why, in the latest available statistics, hospitals averaged fewer than one civilian fire death per year between 1999 and 2002.

The characteristics of the people who still die in hospital fires underline the extent to which NFPA codes have solved the type of hospital fire problem they targeted decades ago. About four of every five hospital fire deaths involve a victim who is so close to the start of the fire as to be described as "intimate with ignition." Smoking and incendiaries dominate the causes of fatal fires in facilities that care for the sick. These circumstances involve very rapid fatal injuries, often too rapid to be reliably prevented by even the best fire protection provisions. Fire prevention strategies are needed and, indeed, the past decade has seen widespread adoption of more aggressive controls and prohibitions on smoking.

Homes for Especially Vulnerable People

During a 4 year period from 1970 to 1973, there were eight care-of-aged facility fires, each killing at least 10 people and collectively killing 112 people. This rapid succession of catastrophic fatal fires stimulated action in a way that the deadliest nursing home fire of all time, which occurred in isolation at the Golden Age Nursing Home of Fitchville, Ohio, on November 23, 1963, and killed 63 people the day after President John F. Kennedy was assassinated, could not. A pattern was found of insufficient fire protection and sprawling, undivided construction based on adding extensions to aging, converted farmhouses. Codes were re-examined, and the new Medicare program provided clout by tying reimbursement eligibility to code compliance with NFPA *101*.

During the period from 1976 through 1985, attention shifted to boarding homes, spurred by a rash of major fatal fires in those facilities in 1979 through 1981. Six severe fires, causing 114 deaths in all, with the first three fires all occurring in the same month, commanded attention. During the period from 1979 to 1984, boarding home residents had a risk of dying in a multiple-death fire that was five times the risk for residents of other residential properties. Analysis of these incidents and other smaller fatal fires showed that many of the residents had characteristics of age or chronic mental illness that should have received ongoing medical attention that the facilities were not licensed or equipped to provide. This gap between the fire protection and other features of the facilities and the needs of their occupants was a more difficult problem than the one posed by the nursing home fires because there were fewer mechanisms to enforce codes.

The factors in what came to be called the "board-and-care" home fire problem were all too familiar and can be summarized as an overall lack of basic fire protection provisions. Contributory factors include inadequate means of egress, combustible interior finishes, unenclosed stairways, lack of automatic detection or sprinkler systems, and lack of emergency training for the staff and residents. Many of the facilities were either licensed as something other than a boarding home (such as a hotel) or were unlicensed, "underground" boarding homes. None of the facilities was provided with automatic sprinkler protection.

There is no particular mystery about how to reduce these risks, either. Enclosed stairs, providing two ways out, avoiding the use of combustible interior finishes, compartmentation, providing automatic detection and sprinkler systems, and training staff and residents in emergency procedures all would greatly reduce the risk of multiple deaths if fire occurs.

These analyses and others consistently point to the difficulty of delivering fire protection to and enforcing codes and standards on the facilities that cater to the poorest and most vulnerable populations. Simply creating and adopting good codes and standards is not enough. State and local authorities must adopt them and enforce them, being sure to pay attention to existing buildings, or this knowledge will lack practical impact where it is most needed.

In 2003, nursing home fires in Connecticut and Tennessee, killing 16 and 14 people respectively, restarted the debate on whether these especially vulnerable Americans are as safe as we believed and wished them to be. NFPA Technical Committees again reviewed the evidence and the options to develop a consensus answer to this question. The *Life Safety Code* added requirements for the sprinklering of all nursing homes, including all existing nursing homes, in the 2006 edition.

Hotels and Motels

From 1900 to the present, 4 of the more than 100 U.S. fires and explosions that killed at least 50 people involved hotels or motels. This compares to 8 in industrial settings, 5 that involved ships, 2 that involved industrial settings and nearby ships, 8 that involved places of assembly, 4 in schools, and 59 in mines. Three of the four hotel fires occurred in a 4 year period, 1943 through 1946—the Gulf Motel fire in Houston, Texas, in 1943, which killed 54 people; the LaSalle Hotel fire in Chicago, Illinois, in 1946, which killed 61 people; and the Winecoff Hotel fire in Atlanta, Georgia, in 1946, which killed 119 people. National conferences on hotel fire safety were convened in early 1947, one by NFPA and another by President Harry Truman; the result included significant changes to the hotel section of NFPA's *Building Exits Code* and model legislation for hotel fire safety, prepared by the Fire Marshals Association of North America, NFPA's member section for fire marshals.

A third of a century later, the 1980 MGM Grand Hotel fire, in Las Vegas, Nevada, inspired an industry response that combined unprecedented widespread code compliance with fire safety provisions that often ran ahead of code requirements. The result has been a dramatic change both in the fire death toll in hotels and motels and in the use of proven fire protection systems in that industry.

In 1981, NFPA published an overview of hotel and motel fire experience leading up to the 85 deaths in the MGM Grand Hotel fire. In the two decades from 1961 through 1980, NFPA

documented 53 hotel or motel fires that each killed at least five people. (In those days, the threshold for a multiple-death fire was three deaths in any property; today, it is five deaths in residential properties.) With more than two fires a year causing at least five deaths apiece, chronic public concern over fire safety when traveling was understandable.

The MGM Grand Hotel fire was not the only fire that shaped public concerns at this time. Certainly, the MGM Grand Hotel fire ran counter to the conventional industry wisdom that fire problems were primarily a matter of older or poorer facilities. MGM Grand was neither. But the MGM Grand fire also was not an isolated incident. Two months after the MGM Grand fire, a second Las Vegas, Nevada, hotel, this one part of a national chain, had a fire that killed 8 people. Then, the year after that, 12 more people died in a fire in another hotel of the same chain. A second chain lost 10 people in each of two fires during each of the 2 years preceding the MGM Grand Hotel fire. These five incidents in a 4 year period combined to create a picture of an industry in need of improvement.

Led by strong industry associations and fire safety–conscious professionals at the major chains, the industry began to respond. In 1980, the year of the MGM Grand Hotel fire, sprinklers were reported present in only one of every nine hotel or motel fires reported to U.S. fire departments. Detectors were reported present in just over one-fourth of reported hotel or motel fires.

An industry-sponsored study of sprinkler usage in 1988 found sprinklers present in roughly half of all properties, suggesting the percentage today is much higher still. The latest data show smoke detectors in more than 80 percent of hotel and motel fires and automatic sprinklers in 40 percent of hotel and motel fires and more than three-fourths of high-rise hotels. It is reasonable to assume that the new level of built-in fire protection had much to do with the dramatic drop in the number of hotel and motel fires since 1980. NFPA statistics from 1988 through 1997 indicated that sprinklers cut the chances of dying in a given fire by 91 percent and also reduced the average property loss per fire by 56 percent.

In terms of the deadliest fires, beginning in 1983, only two hotel or motel fires have killed 10 or more people, and each of them was on the outer fringes of the industry. A 1984 fire killed 15 people in a facility that called itself a rooming house but was classified as a hotel by NFPA because it had too many occupants to qualify as a rooming or boarding house. This facility also included a number of deinstitutionalized former mental patients among its occupants, raising questions about the health care needs of the occupants versus the fact that no such care was provided by the facility. A 1993 fire killed 20 people in a facility licensed for, and principally run for, long-term residents; yet the fire began in, and most deaths occurred in, a section housing transient guests.

In terms of the more familiar names in the lodging industry and the bulk of the facilities in operation, the changes of the past 15 years have moved the fire experience picture in hotels and motels to roughly the same position as nursing homes and hospitals. That is, a steadily shrinking number of fatal victims tend more and more to be people who die in fires they caused or that began very close to them. As with schools and hospitals, so with hotels and motels: the past century has seen dramatic accomplishments—a clear sequence from major fires to major code changes to major changes in the practices in the concerned facilities to major declines in the loss of life due to fire.

Places of Assembly

Seven of the 11 deadliest single-building fires and explosions in U.S. history have involved places of assembly. (The other four were two school fires discussed above, one prison fire, and the 1995 bombing of an Oklahoma City, Oklahoma, office building.) They include the Brooklyn Theater fire of 1876, which killed 285 people and preceded NFPA's founding. Both the Iroquois Theater fire of 1903, which killed 602 people in Chicago, Illinois, and the Rhoades Opera House fire of 1908, which killed 170 people in Boyertown, Pennsylvania, occurred early in NFPA's life and led to an early focus on the dangers posed by inadequate exiting provisions and the kinds of combustible loads that make rapid fire development likely.

From 1909 through 1939, three incidents killed 10 or more people in places of assembly, one of which involved an explosion. A 1919 Louisiana restaurant and dance hall fire led to 25 deaths when relatives rushing into the building to try to save occupants collided with occupants fleeing onto the only exit stairway, leading to the collapse of that stairway. A 1928 dance hall incident, started by ignition of gasoline fumes, killed 38 people. A 1929 nightclub fire spread rapidly via the decorations, and many of the 22 who died took refuge in rooms with no way out.

In 5 years, from 1940 to 1944, three of the worst fires in U.S. history occurred, all involving places of assembly. More than one-fourth of the 746 occupants of the Rhythm Club in Natchez, Mississippi, died in a 1940 fire. Overcrowding, inadequate exits, and highly combustible decorations were all cited as factors in the 207 deaths. Nearly half of the more than 1000 occupants of the Cocoanut Grove nightclub in Boston, Massachusetts, died in a 1942 fire. Overcrowding, inadequate exits, and highly combustible decorations again were cited as key factors in the 492 deaths, with roughly 200 trapped behind one revolving door alone. And 168 of the roughly 7000 patrons at the Ringling Brothers Barnum & Bailey Circus in Hartford, Connecticut, died in a 1944 fire, many of them children.

These three incidents, particularly Cocoanut Grove, are credited with inspiring a rush of tougher codes, focusing on exiting provisions and the use of combustible materials, but also pushing a more comprehensive and appropriate definition of places of assembly. Incredibly, many jurisdictions excluded eating and drinking places from the classification "place of assembly" prior to Cocoanut Grove.

In the half-century since 1944, no incident in a place of assembly has matched the death toll in any of these three incidents, and only one incident came close—the 1977 Beverly Hills Supper Club fire in Kentucky, which killed 165 people. This fire echoed many of the problems of the 1940s incidents. The 165 victims represented less than 10 percent of the 2400 to 2800 occupants reportedly on site, but those occupants represented two to three times the facility's capacity, indicating severe overcrowding. All types of exiting problems were also recorded. More recently, the 2003 Station nightclub fire in Rhode Island, where 100 people died, also involved materials that promoted

rapid fire spread, but also involved an unusual and unsafe heat source—indoor fireworks. And, far more than in the earlier incidents, there was an awareness of how much protection was lost because of the absence of sprinklers.

In terms of accomplishments, the post–Cocoanut Grove code changes worked. Large-loss-of-life fires have not occurred where code compliance has been observed, except for rapid-onset situations, such as explosions. But large-life-loss incidents do continue to occur—less severe individually but still too large and too frequent to be acceptable—because of spotty enforcement. One type of incident, most dramatically embodied in the Happy Land social club fire of 1990, in New York City, has occurred in each of the last five decades and is worthy of special attention—an arson fire using accelerants started in a location that interferes with normal exiting.

The first of these incidents is also the least well documented. A 1947 gambling hall fire began when a gallon of gasoline was thrown on the floor and ignited. The exiting provisions are not known, but 15 people died in the fire. A 1965 restaurant fire began when an arsonist poured gasoline at the main entrance. The 40 to 50 occupants may have encountered a security delay at the rear exit, which also was too narrow; 13 people died, or roughly one-fourth to one-third of the number present.

The succeeding fires involved even worse exiting problems and death tolls that accounted for even larger fractions of the total occupants. A 1973 lounge fire was set in the stairway of the lounge's normal exit. The second exit was poorly marked, and the windows were blocked or barred. The death toll of 32 people represented roughly half of the occupants present. A 1976 fire was set in the only exit of a New York City social club, leaving only windows for escape. The death toll of 25 represented roughly half of the occupants present.

A 1990 arson fire was set in the main exit of New York City's Happy Land social club. There were no other marked exits, nor were the windows useable for escape. Only six of the 93 occupants survived, five by going out an obscure, normally locked door that one of them had a key to, and the sixth by literally running through the fire at the entrance, sustaining critical burns.

None of these properties had complete sprinkler systems or sprinklers in the area of the fire, so they emphasize the value of such systems. But taken together, they also illustrate how the consequences become worse as the deviation from code-compliant exiting provisions becomes worse. If there is literally nowhere to go, everyone will die.

As a result of the 2003 Station nightclub fire, the 2006 *Life Safety Code* was amended to require automatic sprinklers in all new nightclubs with an occupancy load of 50 or more and all existing nightclubs with an occupant load of 100 or more.

Property Classes and Code Compliance

Finally, consider what it will take to accomplish even more in terms of life safety from fire in any of the types of properties discussed thus far. People who die in fires do so in either the *kinds of fires* that codes do not reach or the kinds of *properties* that codes do not reach due to lack of adoption or lack of enforcement.

For schools and hospitals, codes reach nearly everywhere. These properties are tightly controlled. Nursing homes and the lodging industry are not quite so tightly controlled, but are very broadly compliant. Both have active industry associations that have broad membership and are sensitive to fire safety. Both industries have difficulty primarily in exerting control over properties on the fringes of the industry, such as board and care homes. Notwithstanding the emergence in recent years of legitimate board and care homes that provide only personal care to residents who need nothing more, a sizable group of facilities, long referred to as board and care homes, provides only lodging to residents who legitimately need health care as well.

Places of assembly have the problem of widespread noncompliance far more than do hotels or nursing homes. Proportionally fewer properties belong to national chains, which in other industries often lead the move to greater fire safety. Industry associations have less of a track record as leaders in fire safety and, more importantly, capture a smaller proportion of their industry's operating facilities. There is more, and more frequent, turnover in these facilities, which also hampers enforcement efforts, because educating owners and managers about fire safety is a gradual, incremental process, which has to start all over whenever an existing facility "goes under" and a new facility takes its place.

Despite all this, the deadliest fires (i.e., 50 or more deaths) in places of assembly are less frequent and less deadly than they were a half-century ago, which suggests that enforcement and sensitivity to fire safety is better among at least the largest facilities. This is an achievement worth building on.

Manufacturing Facilities

Manufacturing properties are worthy of note because they also include a significant single incident that led to dramatic changes in NFPA codes. The 1911 Triangle Shirtwaist Company fire in New York City still ranks as the deadliest manufacturing facility fire (excluding explosions) in U.S. history. NFPA code requirements for the workplace, particularly exiting provisions, were substantially changed as a result of that fire.

Since NFPA's founding, according to NFPA records, most fires or explosions in manufacturing facilities causing 10 or more deaths involved explosions, or to a lesser extent flash fires or fuel spills. Few such fires are truly comparable to the Triangle Shirtwaist Company fire. One such fire took place only 2 years after the Triangle Shirtwaist Company fire and also involved a New York state clothing manufacturer. The death toll in that fire reached 35 because an external fire escape was engulfed in flames early in the incident.

More than 40 years later, two more garment factory fires, one like the Triangle Shirtwaist Company located in New York City, occurred in 1957 and 1958, killing 15 and 24 people, respectively. In the former, one stairway was open and filled early with smoke, and one fire escape was enveloped in flames and collapsed. In the latter, fire filled a key stairway early when the door to the stairway was wedged open. In 1991, a North Carolina food processing plant fire killed 25 people. NFPA investigators and the U.S. Occupational Safety and Health Administration (OSHA) both pointed to the similarities between this incident and the Triangle Shirtwaist Company fire, in terms of grossly inadequate exiting provisions.

A battle for life safety in manufacturing facilities is still being fought with respect to explosions, which involve a number

of different NFPA codes. During the five decades from 1916 through 1965, the United States averaged just over four manufacturing facility explosions per decade that each killed 10 or more people. During the three decades of 1966 through 1995, the average was just under three such incidents per decade. It is on the thin reed of one fewer incident per decade, on average, that we can say there has been some progress, but the 2000 New Mexico pipeline explosion is a reminder that this hazard still causes significant life loss.

As with fire safety in places of assembly, but even more so, an undeniable century of accomplishment in writing safer codes has been undercut by far less clearcut progress in achieving code compliance. OSHA and the U.S. labor movement, both strong champions of a safer industrial workplace in years gone by, have been substantially weakened in recent years. Perhaps they can still be part of a revitalized coalition, with NFPA, concerned state and local authorities, and the thousands of responsible fire safety–conscious owners and managers of the better manufacturing sites, to improve a situation that still has much room for improvement.

Mines

Mining is cited here to end this section on a true high note, even though NFPA had little input into what has been one of the most remarkable centuries of accomplishment in any class of properties. Most of the 101 U.S. fires and explosions that have killed 50 or more people from 1900 to 1999 have been in mining, specifically coal mining. (Only three of the 59 mining incidents were not coal mines; they were metal mines.)

In the first decade that NFPA tracked, from 1900 through 1909, 15 of the 59 mining incidents occurred, killing a total of 2286 people. At the start of the second decade, from 1910 through 1919, the U.S. Bureau of Mines was formed (in 1910). In that second decade, there were 18 incidents, killing a total of 1882 people. Sometime in the second and third decades, the U.S. Bureau of Mines began issuing rules and guidelines, because by the end of the third decade (1929), they were publishing summaries of what they issued. In the third decade, from 1920 through 1929, there were a total of 14 incidents, killing a total of 1407 people.

In the fourth decade, from 1930 through 1939, during the Great Depression, there were only two incidents, killing a total of 136 people. NFPA 493, *Spontaneous Heating and Ignition of Coal and Other Mining Products,* was first issued in 1936, but, by then, the big decline in the frequency of serious incidents had already occurred.

In the fifth decade, from 1940 through 1949, which includes the wartime demands of World War II, there were seven incidents, killing a total of 533 people. The next 3 decades had one incident each, killing a total of 288 people. The decades from 1980 through 1989 and 1990 through 1999 have had no such incidents. Even though the 2001 Alabama coal mine explosion was one of the 10 deadliest of its decade, its 13 deaths fell far short of the threshold of 50 that was regularly exceeded in the early 20th century.

A natural question, which also applies to the fire experience of garment manufacturing facilities discussed previously, is how much the reduction in fire deaths reflects a reduction in economic activity and associated exposure. Employment in coal mining peaked around the end of the second decade of the twentieth century and declined dramatically until about 1970, when it rose sharply for about a decade, then began declining again to its present levels, the lowest in this century. The decline in mining incidents killing 50 or more people and in the number of people killed in those incidents has been even steeper than the decline in employment in the industry.

ORGANIZING FOR FIRE PROTECTION

Fire department organization is a critically important element of fire protection. The effectiveness of the organization and management of U.S. fire departments determines whether the more than $28 billion (2003 dollars) in annual expenditures for local fire protection are spent well or badly. More important, it also determines whether the more than one million U.S. fire fighters will be used effectively and safely. Protecting the community and protecting themselves are dual responsibilities of a fire department, and both are more likely when planning and preparation are fully used.

Table 3.1.19 gives a brief overview of the resource base of local fire departments. Only 12 percent of local fire departments are composed entirely or mostly of career fire fighters, but they protect 61 percent of the population, and 27 percent of all local fire fighters are career fire fighters. The majority of volunteer fire fighters serve in small rural communities of less than 2500 population.

Figure 3.1.15 shows that the workload for fire departments more than doubled from 1980 to 2004, led by a nearly threefold (179%) increase in emergency medical calls, which constitute now three-fifths of all fire department calls (Figure 3.1.16). Since a third of communities still do not offer emergency medical service, those that do may find medical calls running at 80 to 90 percent of their calls.

TABLE 3.1.19 Selected U.S. Local Fire Department Resources, 2005

Resource	*Number*
Career fire fighters	294,100
Volunteer fire fighters	807,150
Total fire department expenditures (in 2003)	$27.9 billion
Fire departments	30,500
Fire stations	48,400
Pumper trucks (at least 500 gpm)	81,200
Percentage of departments providing emergency medical services (EMS)	67
Percentage of departments providing hazardous materials response	80
Percentage of departments providing wildland fire fighting	85
Percentage of departments providing technical rescue service	57

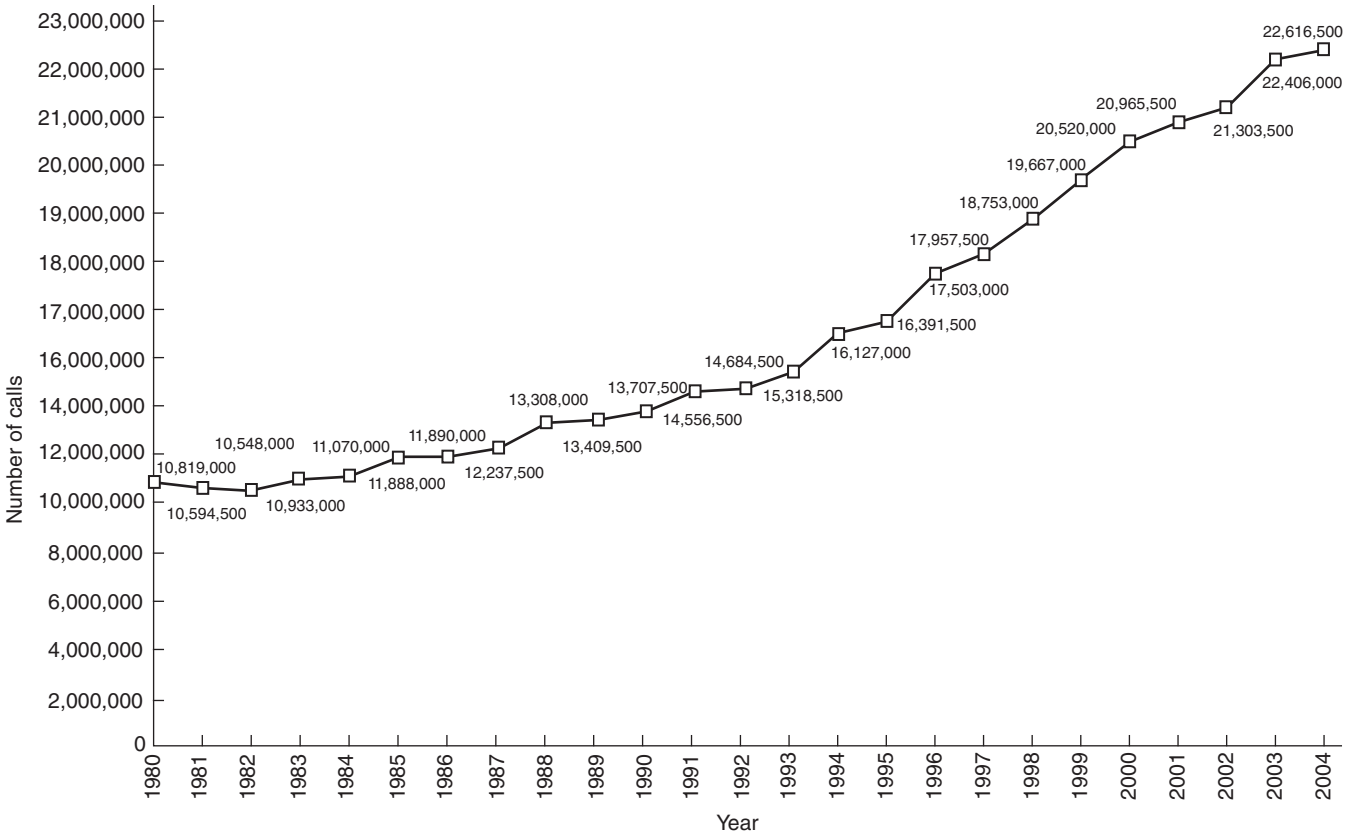

FIGURE 3.1.15 Fire Department Emergency Calls, 1980–2004 (Source: NFPA National Fire Experience Survey)

Fires now constitute only 1 of every 14 fire department calls, or 1 of every 9 mutual-aid calls (see Figure 3.1.16). But fire calls demand the majority of fire department resource utilization, including stress on people and equipment. The potential to overload a department's total resources still comes primarily from fires.

Hazardous materials calls are a small fraction of the total but they also can involve a lot of resources per incident. False alarms today are more often nonemergency activation of automatic detection systems and less often the malicious box-alarm activations that were of so much concern in the 1960s and 1970s. Since 1997, false alarms have been more common than fires.

The increasingly diverse responsibilities of the modern fire department are both an opportunity and a challenge. On the one hand, more duties mean more value delivered to the community. On the other hand, more duties mean a greater chance of overloading the system with simultaneous major calls. Since the rapid rise in calls for service has occurred during a period of generally declining or level staffing, the risk of overload is real.

A more subtle challenge comes from the need to design an emergency response system to cope with different types of emergencies having very different patterns. Emergency medical calls require swift response with a minimum of equipment and personnel. Fire calls require swift response with a large complement of equipment and personnel and may tend to occur in different parts of the community than those where emergency medical calls are concentrated. These competing bases for decision making require sophisticated planning. In many major cities, fire fighters are now required to be trained also as paramedics or emergency medical technicians (EMTs).

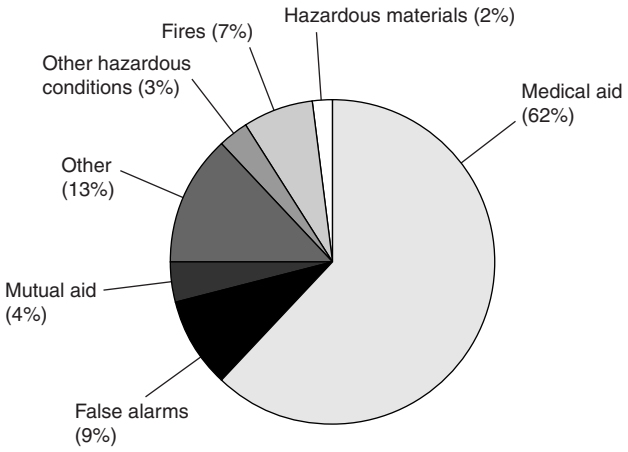

FIGURE 3.1.16 Fire Department Calls, 2004 (Source: NFPA National Fire Experience Survey)

Organizing Before Fire Occurs

Preparing for fire begins with the promotion of fire prevention and built-in fire protection, which fire departments can do in a variety of ways. First, fire departments typically are involved as inspectors and sometimes as certifiers for a wide range of fire-related regulations. Sometimes fire departments support building inspectors in their reviews of building code requirements for new and remodeled buildings. More often, fire departments handle ongoing fire code requirements for commercial buildings. Various permit requirements, from the general ones, such as occupancy permits and business licenses, to specific permits for hazardous materials and processes, also may be handled by fire departments. Smoke alarm laws are among the few examples where existing homes may be covered by these activities. These code and permit inspections not only empower fire departments to control fixed hazards, but also provide an excellent opportunity to educate and motivate occupants on general rules of fire safety. Research has shown this educational effect can reduce the frequency of fire significantly.

Second, fire departments investigate the causes of fires and pass on what they learn to a community whose attention is focused by the immediacy of a recent tragedy. Support for prosecution of arson cases is the most obvious example of the effect investigations can have. Changes in codes and standards can result from these findings, too.

The fire department is also the one constant in local programs to educate the public about fire safety, even though other groups may have primary authority for some programs. Fire departments can serve as catalysts for, and participants in, programs to counsel juvenile firesetters or to teach fire safety to schoolchildren. Fire departments often arrange for extensive programs of fire safety speeches to community groups, increasing community attention to the special programs of Fire Prevention Week in October. Fire departments can circulate fire safety messages by promoting local media use of fire safety public service announcements and by pointing out lessons from news coverage of local fires. Some fire departments are able to pursue even more ambitious programs, such as home fire inspections, using their own resources or acting as change agents to enlist a group of volunteers to do the job.

In summary, the fire department is central to local fire prevention and protection, and fire prevention and protection is central to the duties of the modern fire department.

With regard to preparing for nonfire emergencies, fire departments are increasingly called on to serve as the local agents for enforcement of federal and state laws to achieve "cradle-to-grave" control of hazardous materials. This enforcement may involve regulations on storage, use, and transportation. In many communities, fire department resources for gathering, processing, and acting on information in this new area are severely lacking. Control of hazardous materials is one of the areas in which local fire departments are most in need of help to do the new jobs that are now expected of them.

Organizing Effectively at Fires

Effective fire suppression requires clear policies and objectives, with tactics that follow logically from those policies. A suppression policy or objective is a concise description of priorities for the use of resources available at a fire. Particularly in properties with large numbers of people, containment of fire and protection of large numbers of people outside the fire-involved zone may need first priority, ahead of any efforts to save people and property in areas already involved in fire. Some losses, such as injury or even death of occupants in the room of fire origin, occur so early in a fire that they cannot be consistently prevented by any suppression strategy of the fire department alone.

Objectives imply tasks, such as forcible entry, rescue, application of water, ventilation, and salvage. And each task implies needs for staffing, equipment, the water delivery system, and response time. These needs are also affected by the level of on-site prevention and protection the community or the particular building has adopted.

For example, suppose a building has a certain size and a set of on-site hazards associated with the kind of business or use at the property. These imply a potential fire size for planning purposes. The potential fire size implies a required number of gallons per minute, gpm (L/min), of water that would be needed to control and suppress that fire. The gpm (L/min) requirement, in turn, implies needs for water pressure and pipe sizes serving the nearest hydrants and for hose sizes and pumping capacity in the fire department apparatus that respond. All these requirements also imply a certain staffing level to handle all the needed fireground activity, including (1) forcing entry if necessary, (2) finding and evacuating or protecting any occupants in certain zones of the building, (3) ventilating as necessary, (4) carrying the needed hoses to the potentially distant fire location, and (5) applying water there until the fire is controlled and extinguished. This process is a task analysis of suppression resources and their use. Implicitly or explicitly, such an analysis should underlie all resource decisions.

It should be clear from this example that on-site sprinkler protection or limitations on quantities of burnable materials on site can change the potential fire size, which might permit longer response times or smaller personnel complements. However, if anything and everything is permitted on site, the fire department must plan for the worst, and if they lack the resources to do so, disaster is there, just waiting to happen.

Pre-incident planning can range from the review and rehearsal of strategy and tactics for a single facility to the elaborate planning required to prepare for natural disasters or civil defense emergencies. Large-scale planning of the latter type may involve the development and maintenance of multiagency coordination systems and large-scale incident command and control systems.

Protecting Fire Fighters

Fire fighter deaths on duty declined from the early 1980s to the early 1990s, but have been stuck around a 100 a year in most years since (Figure 3.1.17). The high death tolls up to the early 1980s were led by career fire fighters, but the death tolls since then have been dominated by volunteers. These totals reflect both immediate and delayed effects of acute injuries or illnesses but do not reflect deaths due to long-term chronic illnesses, such as cancer.

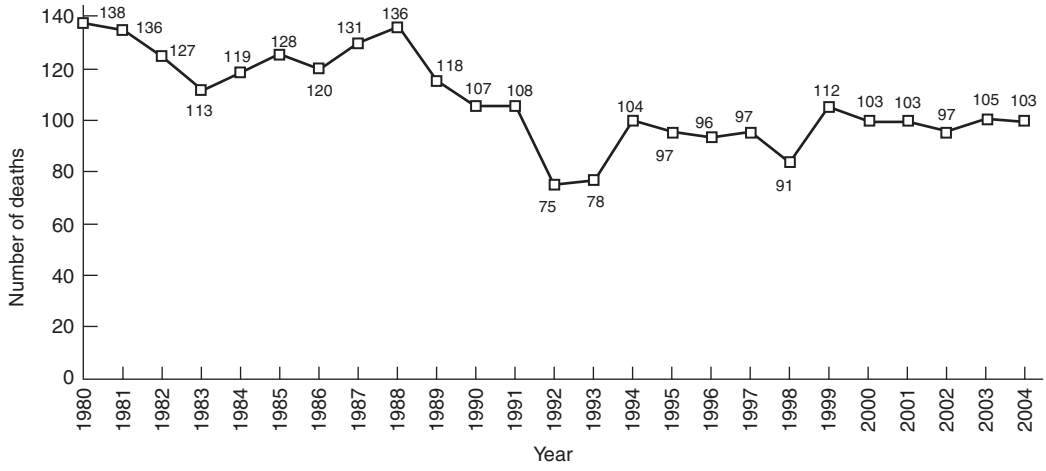

FIGURE 3.1.17 U.S. Fire Fighter Death Trend, 1980–2004. Note: Excludes 330 fire fighter deaths at the World Trade Center in 2001. (Source: NFPA FIDO)

In a typical year, nearly half of all fire fighter deaths in the line of duty involve heart attacks. These deaths are nearly always limited to older fire fighters, at least 38 years of age, and are particularly prevalent in volunteer fire departments, where older fire fighters are more likely to serve. A large fraction of these heart attack deaths involve fire fighters with serious pre-existing health conditions, including arteriosclerosis, hypertension, and previous heart attacks. Since nearly half of all fire fighter deaths involve heart attacks, physical fitness is one of the most important elements of an occupational health and safety program.

In a typical year, one-fourth to one-third of on-duty fire fighter deaths occur during response to, or return from, an emergency call. Vehicular collisions and heart attacks while operating vehicles are both major causes. This scenario affects volunteers more than career fire fighters. Driver training is needed to prevent vehicle accidents. Safe passenger practices must be emphasized because falls from vehicles are also a major cause of fire fighter deaths. Careful attention to the safety of the vehicles themselves, including inspection, maintenance, and repair, is needed, too. Aircraft operations at major wildfires are a special case that results in on-duty fire fighter deaths nearly every year,

Fire fighter safety on the fireground depends on good equipment. Protective clothing for fire fighters is sometimes referred to as the "protective envelope." Many of the advances in this equipment in recent years have come about as a result of a program of research in the late 1970s and early 1980s, under the name Project FIRES, sponsored by the U.S. Fire Administration. NFPA maintains and regularly updates standards for each type of protective clothing and equipment, including those needed for special environments, such as hazardous material incidents or airplane crash fire rescue.

Fire fighter injuries on duty had been stuck at about 100,000 a year until the mid-1990s when they began to decline, falling below 76,000 in 2004. Injuries at the scene of a fire emergency have declined from 65 percent of the total in 1981 to 49 percent in 2004. One reason the total has not fallen is that injuries at the scene of a nonfire emergency have been increasing, from 9 percent of the total in 1981 to 17 percent in 2004.

Chapter Contents

Organizations Involved in Fire Loss Investigation
Access to Fire Scenes for Investigations
Role of NFPA 921
Reconstruction and Failure Analysis Process
Organization for Fire Investigation
Education and Training of Fire Investigation Personnel

Key Terms

benchmark event, failure analysis, fire investigation, fire investigator, fire loss investigation, fire reconstruction, fire scene investigation, fire testing, prefire event, transfire event

Data gathered during a fire loss investigation have several applications, ranging from filling out the fire department incident report to creating a detailed engineering reconstruction and failure analysis of the incident. Understanding the fire origin and cause of a fire can lead to targeted inspection, public education programs, or, perhaps, proposed code changes. An engineering reconstruction and failure analysis can reveal factors concerning the fuel, building, and fire suppression that resulted in the ultimate extent of flame and smoke movement. Building codes and fire safety design standards involved would be included in this analysis, as would construction, operation, and maintenance practices. Results of a failure analysis provide input to insurance loss adjustment and underwriting, improved design practice, and civil and criminal litigation. Failure analysis can also result in changes to codes and standards.

In most fires, origin and cause are expressed in terms of the area of fire origin, the heat of ignition, the materials involved, and the factors that brought them together. (See NFPA 921, *Guide for Fire and Explosion Investigations.*) In the past, only fires that resulted in large loss of life or property received the attention of a complete investigation. In these cases, the engineering reconstruction and failure analysis was often conducted months or years after the fire, when only fragmentary evidence, if any, remained. In these situations, the depth and accuracy of the fire department report can be critical. Recently, insurance claims, subrogation activities, and greatly increased litigation have been concerned with smaller and smaller losses. Thus, more detailed examination is needed of all fires that result in a loss, almost regardless of the extent of the loss.

This chapter discusses fire loss investigation by examining organizations that are involved in fire loss investigations and the reconstruction and failure analysis process. See also Section 3, Chapter 6, "Applying Models to Fire Protection Engineering Problems and Fire Investigations." Information for the fire investigator is located throughout the *Fire Protection Handbook;* however, Section 2, "Basics of Fire and Fire Science," and Section 6, "Characteristics of Materials and Products," are particularly recommended.

ORGANIZATIONS INVOLVED IN FIRE LOSS INVESTIGATION

Organizations involved in fire investigation can be separated into two types: (1) public agencies, or those required by law to investigate fires at the local, state, and federal levels, and (2) private sector organizations.

Local and State

Of the public agencies, the local fire department generally has the primary responsibility to document a fire and to provide an initial determination of the origin and cause. If the department conducts incident reporting as part of the National Fire Incident Reporting System (NFIRS), factors

Richard L. P. Custer, M.Sc., FSPE, is associate principal and technical director at Arup Fire in Westborough, Massachusetts. Mr. Custer is a fellow of the Society of Fire Protection Engineers.

David T. Sheppard, Ph.D., is the senior fire research engineer at the Bureau of Alcohol, Tobacco, Firearms, and Explosives (ATF) where he works on fire investigations and teaches numerous classes. Dr. Sheppard is a member of the Society of Fire Protection Engineers.

that affected the ultimate course of the fire, such as flame spread and the performance of fire protection features, may be included.

When a fire department investigation determines that the fire may have been of incendiary origin, in other words, deliberately set, other organizations may be assigned the legal responsibility for determining fire cause and for the investigation pursuant to suspect identification and possible criminal action. In much of the United States and in all Canadian provinces, the state or provincial fire marshal's office is responsible for investigating incendiary fires. In states or jurisdictions where this is not the case, the local fire marshal or the local police or fire department may have investigative responsibility, either directly by statute or by delegation from the state.

Federal

U.S. federal agencies are also involved in investigating fires. These agencies are generally charged with investigating incidents to determine compliance with federal regulations and to provide input for the regulatory process to reduce human and property losses.

For example, the National Transportation Safety Board (NTSB) conducts complete reconstruction and failure analysis of accidents, including fire-related incidents, which involve air, rail, and highway transportation. Investigations of pipeline incidents and maritime fires are under the authority of the Department of Transportation (DOT). Other federal agencies involved in fire investigations include the Occupational Safety and Health Administration (OSHA) of the Department of Labor; the Bureau of Mines (BoM) of the Department of the Interior; the Federal Bureau of Investigation (FBI); the Bureau of Alcohol, Tobacco, Firearms, and Explosives (ATF) of the Department of Justice; the Consumer Product Safety Commission (CPSC); the Nuclear Regulatory Commission (NRC); and the National Institute of Standards and Technology (NIST) of the Department of Commerce.

The Federal Emergency Management Agency (FEMA) conducts detailed investigations of fire and hazardous materials incidents and prepares reports that can be obtained through the U.S. Fire Administration. Other agency reports are available from the National Technical Information Service (NTIS) in Atlanta, Georgia.

In addition to investigating fires under their jurisdiction, these federal agencies may serve as resources for lab analysis and technical information for state and local fire officials.

Committees of the U.S. House of Representatives and the Senate are often very interested in the results of these investigations, particularly when the incidents under investigation deal with timely public policy topics, such as standards for elderly care facilities, prison fire safety, and terrorism.

Private Sector Organizations

Most of the complete reconstruction and failure analyses of fires other then those that fall under government jurisdiction are conducted by private sector organizations for education, improved design, insurance, and litigation purposes.

NFPA. The National Fire Protection Association's (NFPA) fire investigations program is a long-standing data collection and engineering analysis activity. The purpose of the program is to collect, analyze, and report detailed fire experience data through on-site investigations. This activity assists NFPA in analyzing and documenting facts about fires for technical or educational value; distributing the information to the fire protection community to help prevent future similar fire losses; publishing investigation reports as individual reports, as well as in the *NFPA Journal* and on the NFPA home page; providing technical assistance to state and local officials as an integral service of the NFPA investigation process; determining important "lessons learned" for input to NFPA technical committees and technical programs; and contributing to an increasing fire incident database for analysis purposes.

Several NFPA fire investigations have included or been supplemented by analysis of human behavior patterns, where the discovery of the fire and subsequent evacuation occurred in sufficient time to permit analysis. Human behavior studies have been conducted through on-site interviews with survivors or mailed surveys and have generally been carried out by NFPA staff in combination with leading authorities on human behavior in fire.

NFPA frequently works with fire departments and code organizations during the on-scene investigation. Results of most of these investigations are published as special studies or as reports in various fire protection periodicals.

Insurance Industry. The insurance industry often investigates and reconstructs a fire incident to evaluate the merits of claims submitted or to identify parties for possible subrogation action. Reconstruction may be conducted by insurance company personnel, by an adjustment bureau, or by a consultant.

Individual consultants or consulting firms perform reconstruction and failure analysis for a variety of clients, including property owners, industrial organizations, criminal prosecution and defense and the insurance industry. Consultants are also retained for litigation purposes by law firms to evaluate fire origin and cause, code compliance, conformance with applicable design standards, and other technical aspects of fire loss.

When major financial consequences are linked to investigators' conclusions, it is not uncommon for two or more parties to retain investigators and for two or more theories of fire origin and development to be presented. The need to resolve such disputes is a major reason for the increasing interest in applying state-of-the-art scientific methods and computer fire models, analytical procedures, and test results to fire investigations.

ACCESS TO FIRE SCENES FOR INVESTIGATIONS

Most fire scene investigations take place on private property and fire investigators, whether public or private sector, must assure that they have a legal right to be on the scene; otherwise, their findings may not be admissible in court. The three primary mechanisms for conducting a legally valid scene investigation are exigent circumstances, permission of the owner, or a search warrant.

Exigent Circumstances

Exigent circumstances exist when the fire department arrives on the scene and there is a need to assess whether there is a continuing risk. Exigent circumstances exist while the fire department retains custody of the scene and often ends when there is any break in the on-scene presence of fire department personnel. Rules on the allowable duration of the exigent circumstances depend on the specific jurisdiction.

Permission of the Owner

Permission of the owner is the primary legal mechanism by which public and private fire investigations investigate on scene, after the exigent circumstances have expired and while no criminal act is suspected. Fire investigators will typically obtain the owner's permission in writing to document that they had a legal right to be on scene with the understanding that the owner can limit the areas that can be investigated and revoke permission for scene investigation at any time. Investigators representing insurance companies can usually depend on the owner's permission but should clear access directly with the insurance company or their legal representatives.

Search Warrant

A search warrant is a third mechanism by which public sector investigators gains access to fire scenes. Search warrants are issued by judges and magistrates and such documents are used when an incendiary fire or a crime scene is suspected.

ROLE OF NFPA 921

History of NFPA 921

In 1984, the NFPA Standards Council initiated a project to develop guidelines for fire and explosion investigation under the consensus process used to develop and maintain NFPA standards. At this time the Technical Committee on Fire and Explosion Investigations was established.

Public comments received by the Committee are reviewed and the Committee actions documented in a final proposal that is subject to further public review to permit a commenter to respond to the Committee actions and raise questions during the final approval process. This open procedure results in a document that is representative of the investigative community although there may be individuals who disagree on specific points.

NFPA 921, *Guide for Fire and Explosion Investigations,* was first issued in 1992 and has been revised on a 3 year basis through 2004. To keep from becoming outdated, if there were no new editions proposed, NFPA 921 would have to be opened to public comment and reviewed by the Committee every 5 years.

Use and Contents of NFPA 921

NFPA 921 is widely used for state and local training programs throughout the United States and serves as the basis for the performance criteria in NFPA 1033, *Standard for Professional Qualifications for Fire Investigator.* It is also recognized for training by the International Association of Arson Investigators (IAAI) and the National Association of Fire Investigators (NAFI).

The 2004 edition included chapters on the following:

- Basic Methodology
- Basic Fire Science
- Fire Patterns
- Building Systems
- Electricity and Fire
- Building Fuel Gas Systems
- Fire-Related Human Behavior
- Legal Considerations
- Safety
- Sources of Information
- Planning the Investigation
- Documenting the Investigation
- Physical Evidence
- Origin Determination
- Fire Cause Determination
- Analyzing the Incident for Cause and Responsibility
- Failure Analysis and Analytical Tools
- Explosions
- Incendiary Fires
- Fire and Explosion Deaths and Injuries
- Appliances
- Motor Vehicle Fires
- Wildfire Investigations
- Management of Major Investigations

RECONSTRUCTION AND FAILURE ANALYSIS PROCESS

The complete reconstruction and failure analysis process involves developing a time history for the incident, identifying the location of the fire origin, and establishing the factors that led to ignition and that increased or lessened the severity of the loss. The reconstruction includes prefire history, as well as "transfire" events, or those that occur from the point of established burning to extinguishment. Failure analysis is concerned with the design, construction, and performance aspects of the incident. It is also important in the reconstruction to document the successes. For example, did fire protection features inhibit the spread of fire within a portion of the building?

Time is the framework for reconstruction and failure analysis, and it can be viewed in two scales: the macro scale, where time is measured in increments of days, weeks, and years, and the micro scale, where the increments are in seconds, minutes, and hours. Macro time is prefire, whereas micro time may apply to both pre- or transfire events.

The best way to organize reconstruction and failure analysis information is through the use of timelines or event sequences. In constructing a timeline, it is important to establish benchmark events. A benchmark[1] event can be described as an event that is well documented in time and space and that serves as a point of reference because it can be assumed to have created a set of specific conditions or initiated a sequence of actions that

had a significant impact on the fire. The issuance of a building permit or the time of arrival of the fire department apparatus are good examples of benchmark events. Using time of arrival as a reference event, other events for which the time of occurrence is unknown can be placed approximately in time either before or after arrival of the fire department apparatus. Other examples of typical benchmark events are explosions and the collapse of walls or roofs or calling for multiple alarm response.

A single timeline can be adequate for fires in which only a few events occurred. For more complex situations, separate timelines on the same scale can be used for the history of the building, the evolution of the "model codes," the installation and maintenance history of a suppression system, human activity, or any other time-related aspect of the incident. STEP (sequentially timed events plotting) procedures have been developed to deal with complex accident situations such as major fires.*

Prefire timeline information can be obtained from building permits, plans and specifications, inspection reports, fire and building codes, and fire research and engineering literature. Sources of information for use in the development of transfire timelines include the fire department incident report; recordings of fire department radio transmissions during the incident; photographs and video footage shot during the event by news media, private citizens, or fire department personnel; and interviews with fire fighters and other witnesses.

It should be pointed out that, in many cases, only parts of the reconstruction and failure analysis process are carried out. Many different organizations may be involved in the investigation, often at different times. Because people may have to rely on information gathered by others, an understanding of the whole process makes it easier to obtain the most complete and accurate data at each step.

The basic steps of overall reconstruction and failure analysis are examination of the scene, collection of background data, testing, incident reconstruction, and specific failure analysis. Many of these steps are outlined in NFPA 921.

Examination of the Scene

Examining the fire scene is critical to the entire reconstruction and analysis process. It is here that the physical and photographic evidence is gathered and the fire damage is documented through maps and diagrams.

Transition to Digital Cameras

In the past, 35mm format photography has been the most common method of photographic documentation. Recent trends have favored the use of digital images. One advantage of digital photography is the instant confirmation that a difficult photograph, which is often taken in poor lighting conditions, has been taken properly. Although there has been concern that digital images can be altered or enhanced, it should be noted that similar changes can be made with film as well and that brightness and color balance is often adjusted during commercial film processing. It is important that an original archival copy of each film or digital image be maintained that can be testified to in court as a "fair and accurate representation" of what was seen by the investigator(s).[2]

Fire Scene Documentation

As many photographs as possible should be taken at the scene, and each photograph should be documented on a diagram with a description of the direction of view and contents of the photograph. The techniques of fire-scene photography have been well reported and can be applied to reconstruction and failure analysis.[3–5] Color photography is recommended.

In addition, maps and diagrams should be prepared that include dimensions and interior layout of the building, the location and degree of fire damage, the location and types of fuel materials, and the locations of victims. The location of fire protection features, such as firewalls, detectors, and suppression systems, should also be noted.

In many cases the first indication of the fire will come from activation of security devices transmitted to alarm companies from passive infrared (PIR) or ultrasonic motion detectors or from perimeter security contact sensors on doors or windows. Activation may indicate the presence of heat from a fire or entry into the premises. For this reason, the location and orientation of PIR sensors and the location of contact sensors and any associated signal wire should be documented. Evidence of activation can often be recovered from local alarm panels if undamaged or from fire alarm or security devices. It is also helpful to determine the prefire location and nature of fuel items as well as the prefire location and activities of fire victims.

Often, buildings will be modified considerably over their lifetimes, and an individual reviewing the original plans could receive a false impression of the building at the time of the fire. Thus, it is important to record the architectural, construction, and fire protection features of a structure, both as built *and* at the time of the fire.

When fire suppression systems are present, the positions of valves, the locations of discharge nozzles, and the locations and types of detectors used to operate the system should be noted. It may also be necessary to evaluate the water supply in order to determine if it was adequate. With special systems, such as those that use halon, CO_2, dry chemicals, or any clean agent fire extinguishing systems such as those described in NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems,* agent storage tanks should be checked to determine whether the system discharged as designed.

It is important to interview or review the interviews of fire department responders to determine what actions they took on the scene. Some of the damage may have occurred during fire fighting and overhaul and not as a direct result of the fire. For example, ventilation of a building to facilitate fire suppression activities may result in an increased burning rate at the area of venting, thus increasing the damage at that point.

A careful study of the damage patterns, combined with on-site interviews and a knowledge of the ignition sources, location of fuel materials present immediately before the fire, and fire

*Any event for which the actual time of occurrence is known is a "benchmark" event. A "hard time" timeline has benchmarks for each event. A "soft time" or "relative time" timeline has the sequence of events known, relative to each other, but not all of the actual times. Benchmark events are exceptions in a relative time timeline, and their known times of occurrence often can set bounds on the times of other events.

dynamics, should be used by an investigator to determine the area of origin. If possible, the source and form of heat of ignition and the type and form of the materials first ignited should be determined. Burn patterns, such as a "V," low burns, and multiple "points of origin," can often be misleading and should only be used to establish origin and cause when they are unambiguous or are supported by other physical evidence. The investigator should collect evidence, develop hypotheses or theories about the origin and cause, and test these theories to see which the evidence supports.

The investigator should keep in mind that the burn patterns seen after a fire represent the total burning history of the event, including damage that may have occurred during extinguishment and overhaul. As a rule, patterns observed in fires that are extinguished early in their development are more meaningful and useful than those remaining after the near-total destruction of a building or a portion of a building.

Indicators, such as depth of char, should be used with care. The burning rate of wood traditionally has been calculated as approximately 1.4 in. in 60 minutes (0.6 mm/min). This figure has been used to estimate the time of burning and to detect the presence of flammable liquids. Research has shown that the traditional calculation varies substantially, depending on the radiant heat flux and ventilation. The rate of burning can be as high as 10 in./hr (4.3 mm/min).[6]

Investigators should also be careful not to assume that certain burn patterns can be used as sole proof of the presence of flammable liquids. Factors such as ventilation, room flashover, floor clutter, room contents, fire duration, fire-fighting activities, and overhaul can affect the patterns seen by investigators. Corroborative evidence, such as pertinent chemical traces or the detected absence of an appropriate prefire fuel load, is needed to establish the presence of flammable liquids. The color of observed smoke is not necessarily evidence of the presence of flammable liquids. A number of recent studies have been carried out to identify some of the patterns that can develop from different ignition and ventilation scenarios.[7–9]

In visualizing conditions in the area of origin, it is often helpful to reconstruct the scene physically by replacing the carpet, furniture, and other items in their original locations. Although interviews are conducted at many different times in the reconstruction and failure analysis process, those taken at or close to the time of the incident also can be very useful, particularly in describing the course of the fire. Whenever possible, events described in interviews should be related to benchmark events.

Arc Fault Mapping

The path of electrical supply wiring circuits that were energized at the time of the fire should be examined for the presence of arcing because the location of the arcs may be used to assist in determination of the progression of the fire, a technique called arc fault mapping.[10,11]

On-Scene Fire Investigation

Private sector investigators are often not called in to evaluate a fire scene until well after the incident. Frequently, the scene has been disturbed, or, in some cases, the building has been restored or removed. In these situations, the investigator should review physical evidence collected and photographic evidence. Examination of photographs using 7- to 10-power binocular microscopy can often reveal details, particularly when low-speed film has been used. If possible, copies of all photos and videotapes taken of the scene should be obtained. Grouping them for study, chronologically and by area depicted, is useful in documenting the amount of scene disturbance over time. Fire, police, and autopsy reports, as well as witness statements, should be reviewed.

Although an actual on-scene investigation of a fire is most desirable, careful analysis of a well-documented fire can lead to reliable conclusions or assessment of conflicting opinions regarding the origin and cause of many fires, as well as provide information for failure analysis. The effectiveness of a delayed investigation and analysis depends on the extent of the fire, as well as the degree of documentation. In some cases where there has been total or near-total destruction, neither an on-scene well-documented investigation nor subsequent delayed analysis can establish origin or cause.

Collection of Background Data

Although some of the background data, such as accounts of activities immediately before the fire, can be gathered at the scene very soon after the fire, much of the information needed for the investigation will be gathered later.

Building plans, permits, and the codes in effect at the time of approval should be obtained, along with the specifications and drawings for the building fire protection features. If any major modifications were made to the building or its fire protection systems or if there was a change of occupancy, the codes, plans, and permits should be obtained as well. These materials should be reviewed as part of the reconstruction process, because the changes may have influenced the course of the fire.

Other background data include instruction or training manuals, maintenance records, data on construction and interior finish materials, the previous fire history of the building or equipment involved, the amount of any previous fire damage, the location of contents, and the physical and burning characteristics of the contents. Maintenance records can often reveal problems with equipment that might have been part of the cause of a fire. This step also involves obtaining detailed statements from the building occupants to determine the circumstances leading up to ignition and established burning.

For many fire scenes there can be a number of investigators involved such as the fire department, insurance companies, owner's representative, and experts for potential or actual litigants conducting independent investigations concurrently. Although the investigative data and reports of other investigators may not be available in the early stages of an investigation, it is important that, to the extent possible, investigators evaluate this information during later stages of their investigation to assess whether their determinations should be revaluated with the addition of new data.

Testing

See also Section 6, Chapter 3, "Concepts and Protocols of Fire Testing."

In collecting samples for testing, it is important to know the sizes and/or amounts of the sample needed for each test, as well as the conditions under which the samples should be transported. This information can be obtained from a testing laboratory or by reviewing a copy of the test method.

There are several types of tests that are commonly utilized by fire investigators: (1) identification tests of unknowns, (2) flammability tests, (3) performance tests, and (4) demonstration tests.

Identification of Unknowns. Identification of unknown materials is performed by analytical laboratories using techniques such as gas chromatography and mass spectroscopy to identify unknown materials, particularly for identification of possible ignitable liquids that may have been used as accelerants. Such analysis should be conducted in accordance with the following appropriate ASTM standards: ASTM E1385, *Standard Practice for Separation and Concentration of Ignitable Liquid Residues from Fire Debris Samples by Steam Distillation;* ASTM E1386, *Standard Practice for Separation and Concentration of Ignitable Liquid Residues from Fire Debris Samples by Solvent Extraction;* ASTM E1387, *Standard Test Method for Ignitable Liquid Residues in Extracts from Fire Debris Samples by Gas Chromatography;* ASTM E1388, *Standard Practice for Sampling of Headspace Vapors from Fire Debris Samples;* ASTM E1412, *Standard Practice for Separation of Ignitable Liquid Residues from Fire Debris Samples by Passive Headspace Concentration with Activated Charcoal;* ASTM E1413, *Standard Practice for Separation and Concentration of Ignitable Liquid Residues from Fire Debris Samples by Dynamic Headspace Concentration;* ASTM E1618, *Standard Test Method for Ignitable Liquid Residues in Extracts from Fire Debris Samples by Gas Chromatography-Mass Spectrometry;* and ASTM E2154, *Standard Practice for Separation and Concentration of Ignitable Liquid Residues from Fire Debris Samples by Passive Headspace Concentration with Solid Phase Microextraction (SPME).*

Other useful analysis techniques for identification of unknown materials include FTIR (Fourier transfer infrared) analysis, EDS (energy dispersive spectroscopy), and metallurgical or X-ray analysis. These methods can identify various molecules or atomic components of the unknown for comparison to data from known materials.

Flammability Tests. Properties of material flammability and combustion that may be determined by test include ignition temperature, flame spread of materials, fabric flammability, flashpoint, and rate of heat release, among others.[12–19] It is important to remember that the reported results from most flammability tests are not intrinsic properties of the materials, but instead are dependent on the specific test method used.

Cone calorimeter testing is among the many types of flammability tests conducted and can provide information on the heat release rate of materials. Figure 3.2.1 illustrates the cone calorimeter apparatus.

Performance Tests. Performance tests are conducted to evaluate conditions of fire protection systems at the fire scene. Examples of performance tests include waterflow tests on sprinkler systems, flow rate or leakage tests on natural gas or propane distribution systems, and many others. The performance tests should be conducted using standard methods. The investigator must be cognizant of the conditions during the performance tests that may be different than those that existed during the fire and be ready to compensate for them or explain the effects on test results.

FIGURE 3.2.1 The Cone Calorimeter (Courtesy Fire Testing Technology Ltd.)

Demonstration Tests. Although special nonstandard tests, sometimes called "demonstrations," can often be revealing in understanding the course of a particular fire, results of these demonstrations can be misleading because the test may not be truly representative of the actual event. Factors such as ventilation, arrangement and types of the fuels, or even the point of ignition can have a significant effect on the outcome of the test. In other words, a great deal needs to be known about the specific conditions at the time of the fire, and these conditions must be reasonably reproduced and fully documented in the demonstration. Special tests or demonstrations should be conducted by personnel familiar with full-scale fire testing under laboratory conditions to permit control of such variables as ambient temperature, relative humidity, and wind effects. It is also important that someone with advanced knowledge of fire dynamics has evaluated the special test and can explain why the results of the special test can be applied to understanding the fire scene

despite the inevitable difference between the test setup and the actual fire scene.

Figure 3.2.2 illustrates a demonstration test conducted by the Bureau of Alcohol, Tobacco, Firearms, and Explosives.

Reconstruction and Analysis

Fire reconstruction is an organized, step-by-step portrayal of the most likely course of the fire under study, from the ignition sequence through established burning to the limits of flame and smoke movement at the time of extinguishment. Fire reconstruction is based on the facts developed through on-scene investigation, background studies, and testing. The reconstruction should explain the speed and direction of fire growth and smoke spread within the compartment or area of origin and beyond. It also should explain the effects of barriers and automatic suppression systems on fire spread and growth and the effects of manual extinguishment. The reconstruction should also evaluate the performance of the building's life safety features relative to injury or loss of life.

In sorting through the facts to develop the reconstruction, it is often useful to apply the system safety techniques of failure modes and effects analysis (FMEA) and fault tree analysis.[20] These methods help identify alternative sequences of events that could have led to the observed fire situation, such as the development of room flashover or fire breaching a fire wall. The alternatives can then be evaluated against the evidence to determine the most likely scenario. These techniques are particularly valuable where complex or interrelated machinery, buildings, or human activities are involved.

Computer modeling techniques can also be used to predict the outcome of a series of possible fire causes and growth scenarios. The model results can be compared to actual events to narrow down the likely scenarios for a given event or to evaluate the possible effects that fire protection equipment, such as detectors or sprinklers, might have had on the outcome of a fire. The analyses of the DuPont Plaza and the First Interstate Bank fires are examples of model applications.[21,22]

Analysis of the ignition sequence (fire cause) is concerned with three specific items: (1) size, nature, and source of the ignition energy; (2) physical and chemical fire properties of the materials ignited; and (3) circumstances, either human or mechanical, that brought the energy in contact with the fuel. In selecting the most likely ignition source, the energy available from a candidate source must be compared with the ignition energy requirements of the fuel in its given form. For example, given the same material and heat source, ignition is more likely if the material is present in a finely divided form than if it is in a solid mass. Energy available at the source, such as temperature and thermal radiation, distance from the fuel to the energy source, and time of exposure to the source of energy, are also factors that need to be considered in ignition sequence analysis. The term *competent ignition source* is used to describe a source that has sufficient energy and temperature to raise a particular fuel to its ignition temperature during the postulated exposure time. For example, an electric arc may be at a temperature well above the ignition temperature of a particular fuel but be of short duration and not provide enough total energy to result in ignition.

FIGURE 3.2.2 Setup for a Demonstration Test (Courtesy Bureau of Alcohol, Tobacco, Firearms, and Explosives)

Circumstances that result in ignition generally involve human factors or equipment failure. Careless welding, poor housekeeping, and improper selection or misuse of materials are examples of human factors. Valve rupture and combustion control failure could be considered equipment failures. Ultimately, most equipment failures can be traced to design, manufacturing, installation, or maintenance problems or to misuse.

An extensive compilation of data on materials, ignition sources, and ignition scenarios is available in Babrauskas.[23] If established burning is achieved after ignition, it must be determined why the fire continued to grow to full room involvement—that is, flashover, or, in the absence of compartmentation, such as that in a warehouse or industrial building, why it reached a certain extent. In providing answers, a number of factors must be evaluated, including the rates of heat release of the fuels, continuity of the fuels (i.e., the proximity of fuel packages to each other) and location of fuels relative to walls, compartment ceiling height, ventilation, and interior finish.

Heat release rate is one of the more important factors in analysis. In many instances, a fire reported to have grown or spread "unusually fast" is characterized as suspicious or incendiary when, in fact, the growth rate may have been due to a combination of the burning properties of the materials and the nature of the compartment in which the fire burned.

It is important to note that it is not possible at this time to calculate the heat release rate of complex materials and that the only accurate heat release rate data come from experimental tests. A number of experimental studies have been carried out to characterize the burning rates of actual materials and furnishings.

A number of studies have been carried out to characterize the burning rates of materials and furnishings. Data can be found in NIST reports and in Appendix B-2.2 of *NFPA 72®*, *National Fire Alarm Code®*.[19,24–27] The roles of heat release rate, fire location, and ceiling height in fire development have also been reported.[28] Alpert's work includes methods to estimate ceiling temperatures and ceiling gas velocities. Guidance on estimating the likelihood that a given fire size and room ventilation combination can develop flashover also is provided in NIST reports and the *SFPE Handbook of Fire Protection Engineering*.[29–31] See also Section 2, Chapter 4, "Dynamics of Compartment Fire Growth," of the *Fire Protection Handbook*.

The performance of automatic suppression systems in controlling the growth and spread of the fire also must be evaluated in the reconstruction process. Here, the factors to be reviewed include the appropriateness of the agent being used; the system response time, as related to the detection devices used, relative to ceiling height and fire growth rate; location of the agent discharge nozzles relative to the source of the fire; agent availability, including rate of discharge, pressure, and adequacy of supply; and conformance of the system design and installation with NFPA standards, industry design, and installation manuals. For example, a sprinkler system may have failed to control a fire due to a very high ceiling that delayed the response time, combined with low water pressure that could not produce the needed waterflow rate.

Another component of the reconstruction is barrier performance. Barrier performance evaluation focuses on the nature of the barrier, whether rated or not rated, barrier construction, the thermal stresses to which it was exposed, and the manner in which the barrier failed. Barriers can fail by passage of flame or hot gases through a small opening, by a hot spot failure, by movement of flame and hot gases through open doors, or by barrier collapse, resulting in a massive failure. Failure of opening protection, poor construction practices, modifications to the barrier after construction, and fire stresses that exceed those assumed in the design can be significant transporters of products of combustion beyond design limits.

Manual suppression activities, whether by a municipal fire department or a plant fire brigade, can have a significant effect on the outcome of a fire. In the absence of fire suppression systems, the response time of the fire department for a given fire will influence the size of the fire at the time of agent application. For ease of analysis, the response time can be broken down into the following segments: detection time, alarm transmission time, dispatch time, travel time, and time from the arrival of fire suppression personnel to agent application. Problems resulting in delays in any of the above time segments will extend the limits of flame and smoke travel. Examples of factors that could cause delays are the absence of automatic detectors, the absence of people in the building, or an improperly designed detection system. Equipment failure or out-of-service fire apparatus can also delay response time. Weather, terrain, traffic, and the condition of apparatus can extend travel time to the incident. Frozen hydrants, blocked access, and shortage of personnel are also examples of factors that could delay application of fire suppression agents.

The reconstruction process must also consider the performance of the building life safety system. This includes the detection and alarm system, the building egress system, and the smoke control system. In addition to the factors discussed above that affect detector response, the audibility of alarms plays a role in life safety. Guidance on this topic can be found in work by Nober,[32] in *NFPA 72,* and in the *SFPE Handbook of Fire Protection Engineering.*[33] Building egress factors include the capabilities of the occupants and the number, capacity, and protection of the egress routes. The movement of smoke in buildings is related to the temperature of the fire gases; differences between inside and outside temperatures, or the stack effect; effects of the building's heating and air conditioning systems; and effects of wind.

Failure Analysis

In a fire safety context, failure can be defined as a fire that results in personal injury, death, or property or monetary losses, or in conditions that prevent buildings or mechanisms from functioning as designed. In fire failure analysis, the objective is to use on-site and background data, testing results, and reconstruction to identify the primary and contributing causes of the failures and their sources. The sources of failures include basic design, material or equipment selection, material or equipment defects, construction or assembly, testing, postconstruction modifications, service conditions, and unanticipated conditions or abuse.

The analysis is made by comparing the causes of failures with codes, standards, design practices, and the state-of-the-art technology present at the time of the fire. In the analysis, it is important to identify noncompliance with the standard practices, but it is even more important to note where compliance with the standards failed to provide the expected or needed degree of fire safety. In either event, failure analysis should provide recommendations for how the failures could have been prevented or how the knowledge gained can be applied to preventing similar failures in the future.

ORGANIZATION FOR FIRE INVESTIGATION

It is a good idea to be prepared in advance for the investigation of a fire. The preparation may range from identifying an individual or company to hire as needed to the organization of a permanent fire investigation unit complete with full-time staffing, vehicles, and a laboratory. The level of organization selected depends on the size of the organization, the frequency of need, the resources available, and the legal or statutory requirements. One other factor to be considered is whether or not the organization is in the public sector—the fire department, police department, state and federal government, and so on—or in the private sector—insurance company, product manufacturer, major hotel chain, and so on. Frequently, public sector needs will include more than just the ability to conduct a fire scene investigation. Should it be determined that the possibility of arson exists, the likelihood of criminal or civil action often requires the involvement of the police or persons trained in the legal aspects of arson and fraud investigation.

Public Sector

In the public sector, the fire department personnel responding to the scene carry out most initial investigations. If the cause is easily determined and does not appear to be of a potentially criminal nature, the investigation ends at that level. When the cause cannot be determined, a fatality is involved, or arson is suspected, additional help is generally dispatched. In a small fire department, the local police or the county or state fire marshal's office may be contacted. In some jurisdictions, the assistance may come from the county or state police.

In large cities, a fire investigation unit is usually formed. The unit may be made up of fire department personnel and be wholly within the fire department, or the unit may be within the police department. Regardless of where the unit is placed organizationally, it is generally recommended that both fire investigation and police functions be represented in the background and training of personnel. This objective is often accomplished by selecting individuals from both departments to serve in the fire investigation unit.

In some jurisdictions, an investigations unit is established in the local criminal prosecutor's office. Such a unit will usually have arson detection and prosecution as its major focus where the caseload is high. A special prosecutor is often assigned specifically for arson, and that individual frequently is trained in fire investigation techniques.

In many instances, fire investigation units in both the fire and police departments are called arson investigation units. Determination of arson can usually come only after a thorough fire investigation in which other possible causes are ruled out and physical evidence of an incendiary fire is established. This provision should be stressed to investigative personnel so they do not come to believe that their role is to find arson. The term *fire investigation* is more appropriate to the work that is done than arson investigation. If arson is a major problem in a community, special arson task forces can be established to identify arson-for-profit groups, associating real estate buying and selling and insurance patterns with arson and arson prevention activities. This work is less concerned with actual fire scene investigation, and deals more with the establishment of motivation, insurance manipulation, and patterns of arson occurrence.

Some federal agencies, such as the General Services Administration or the military services, have personnel who investigate fires involving their facilities. These personnel are generally assigned fire investigation in addition to other functions such as facility safety or fire protection design. In the event of a major fire, an agency may conduct its own investigation or use an outside consultant to assist its own personnel.

Private Sector

In the private sector, large insurance companies may have investigative units that conduct fire scene investigations and perform arson and fraud detection and control functions. Some companies employ adjustment bureaus or private investigators to make the initial cause determination, and follow up with their own personnel if it appears that arson or fraud is involved or if there is a particularly large loss. Small companies may rely exclusively on outside investigation services.

A number of large industrial companies also maintain a fire investigative capability, often located in their risk management or loss prevention groups. These groups or individuals may investigate fires in company facilities or fires involving products or systems designed, manufactured, supplied, or installed by the company. These investigations may be for the purpose of future loss prevention or plant safety programs, or they may be carried out in response to actual or potential litigation. An important function of this type of investigation is the identification of the causative factors in the fire that could lead to improved design, manufacturing, installation, or operating practices.

Organizations such as NFPA and the U.S. Fire Administration also investigate fires in order to determine "lessons learned" for broad reporting purposes.

Small companies may not be able to afford their own investigation staffs. In such cases, an appropriate outside capability should be identified in advance for use if the need arises. The individual or firm selected should either have or be given some knowledge of the specific products, facilities, or operations that are likely to be involved.

EDUCATION AND TRAINING OF FIRE INVESTIGATION PERSONNEL

The nature and extent of education, training, and experience needed by investigators obviously varies greatly with the specific goals and objectives for fire investigations set by the organization where they are employed and by budget resources. Some basic performance requirements for fire investigators are provided in NFPA 1033. The level of knowledge needed by a fire ground officer faced with a residential fire extinguished early in its development will be less than that needed by an investigator from the department's fire investigation unit. This investigator will have to deal with fires extinguished in more advanced stages, where the evidence of cause is often much less clear. In addition, this investigator will have to deal with fires in the full range of occupancies found in the unit's jurisdiction. This could include residences, office structures, warehousing, manufacturing, and heavy industry.

The private sector investigator employed by a petrochemical company may need a degree in chemistry or chemical or fire protection engineering in addition to the basic fire scene investigation skills. The specialist in arson investigation will need education and experience in the legal aspects of civil or criminal investigations, or possibly both.

Today, research and development is ongoing in areas of knowledge related to fire investigation, and the investigative techniques that were used in the past are being refined. For this reason, fire investigators should stay current with the latest innovations and knowledge in their field. As the state-of-the art in fire investigation develops, previous determinations may need to be reevaluated based on the current state of knowledge.

Education

In the past decade, a great deal of data regarding the nature of the ignition process and the forces that control fire spread and growth has emerged. Research by university, government, and insurance laboratories has developed information that can explain much of the evidence remaining after a fire has been extinguished and assist in determining origin and cause.

To determine adequately the origin and cause of a fire, the modern investigator needs a basic knowledge of physics and

chemistry, preferably at the postsecondary-school level. The investigator should be familiar with the concepts of heat release rate, fire plume and ceiling layer development, compartment flashover, and full room involvement. The investigator should also have knowledge of electrical power distribution systems and the failure modes of common electrical equipment and appliances.

All fire investigators should also have some knowledge of the legal aspects of investigations, such as how to gain access to a scene, how to take and handle evidence, and how to question witnesses.

Fire science courses offered at many postsecondary schools today can provide much of the needed background. Where such facilities are not available, basic science courses supplemented by independent reading can be employed. In some areas of the country, the U.S. Fire Administration's Open Learning Program is also available through selected local colleges and universities.

In fire investigation units to which both police and fire personnel are assigned, personnel should be cross-trained in basic fire science and law enforcement. Departments that become familiar with each other's technology and terminology benefit from enhanced communication, more complete and thorough investigations, and more successful prosecutions.

Advanced education might include college-level courses in such areas as forensic science, industrial safety, insurance, accident investigation, and fire protection engineering.

Training

All investigators should be trained in the basics of fire scene investigation, which include adequate documentation of the scene, origin determination, and cause determination. Specific emphasis should be placed on techniques for debris removal and scene reconstruction. Although much of this knowledge can be gained by studying text materials, there is no substitute for field experience. Even limited hands-on work can be of great value in relating the text materials to "the real world."

SUMMARY

Fire loss investigation ranges in complexity from completing a fire incident report to detailed engineering reconstruction and failure analysis. Once rare, fire loss reconstruction and failure analysis is becoming more common. As described in this chapter, that process may include examination of the fire scene, collection of background data, testing, and the organized, step-by-step portrayal of the most likely course of the fire under study.

The complexity of the fire loss investigation dictates the complexity of training needed to conduct the investigation. NFPA 1033 prescribes minimum basic competencies. In addition, a basic knowledge of physics and chemistry is needed. College-level study in areas such as forensic science, insurance, accident investigation, and fire protection engineering is needed for the successful and credible investigation and reconstruction of complex fires.

How do we know what we know about fire? Where do the statistics come from? Although some tests can be done in laboratories, laboratory tests do not explain what causes the largest number of fires or how often fire kills people. In this chapter, several real-world data sources for fire analysis are described. Most of this chapter will focus on the U.S. National Fire Incident Reporting System (NFIRS), the largest and most detailed fire incident database in the world and the source of most of what we know about fire.

NFIRS provides a standard format for data collection, enabling aggregation of and comparisons across stations, communities, and states. NFIRS was designed to meet the needs of both the people collecting the data and the people who use it.

NFIRS has been widely used since 1980 and has added and dropped data elements at several times in different versions. Version 5.0 of NFIRS, first introduced in a few areas in 1999, was designed to give local fire officers greater ability to document their department's activities and experiences and represents a major departure from the structure of earlier versions. By 2003, the vast majority of U.S. fire departments participating in NFIRS were using the Version 5.0 system.

NFPA's annual fire department survey, the source of the "big picture" on fire problems and the scaling ratios to be used with NFIRS will also be discussed in some detail. Additional information will be provided on the following:

- NFPA's Fire Incident Data Organization (FIDO), an anecdotal database
- The death certificate database
- The National Electronic Injury Surveillance System (NEISS), a system that tracks injuries treated at emergency rooms
- The FBI's Uniform Crime Reporting System (UCR), the source for data on arson arrests
- Some fire incident data collection systems elsewhere in the world and international fire data collection efforts

The use of fire data and the implications of NFIRS Version 5.0 for fire data analysis are discussed in Section 3, Chapter 4, "Use of Fire Incident Data and Statistics."

HISTORY OF NFIRS

The need to collect aggregated fire data was realized and identified in 1972 when President Nixon's Commission on Fire Prevention and Control issued the report *America Burning.*[1] Among other things, the report noted that the United States had one of the highest fire death rates at that time in the industrialized world. As a result of the report, it had become painfully obvious that we had a serious fire problem in the United States, yet we knew very little about its exact nature. This alarming fact led directly to the National Fire Prevention and Control Act, Public Law (P.L.) 93-498, in 1974. The act directed the formation of the U.S. Fire Administration (originally called the National Fire Prevention and Control Administration) in order to initiate a national focus on the fire problem. Section 9 of the act established the National Fire Data Center to "provide an accurate, nationwide

Marty Ahrens is manager of fire analysis services at NFPA.

Stan Stewart is an information technology specialist within the U.S. Fire Administration's National Fire Data Center.

analysis of the fire problem, identify major problem areas, assist in setting priorities, determine possible solutions to problems, and monitor the effectiveness of programs to reduce fire losses." The National Fire Data Center established the National Fire Incident Reporting System to meet their charter.

Early data collection efforts varied throughout the country. Many local fire departments used their own systems of documentation. For small fires, the department log was often the only documentation that an incident occurred. Most reports were simply narratives of the incident and actions taken to manage it. Pulling meaningful information or even simple statistics from narratives, however, is an exercise in frustration at the local level and nearly impossible at the state and national levels. Fire service leaders and NFPA had recognized this as a problem for a long time.

By 1969, NFPA had already identified data elements and developed standardized classifications for recording and reporting fire incidents. NFPA 901, *Uniform Coding for Fire Protection,* provided the classification system for the then new National Fire Incident Reporting System (NFIRS). (Some data elements in the standard were not included in NFIRS.) The 1976 edition of the incident and civilian casualty codes and the 1981 edition of fire service casualty codes were used until NFIRS 5.0 was released in 1999.

The first *Fire in the United States* report was published by the U.S. Fire Administration's National Data Center in December 1978. The authors noted that better fire data were needed: "The most detailed data on fire causes were available for a full year for only two states—California and Ohio. A few other states had detailed data, but not in a form that was easily comparable. The limited State data available this year were supplemented by data from seven cities (in other states) with compatible data systems."[2] California's data were for 1975, and Ohio's data were for 1976.

The second *Fire in the United States* was published in 1982.[3] This report looked at fires in 1978 and included full-year data for 15 states. Other volumes have appeared since then, usually on an annual or biannual basis. In the late 1970s and early 1980s, the USFA provided states with funding and other resources to help implement NFIRS in their states. By April 1981, 38 states and the District of Columbia were either participating in NFIRS or preparing to participate.

One of the long-term goals of NFIRS is to promote local fire incident reporting. Because of fiscal, technical, or personnel issues, some participating states have had years in which they were unable to submit data. Consequently, it is hard to precisely define which states are or are not participating in the national system.

NFIRS—A THREE-TIERED SYSTEM

Local fire departments, state fire agencies, and the federal government all play critical roles in collecting NFIRS data.

NFIRS at the Local Level

Fire officers and fire fighters at the local level provide the basis of the system. Without their efforts, this system could not work. By completing a fire report, a fire officer does three important things. First, he or she is making a legal public record that documents the incident. Second, the fire officer's report provides information to senior officers and fire department managers so that they are kept informed about what is happening within their areas of responsibility. This allows them to evaluate the performance of their units at the incident and to talk intelligently about the incident to the media and others. Good information about a fire can motivate change in fire protection approaches in a community or even the nation. The MGM Grand Hotel fire in Las Vegas, Nevada, in 1980 helped to trigger a wave of improvements in fire safety.[4] More recently, the 2003 Station Nightclub fire in Rhode Island led to more requirements for sprinklers in these properties.[5]

Finally, the fire report provides data on the fire problem to fire service management so that they can track trends, gauge the effectiveness of fire prevention and fire suppression measures currently in practice, evaluate the impact of new methods, and indicate those areas that may require further attention.

For the first two purposes, the report format may vary considerably. The report may be as brief as a basic fact statement or as lengthy as an extensive discussion of the fire, supported by photographs, witness statements, laboratory test results, and physical evidence. The length and complexity of the report will depend on the size and nature of the fire, the local fire service manager's need for specific data, and the resources available for obtaining information and completing reports. They also depend on the training and motivation of the person filling out the report.

A fire report should include, at some level of detail, a time-staged description of the circumstances related to the initiation, discovery, growth, and termination of the fire, along with a description of any casualties or damage resulting from the incident. This report should be in the words of the fire officer and must be complete so that people who were not at the fire scene can understand what happened.

A standardized format is required before statistics can be extracted to meet the third purpose. Statistics can reveal patterns or trends, enable comparisons across jurisdictions, and play an important part in service and program evaluations. NFIRS provides a format to make it possible to obtain these statistics.

Fire officers who use NFIRS to document incidents are simultaneously collecting and providing data on the time of the incident, the occupancy, the area where a fire started, what caught fire, what started the fire, property damage, casualties, whether sprinklers and detection equipment were present, and whether they worked. Using the NFIRS structure and codes, these fire officers provide data on what worked to keep small fires from growing in addition to documenting what went wrong at big fires. The reports may be handwritten or entered directly into a computer. The older systems were built around paper formats, although the data may have been entered directly into a computer. Version 5.0 was designed as a modular, computer-based system in which the user is shown the questions that must be answered. Paper forms are still used but seem cumbersome because all questions must be shown, including those that are not relevant to all incidents. Figure 3.3.1 shows an example of an NFIRS 5.0 basic module report form.

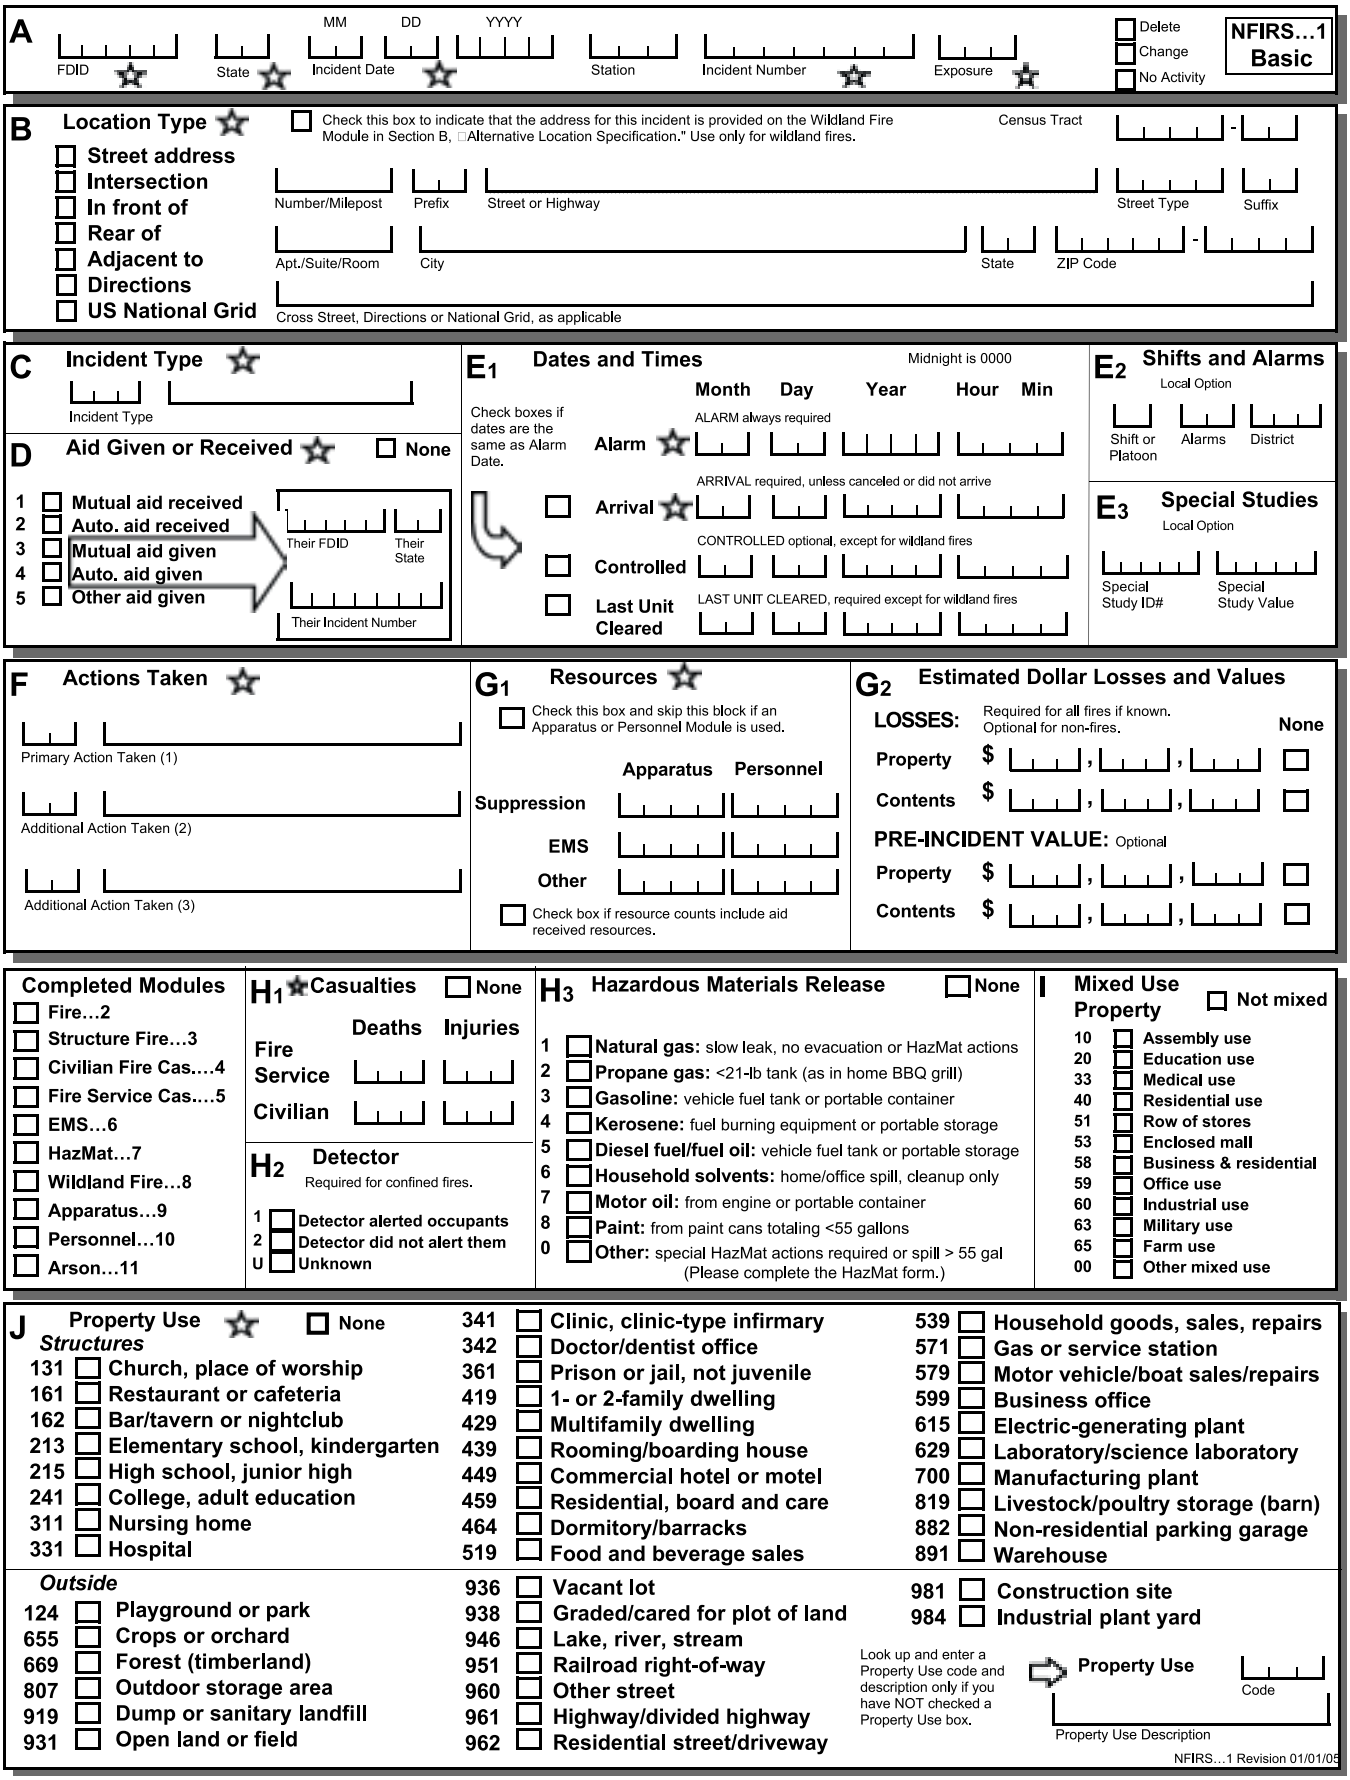

FIGURE 3.3.1 Example of NFIRS 5.0 Basic Module Report Form

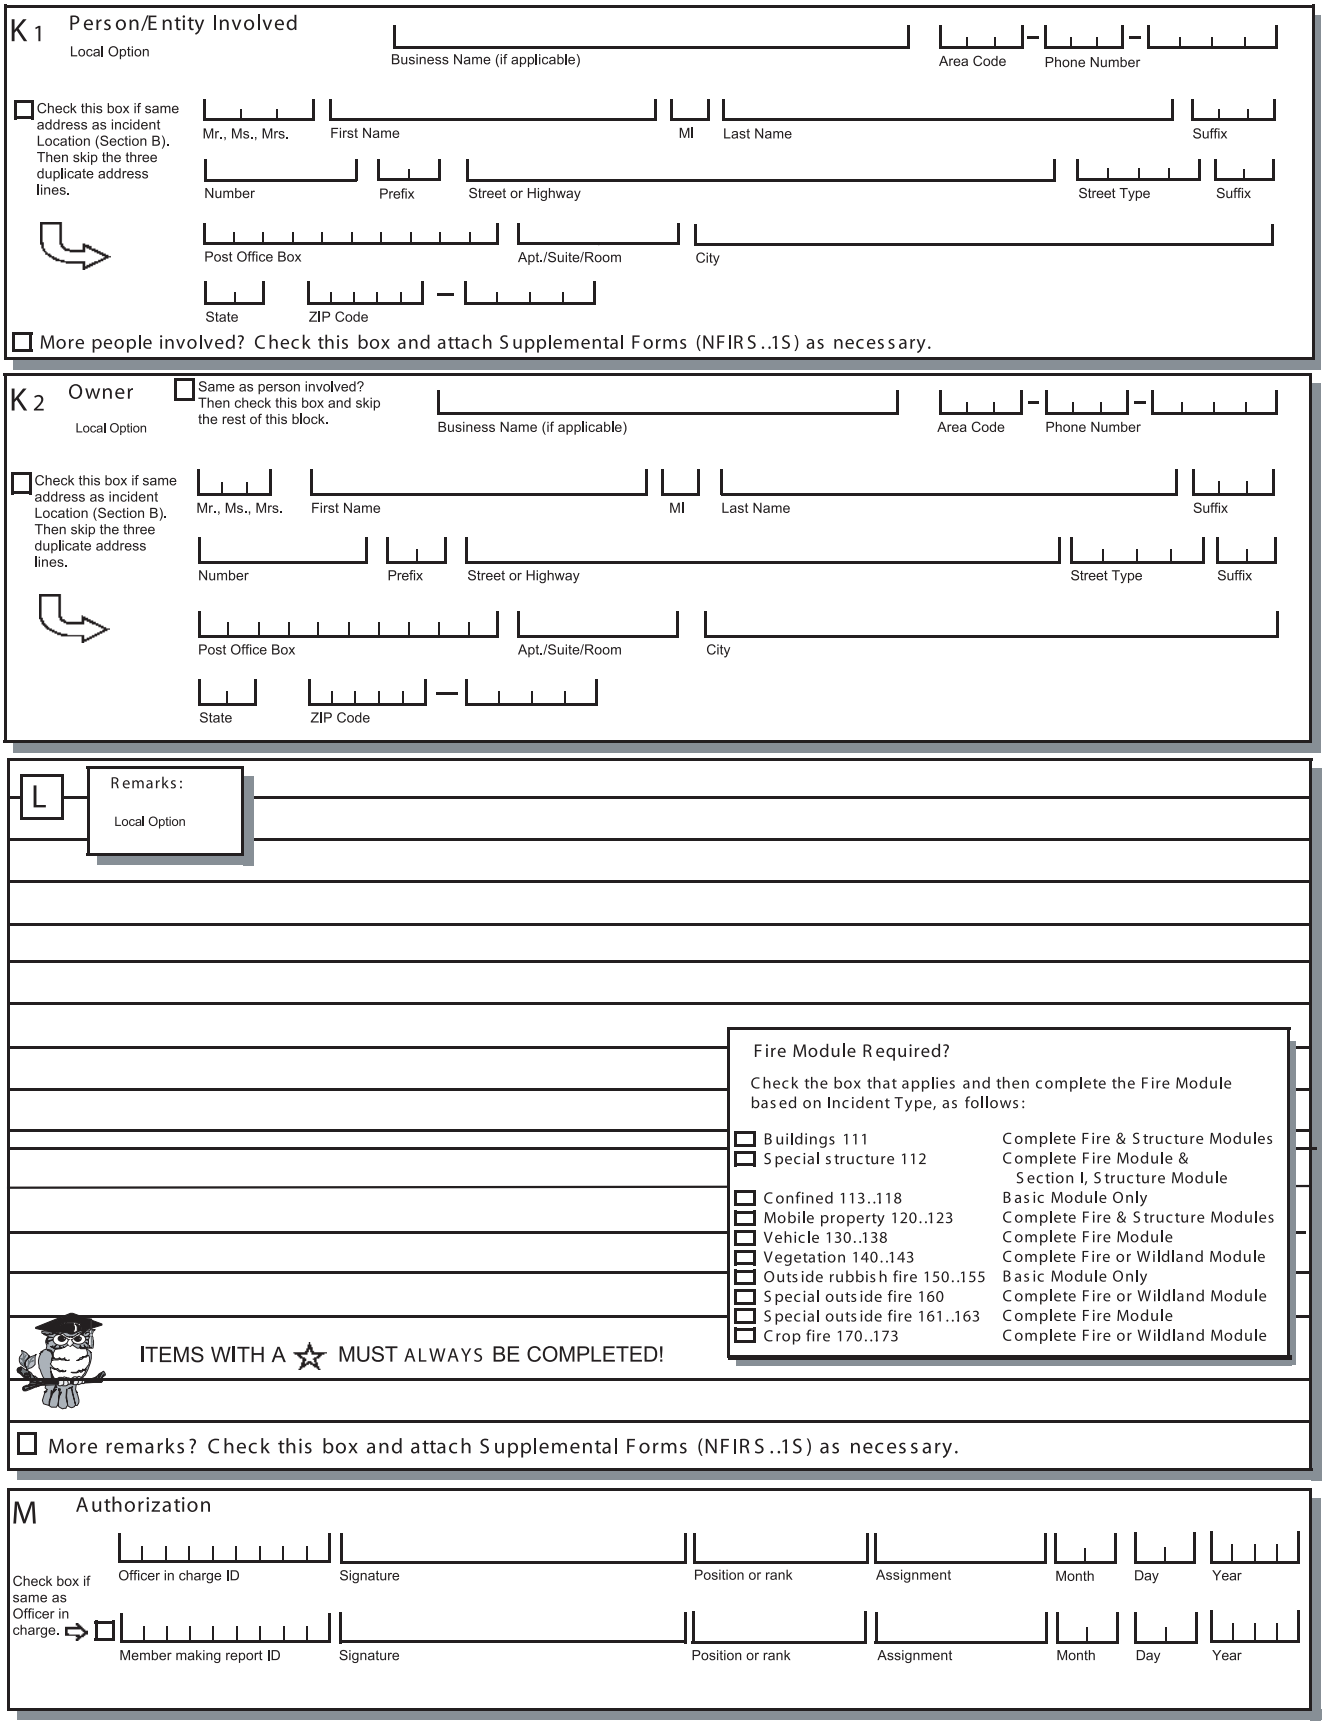

FIGURE 3.3.1 Continued

All the data in the National Fire Incident Reporting System originally come from local fire officers and fire fighters. More than 19,000, or over 60 percent, of the nation's fire departments reported at least one incident to NFIRS in 2004.[6] More and more fire departments see NFIRS as a tool for local use. As computers have become more powerful and software easier to use, the NFIRS system has become a vital management tool. Because Version 5.0 was designed to capture data about all types of incidents, not just fires, it can provide essential information about department activities. A fire chief can see which companies are busiest, what the leading fire problems were last year, and how many incidents of each type occurred. Some departments use the statistics to justify budgets or apply for grants. Departments seeking funds under the 2006 Assistance to Firefighters Federal Grant Program must participate in NFIRS.[7]

Some departments integrate NFIRS data with information concerning other department activities to create a comprehensive management information system (MIS). Some systems transfer computer-aided dispatch (CAD) information directly into the appropriate incident report fields.

NFIRS Reports as Local Records. Although analysts think of NFIRS as a tool for research about fire, at the local level it is first an organized record-keeping system. The incident report describes where and when the incident occurred, the resources used, and the services performed. It provides the framework to collect information about how the fire started, how fire protection systems worked, and the nature of any injuries. These reports are public records. At times, the needs of the researcher for details and the needs of the fire service for efficiency conflict; the needs of the fire service will take priority. At times, coding practices may violate NFIRS rules but make perfect sense. The field "item first ignited" describes the shape or form as the object or substance is customarily used, such as upholstered furniture, fuel, or clothing. The field "type of material first ignited" captures information about the composition of the object or substance, such as cotton, sawn wood, or gasoline.[8] Under these rules, it is inconsistent to see a fire in which the form of material first ignited was upholstered furniture and the type of material was gasoline. However, from a documentation standpoint, this may be a very accurate description of an incendiary fire. In the old days of paper forms, a fire officer might have written, "Gasoline poured on chair cushion." NFIRS training should encourage consistency between these two fields and further explanation of specific circumstances in the narrative.

Cause and Origin Skills Essential Parts of Local NFIRS. The persons responsible for reporting the data should be trained and capable of investigating a fire to determine the origin, cause, and circumstances of the fire. Their determinations become the data used by the system. Weaknesses here can undermine the validity of the data and of any analyses performed on the data.

The fire department should have certain standards that apply to all its record-keeping operations. Such standards will help make the data more uniform from report to report and application to application. Standardization aids all users of the data, makes analysis more accurate, and is essential if data is to be automated. Some areas where department standards should be developed include the following:

- Methods of entering the names of persons and businesses on records (NFIRS 5.0 provides a clear system for people's names but businesses are trickier)
- Recording addresses of buildings with multiple or ambiguous addresses, as well as nonstructure locations, such as those on highways or at street intersections
- Designating apparatus. Should it be done by company assigned? Serial number? Shop number?
- Designating employees. Should it be done by name? Badge number?
- The common abbreviations that are acceptable to use

Updating incident reports is crucial to an accurate fire data system. The updating of incident reports as better or more complete information becomes available is often not done. This is a major problem in the quality of information available. The lack of updates is especially common for fatal fires and large-loss fires, for which the initial incident report is left incomplete pending an investigation but does not get updated after the investigation is complete.

Each department should have detailed written procedures explaining how to perform each step in report compilation. These procedures should address such issues as how the reports are to be edited, processed, and filed; within what time frame; and how they are to be corrected or updated. Everyone responsible for completing any portion of the report should understand the procedures and schedule for completing, correcting, and forwarding the data. Delays in submitting data will result in delays in assembling the complete report and in making it available for use.

Record Retention. Local fire officials must obtain or develop a record retention schedule for all their records. There should be a written policy that details the length of time a report is to be retained in the active files, the length of time it should be kept in inactive storage, and when it can be discarded. The community attorney's office can help to determine legal requirements for retaining records; that office should review the final written policy before its implementation.

Obviously, paper records require storage space. Storage space costs money. As the files become more voluminous, the likelihood that material will be lost or misfiled also increases. On the other hand, costs for electronic data storage have decreased in recent years. There may be different retention requirements for computerized records, which require less space and are useful for multiyear analysis.

Ongoing changes in the computer industry pose challenges for record retrieval. As new technology and programs replace old, will the older electronic records be accessible? It is now hard to find a machine that can read data on a 5¼-in. floppy disk. Because the media can deteriorate, duplicate copies of archived records are advised. Before discarding old software, users should confirm that a new version or system can retrieve old records in an acceptable format.

Motivation to Complete Reports. Better data come from fire fighters who see, use, and understand the compiled statistics. Although far more fire fighters will complete the forms than actually access the data, data quality will improve if the fire

fighters collecting the data understand something about how it is analyzed. Training officers and command staff are encouraged to share reports describing activities at their own department, their state's annual reports, and statistical reports produced by the USFA and NFPA with their fire fighters to ensure that they know their completed reports are used.

NFIRS at the State Level

States generally set the minimum requirements for data collected by local departments. Some states use the standard NFIRS forms or layout without modification and allow or encourage local departments to use the federal NFIRS software. Others have arrangements with specific software vendors. Still others encourage their departments to find the commercial software that best meets their needs. Some states have added a few additional data elements or changed the format slightly.

Vendors selling NFIRS software in a state must check with the state authority to be sure that their software collects all the information the state requires. Local departments should also check with the state before making a purchase. Many states now accept only data collected in Version 5.0. Many no longer accept paper reports.

State fire agencies administer NFIRS in a variety of ways. In some states, one person has primary responsibility for the whole system—the training, quality control, entry, analysis, and report writing. In others, these responsibilities are divided among several individuals or divisions.

NFIRS at the Federal Level

Periodically, after the NFIRS data have been entered and checked for errors, state NFIRS administrators send the compiled data from each incident or release the incidents to the USFA via the federal server. The power of NFIRS at the national level comes from having the details of individual incidents as opposed to a collection of state totals. It is impossible to predict all of the questions that will arise. Although a few fields are not forwarded, most are. This makes it possible to run new queries on specific items.

The USFA provided states with software that may be used to run NFIRS at the state level. The USFA also provides and maintains basic software for local fire department use. This software allows users to enter data directly into a federal server with state partitions or maintain a local database of NFIRS data. State program managers monitor the quality and reporting status of their fire departments.

The USFA also maintains the NFIRS Support Center. People may contact the support center via telephone at 1-888-382-3827 or online through http://www.usfa.dhs.gov/fireservice/nfirs/support/. The Support Center answers questions about NFIRS, the USFA software, specific coding questions, and requests for data information or reports. The center also provides information about NFIRS training and makes referrals when technical assistance is required. The National Fire Data Center processes the data after it is submitted or released by the states. It periodically publishes *Fire in the United States,* the Topical Fire Research Series, and other analyses. After the data are compiled nationally, other users, such as the NFPA, the U.S. Consumer Product Safety Commission (CPSC), and private entities, may obtain the data for their own analyses.

NFIRS Training

The USFA, through the National Fire Academy (NFA), sponsors an NFIRS program management course at the NFA. The course enables participants to promote, support, and manage NFIRS data collection. The content includes data collection, processing, analysis, and presentation of useful, timely, and accurate information about fire department activities. It is designed for new and experienced state, metropolitan, and fire department NFIRS program managers. Participants learn from both structured classes and from each other.

The USFA also provides NFIRS training through the State Weekends training program. States may select NFIRS as one of the available state weekend offerings.

NFIRS DEFINITIONS

One of the benefits of NFIRS or any systematic data collection effort is the standardization of terminology. However, this means taking the time to examine terms or words that are familiar in everyday usage but have very specific meanings in the system's context.

Defining *Fire*

The *American Heritage Dictionary* (3rd ed., 1994) gives two relevant definitions for the word *fire:* (1) "A rapid, persistent chemical change that releases heat and light and is accompanied by flame, esp. the burning of a combustible substance and (2a) Burning fuel or (2b) A destructive burning."[9]

Yet fires in NFIRS include only those fires that are considered "hostile." Appendix C, Glossary and Abbreviations, in the *NFIRS 5.0 Reference Guide* defines *fire* as "Any instance of destructive and uncontrolled burning, including explosion, of combustible solids, liquids, or gases." Fire does not include the following, except when they cause fire or occur as a consequence of fire:

- Lightning or electrical discharge
- Rupture of a steam boiler, hot water tank, or other pressure vessel due to internal pressure and not to internal combustion
- Explosion of munitions or other detonating material
- Accident involving ship, aircraft, or other vehicle
- Overheat condition[10]

Fire department responses to someone burning with a permit or unauthorized burning would not be considered hostile fires and would not be counted as fires at all unless they got out of control.

Structure Fire

Structures include buildings but are not limited to them. Tents, storage tanks, tunnels, and covered walkways would all be considered structures but not buildings. In older versions of NFIRS, any fire inside a structure whether it involved the structure or

not, or any fire under or touching a structure that involves the structure would be considered a structure fire. This is still true in Version 5.0, with one notable exception. In older versions, a vehicle burning inside a structure was considered contents of, or the equipment involved in, a structure fire. Judging from the large number of vehicle fires that occurred at parking garages, it is clear that this convention was not always observed. Under the Version 5.0 rules, a vehicle burning inside a structure would be considered a vehicle fire unless the structure became involved. At that point, the incident becomes a structure fire, but vehicle information can be picked up in the mobile property section.

Under the rules established for Version 5.0, abbreviated reporting is allowed for certain types of confined structure fires, including fires confined to cooking vessels, chimneys, incinerators, fuel or oil burners or boilers, trash compactors, and trash or rubbish with no flame damage to the structure or its contents. This means that only the Basic Module would be completed. States and local fire department officials may elect to require full reports on all of these fires. Because no causal information would be collected on abbreviated reports, full reports are suggested when incidents might be incendiary.

Civilian and Fire Service Casualties

Distinctions are generally made in discussing civilian and fire service injuries and deaths. Civilians include anyone, including the police or other emergency personnel, who is not a member of the fire service.

Different data collection systems have defined fire deaths somewhat differently. According to NFIRS, fire deaths include anyone who dies as a result of the fire within one year of the fire. Although smoke inhalation and burns are the most common causes of fire deaths, a person would be considered a fire fatality if fatally injured while jumping out of a burning building or if a fatal heart attack struck during a fire. In some cases, particularly vehicle fires that were caused by collisions, it may be necessary to obtain autopsy results to determine whether an individual should be counted as a fire fatality. People who died immediately of trauma would not be counted.

NFPA uses death certificates to compare fire death rates among the states.[11] The National Center for Health Statistics (NCHS) uses the International Classification of Disease codes,[12] now in the 10th edition, to document external causes of mortality on death certificates. Different organizations use different combinations of these codes to identify fire deaths. NFPA and the National Safety Council[13] use the underlying or external cause of injury codes denoting exposure to smoke, fire, and flames, which fall into the larger category of "non-transport, unintentional injuries." The USFA also includes smoke, fire, and flame deaths resulting from intentional self-harm or assault (in the suicide and homicide categories); pathological fire setting (in the habit and impulse disorder category); discharge of firework (in the explosion category); and exposure to smoke, fire, and flame with undetermined intent.[14] In Version 5.0 of NFIRS, however, the incident type for a fireworks explosion with no fire is not included in the fire category, and such a fatality would not be counted as a fire death.[15] Death certificates may list fire deaths caused by collisions simply as motor vehicle accidents. A fire death from these incidents could only be identified by looking at fatalities with the primary cause of death listed as burns, smoke inhalation, or a combination of the two. When a body is found at an arson scene, it is necessary to determine whether the victim died before or as a result of the fire. The NFPA and USFA track fire fighter fatalities individually and do not place a time limit on the death.

Equipment Involved in Ignition

"Equipment involved in ignition" refers to the equipment that provided the heat that started the fire. This does not mean that the equipment malfunctioned in any way. Even if the equipment was misused, if it provided the heat, it should be documented. An upholstered chair may be too close to a space heater. An iron may have been left on. Also, fixed wiring inside the wall should be considered a type of equipment.

Arson, Incendiary, Suspicious, and Intentional Fires

Many people are interested in arson. Older versions of NFIRS had two categories of ignition factors that, for statistical purposes, were generally grouped together as arson. *Incendiary* was used when a legal decision had been made or physical evidence indicated that a fire was deliberately set. *Suspicious* was used when circumstances indicated that the fire may have been deliberately set, multiple ignitions were found, or there were suspicious circumstances and no natural or unintentional cause could be found. Although suspicious was not appropriate as a final cause following an investigation, many fires were not fully investigated, and this cause could serve as a flag.

Intentional replaces the terms *incendiary* and *suspicious* on the Fire Module cause categories of Version 5.0. (*Incendiary* is still a choice on the Wildland Module.) When older data are converted to Version 5.0, *incendiary* and *suspicious* are converted to *intentional.*[16] None of these terms correspond exactly to the term *arson,* and this distinction will need to be explained. Because Version 5.0 can capture data about the age of the person involved, it is quite possible to see a fire intentionally set by a five-year-old. This would be below the age of responsibility in most, if not all, states.

The Fire Module is not required for certain confined structure fires, including contained trash or rubbish fires, or for outside rubbish fires. If these forms are not voluntarily completed when a fire appears incendiary, the level of information gathered may be insufficient to pursue an investigation.

Substantial shares of these trash fires were considered incendiary or suspicious under older versions of NFIRS. Dropping the suspicious choice and required causal coding for certain incidents is likely to result in an artificial drop in arson incidents. This will make reliable trend analysis of the subject extremely difficult during the transition.

GETTING TO NFIRS 5.0

The previous material alluded to some of the changes in Version 5.0. What other changes have been made? Who decided what would change?

On the basis of feedback from state program managers and departments in the late 1980s, the USFA began entertaining the possibility of a revision of the NFIRS 4.1 version. Although the initial plan was for an incremental change to version 4.1, it soon became apparent from user feedback that nothing less than a sweeping revision would be acceptable. The U.S. Fire Administration, through its cooperative partnership with the National Fire Information Council (NFIC), sponsored a series of workgroups made up of fire departments, NFIRS state program managers, national data users, and fire software vendors whose charter was to examine every aspect of the way data were being collected in previous versions, apply the lessons learned, and develop consensus requirements for a new NFIRS system. (The USFA had funded NFIC, an organization of NFIRS program managers from participating states, the District of Columbia, and fire departments protecting populations of at least half a million from the early 1980s through 2004. NFIC provides specialized training to its members and advice from the field to each other and the USFA. Due to budget cutbacks, these cooperative agreements have not been funded in recent years.) The process took seven years to complete and included input from users of the system and its data at all levels. The results were some dramatic changes in the NFIRS system.

The USFA and NFIC began working on the new NFIRS in 1989. NFIC members surveyed fire departments of different sizes to see what they liked and did not like about the existing system. NFIRS consumers, such as the NFPA, the Consumer Product Safety Commission (CPSC), the National Highway Traffic Safety Administration (NHTSA), and private industry groups, were consulted about their data needs.

Choosing Data Elements

All agreed that the data requested must be (1) reportable, that is, something that could be described in a codable or quantifiable manner, (2) collectable—the information must be readily available without spending an excessive amount of time to obtain it and users must be willing to report it, and (3) usable. Code developers want very specific information, but sometimes they want more detail than fire fighters can be expected to provide. Even if the data can be collected, if that particular information is not used, it is a waste of time to collect it. Fire fighters also indicated that they had difficulty with certain data elements and questioned the reliability of those elements. For example, it was difficult to accurately determine whether all openings were protected, a critical piece of information in determining the type of construction. Consequently, the field "construction type" has been dropped from Version 5.0.

Fire fighters also resented filling out the same information repeatedly on many of their minor fires. By expanding the "situation found" ("incident type" in Version 5.0) to three digits, specific codes could be assigned for confined food on stove fires and confined chimney fires. For certain types of confined structure fires and for outdoor rubbish fires, fire fighters will complete little more than basic dispatch information. Table 3.3.1 summarizes the changes in NFIRS 5.0.

Different Circumstances Triggering Different Modules

NFIRS 5.0 is modular in design and uses only the modules necessary to describe the incidents. Identifying and dispatch data such as dates, times, incident type, and occupancy are collected for all incident types in the Basic Module. Local authorities may also require owner and occupant information and narratives. That is the extent of the information required by the NFIRS for nonfire incidents, confined structure fires, and outside rubbish fires.

More detailed information is collected in other modules to further describe specific circumstances of an incident. The modules used by NFIRS 5.0 are as follows:

- Basic Module (mandatory)
- Fire Module (mandatory)
- Structure Fire Module (mandatory when the fire is a structure fire)
- Civilian Casualty Module (mandatory when there is a civilian fire casualty)
- Fire Service Casualty Module (mandatory when there is any fire service casualty)
- EMS Module
- Hazmat Module
- Wildland Fire Module
- Apparatus or Resources Module
- Personnel Module
- Arson Module
- Juvenile Firesetter (submodule of the Arson Module)
- Supplemental Module

Basic Module. The modules identified as mandatory must be used when triggered by incident type or casualty data entries in the Basic Module.

Fire Module. For nonconfined fires in their jurisdiction, fire fighters must complete the Fire Module that collects information about property details and on-site materials, fire causes, any equipment or mobile property involved, the area of origin, material first ignited, human factors, and any fire suppression factors.

A broad cause category has been introduced that contains the following choices:

1. Intentional
2. Unintentional
3. Failure of equipment or heat source
4. Act of nature
5. Cause under investigation

U. Cause undetermined after investigation

Code 5, "Cause under investigation," makes it possible to identify reports that might need revisions. Local departments must have procedures to update these records when new information becomes available. These causal data are not required for the specified confined structure fires or outside rubbish fires. The field "Factors contributing to ignition" provides the opportunity to document more specific causal factors when the Fire Module is used.

TABLE 3.3.1 Summary of Changes in NFIRS 5.0

Elements Dropped in Version 5	*New Basic or Fire Data*	*New Structure Fire Data*	*Other New Data*
Method of alarm	Three-digit incident types	Type of detector, sprinkler	Optional Modules: EMS, Wildland, Hazmat, Arson, Juvenile Firesetter, Personnel, Resources, Supplemental
Method of extinguishment	Expanded mutual aid data	Sprinkler and detector effectiveness	
Extent of smoke damage	Reduction in property use codes	Sprinkler heads operating	
Avenue of smoke travel	Abbreviated reporting for certain confined structure fires, outside trash fires	Reason for detector or sprinkler failure	
Type of material generating most smoke	Suppression factors	Structure status (vacant, occupied, under renovation)	
Form of material generating most smoke	Broad causal factor categories including pre- and post-investigation undetermined	Number of stories above and below ground	
Construction type	Human factors	Material contributing to flame spread	
Fire fighter injury equipment unless a factor in injury	On-site materials	Number of stories by flame damage	
	Mobile property identified only if involved in ignition		
	Multiple actions taken, factors contributing to ignition		
	Pre-incident property value		
	Separate loss fields for contents and structure		
	Expanded, more specific equipment involved in ignition		
	Separate fields for equipment portability, power		
	Numeric entries for number of units, buildings, acres burned		
	Codes on basic form for minor hazardous releases		
	Incident types indicate fires in mobile buildings		

Structure Fire Module. The Structure Fire Module is completed for building fires. Only the question on structure type is completed for structures other than enclosed or portable or mobile structures. This includes tents, open platforms, fences, and the like. The Structure Fire Module captures information on building status and size, the floor or story of fire origin, the extent of and material contributing to flame spread, and detection and automatic suppression system performance.

Civilian and Fire Service Casualty Modules. The Civilian Casualty Module is required for, and used only for, civilian fire injuries. It captures information such as the cause of injury, the victim's location, and factors contributing to injury. Race and ethnicity are now captured in this casualty module.

Several fields have been added to the Civilian Casualty Module that may be of particular interest to those dealing with performance-based codes. These include the story or floor of the injured occupant, first, at the time of ignition and, second, at the time of injury, if different. In addition to location at ignition, information is now required on the location at time of injury.

Severity gradations of minor, moderate, severe, life threatening, and death are now provided, instead of just injury or death, the choices in older versions. Human and other factors contributing to the injury are also captured. The victim's name, age, and gender and the cause, activity at time, and the nature and severity of injury are captured on both types of casualty modules.

The Fire Service Casualty module is used for all fire service injuries, including those resulting from events other than fires. This module captures information about whether the victim was a career or volunteer fire fighter, lost time injuries, type of location at injury, and the nature of any protective equipment failures that contributed to the injury.

The Basic, Fire, Structure Fire, Civilian Casualty, and Fire Service Casualty Modules are the mandatory modules associated with NFIRS. State or local authorities may require completion of the new Emergency Medical Services (EMS), Hazardous Material, Wildland Fire, Arson, and Juvenile Firesetter Modules when appropriate.

EMS Module. In its infancy, fire department activity reporting was limited to fires only, at least on a national level. Little recognition was given to the other activities that fire departments were performing on a daily basis. As fire department management became more responsive to the budgetary concerns and restrictions of fiscal policy, the need to justify all activities and expenditures grew. Many local fire departments began to collect data on their own, using the NFIRS program to attempt to gather management information concerning all of those other activities and stretching the program in directions that were never anticipated.

Recognizing that emergency medical services (EMS) activities represent a significant portion of what fire departments are currently doing, an EMS reporting module was included in NFIRS 5.0. The starting point for development of the EMS Module was the Final Report of the 1993 Uniform Pre-Hospital Emergency Medical Services (EMS) Data Conference sponsored by the National Highway Traffic Safety Administration (NHTSA).[17] This document contains the 80 EMS data points and their definitions as agreed upon by the participants of the conference as being "essential" or "desirable" for EMS data systems.

Upon review of the NHTSA data elements, the NFIRS 5.0 development team concluded that many of the data elements did not pass the test for collectable, reportable, or usable. As a result, patient care reports and EMS data forms from fire departments and state EMS agencies across the country were assembled and compared for data elements that were universally collected and reported. As much as was practical, NHTSA codes and definitions were retained to provide linkage to databases that employ these codes.

The EMS Module is not intended to replace or otherwise interfere with state or local EMS patient care reporting requirements, nor is it intended to be a comprehensive EMS patient care report. Instead, the data elements in this module should be viewed as "core elements" around which a complete patient care report can be built.

Hazmat Module. The Hazmat (hazardous material) Module captures the substance, container size, amount released, cause and circumstances of release and mitigation, evacuation information, and disposition for hazmat incidents. Multiple substances and associated containment activities may be documented in this module. Common, minor releases (such as gasoline leaking from a vehicle fuel tank or propane gas escaping from a grill cylinder) that do not require specialized resources can be documented in the Basic Module.

Wildland Fire Module. The Wildland Fire Module may, if local or state authorities permit or require, be used to document brush, grass, forest, crop, or other vegetation fires, as well as incidents of unauthorized, controlled, or prescribed burning. Unauthorized, controlled, and prescribed burning incidents are not counted as hostile fires.

This module allows for alternative forms of incident location, such as latitude and longitude or township. Area type, property ownership type, fire causal data, weather information, number of buildings ignited or threatened, crops burned, National Fire Danger Rating System (NFDRS) fuel model at origin, and fire behavior are collected in this module. If an identified person was involved in the ignition, the age, gender, and activity data are also collected.

Apparatus or Resource and Personnel Modules. The NFIRS 5.0 system includes the optional Apparatus or Resource Module and Personnel Module. After completing an incident report, an officer can identify the apparatus and personnel that were dispatched and how they were used to handle the incident. This provides the means to examine resource needs and deployment, something that could not be done with previous versions of NFIRS. These modules are generally for local use and completed at the discretion of the local authority.

Arson and Juvenile Firesetter Modules. The Arson Module captures motivational factors, group involvement, and specific circumstances of the crime. The Juvenile Firesetter Module captures information about the child, family, and risk factors. Disposition is captured on both of these modules. Names of individuals are not part of these modules or the EMS module. If the Juvenile Firesetter module is completed, a juvenile's age may not be recorded on the Fire Module.

Supplemental Module. Information about additional persons or entities involved, special studies, and remarks are captured in the Supplemental Module.

Legacy Data

Because many fire departments continue to collect data using the older version, the data they collect for the dropped data elements (construction type, method of alarm, method of extinguishment, extent of smoke damage, avenue of smoke travel, and form and type of material generating most smoke) is still included as legacy data in the national database.

Better Documentation of Nonfire Incidents

Anyone involved with the fire service or fire protection knows that fires are only part of the story. As was mentioned previously, earlier versions of NFIRS provided limited ability to track nonfire incidents. With the exception in recent years of some hazardous material incidents, nonfire incidents were not compiled by the USFA. This changed with Version 5.0. The fire ser-

vice can now obtain more detailed information about EMS-type calls and other nonfire emergencies. They are also better able to track calls by station and mutual or automatic aid incidents.

Fire Protection Systems

The three-digit incident type provides specific information about false alarms and indicates whether the detection equipment was designed to respond to heat, smoke, or carbon monoxide. The fire protection community has been plagued by a lack of information about sprinkler systems. Incident type codes in the Basic Module capture sprinkler activations due to unintentional tripping or malfunctions. Data from the Structure Fire Module indicate whether an automatic extinguishing system was present in the fire area, the type of system present (wet, dry pipe, dry chemical, foam, halogen, or carbon dioxide), whether it was effective, how many heads operated, and the reason if the system failed or was not effective.

Similar detailed information is collected on fire detection systems, including detector type (smoke, heat, combination smoke and heat, sprinkler with waterflow detection, more than one type present, and other), detector power supply, detector operation, detector effectiveness in terms of alerting occupants, and failure reason if the detector failed to operate.

Occupancy Groups or Property Use

The number of property use codes has been dramatically reduced. Residential occupancy code choices include one- and two-family dwellings, multifamily dwellings, rooming houses, hotels or motels, residential board and care, sorority or fraternity houses, barracks or dormitories, other dormitory-type residences, and other residential. A separate entry documents the number of units in each. (When older property use data with number of units are converted forward, a midpoint value is generally assigned.) Similar reductions have been made in the mercantile, basic industrial, manufacturing, and storage categories. Code 700 now covers all manufacturing or processing. The specifics are captured by documenting on-site materials and indicating whether these materials were used in or stored as (1) bulk storage or warehousing, (2) processing or manufacturing, (3) packaged goods for sale, or (4) repair or service. Up to three on-site materials may be listed.

The general property use classification is captured in the Basic Module. The Fire Module captures details about number of units and on-site materials.

Structure Status

The Structure Fire Module also collects information about the status of the structure. In the older versions of NFIRS, separate occupancy or fixed property use codes identified vacant buildings or buildings under renovation or demolition. However, many were still coded according to their intended use. Every fire fighter knows that fighting a fire in an abandoned mill is different from fighting one in a vacant dwelling. Separate codes indicate whether the structure was under construction, occupied and operating, idle, under major renovation, vacant and secured, vacant and unsecured, or being demolished.

Property Damage

Direct property damage provides one measure of fire problem severity. In older versions of NFIRS, when this field was left blank, the dollar loss was assumed to be zero. A checkbox in Version 5.0 indicates that there was no loss. While the information is required when known, presumably the field will be left blank if unknown. Property damage estimates are provided by the fire service. Sometimes they have input from insurance adjusters; in many cases, they do not. Loss figures are estimates on the basis of the expected replacement cost of the property damaged. Property damage for the property and its contents are now separated into two fields. Pre-incident property and contents values are optional. Caution should be used when comparing these values. In many cases, it would be inappropriate to claim credit for saving all of the nondamaged property. These data are collected in the Basic Module.

One of the frustrations with older versions of NFIRS was the inability to accurately gauge the severity of a fire. Dollar loss was influenced by the value of the property. When extent of flame damage was confined to the structure, the damage might have been to just one exterior wall. Version 5.0's Structure Fire Module captures data on the number of stories with minor (1–24%), significant (25–49%), heavy (50–74%), and extreme (75–100%) damage. The "extent of flame damage" field is still present, although the code for "confined to part of room or area of origin" was dropped. The size or dimensions of the main floor are now required.

Direct Entry of Numeric Data

Users of NFIRS data from the older systems were often frustrated by fields in which numeric values, such as number of stories or fire fighter responses before injury, were coded. Too often, it was unclear whether the individual completing the form was using the codes or using the raw numbers. In Version 5.0, these are direct entries. Version 5.0 also captures the number of stories above and below grade.

More Specific Choices for Equipment Involved

The equipment involved in ignition (or release on the Hazardous Material Module) field has far more specific choices than in older versions. In addition, portability is now a separate field. A portable space heater might be coded as a heater, excluding catalytic and oil-filled (code 141), and in the portability box, portable would be checked. In the past the fuel or power source for equipment was generally found in the "form of heat of ignition" field. That field has been functionally divided into two: "heat source" and "equipment power."

Suppression Factors

Up to three suppression factors may be entered in the Fire Module. Suppression factors are circumstances that contributed to the growth or spread of the fire. These include specific building construction or design factors; an act or omission, such as blocking a fire door; the building contents or fuel load; delays; problems with protective equipment such as water supply,

suppression systems, or fire protection assembly; egress or exit factors, such as overcrowding, window type, or occupant characteristics; and natural conditions.

Human Factors

Life safety educators are very happy to see the ability to capture data about human factors in the Version 5.0 Fire Module. Some of these factors could be captured for civilian casualties in older versions but not for fires without casualties. Human factors include asleep, possibly impaired by alcohol or drugs, unattended (or unsupervised) person, possibly mentally disabled, physically disabled, multiple persons involved, and age (with another field to record the age). An additional field captures the gender of the principal person involved when age was a factor. Similar data are captured on the casualty report for any civilians injured by fire.

Factors Contributing to Injury

A new field in the Civilian Casualty Module, "factors contributing to injury," allows up to three entries. These include the following:

- Various egress problems, such as crowd situations with limited exits, locked exits, or security bars
- The fire pattern itself, such as trapped above or below, vision impaired by smoke, clothing igniting while escaping, or exits blocked by flame or smoke
- Escape difficulties, such as choosing inappropriate exit route or reentered building
- Collapse of the roof, floor, or wall
- Vehicle related factors
- Equipment related factors such as unvented heating equipment or improper use of heating or cooking equipment
- Other factors, such as clothing burning before the individual tried to escape

Other Differences and Options

In some cases, similar data are collected in different modules. Either the state or local fire department will determine whether the Wildland Module or the Fire Module will be completed for forest fires. These modules use the same codes for some fields, but the broad cause codes are different.

Because different jurisdictions have different data needs, and because many information needs cannot be anticipated, Version 5.0 has the ability to generate "plus one" codes by adding an extra character to the codes in each field. These extra codes are not a part of the national database. Local fire departments should check with their state authorities before implementing their own "plus one" codes to ensure that no conflict exists between the state and local needs.

Several fields in the Supplemental Module have been set aside for special studies. Fire officers must know what the codes cover. Version 5.0 has the ability to provide much more detailed documentation and data about fires. However, this can happen only if the fire fighters who complete the forms know that the codes exist. The developers of 5.0 worked hard to make the system easier for and more responsive to the fire service. A danger exists that, in this era of pull-down menus, individuals may not even know that a particular optional field is relevant or that a certain code is available. Dry as the material is, anyone who completes NFIRS forms should occasionally thumb through the coding manual as a reminder of the type of information collected in each field.

Difficulty of Change

The transition to NFIRS 5.0 involved changes in what and how data are recorded, in data and editing specifications, in computer systems, training, manuals, and analysis. With such a major overhaul, the transition has sometimes been difficult. The USFA established the previously mentioned NFIRS Support Center with a 24-hour toll-free number (1-888-382-3827) and online e-mail capability at http://www.usfa.dhs.gov/fireservice/nfirs/support to facilitate the process and enable fire fighters to quickly obtain answers to their NFIRS questions.

Version 5.0 of NFIRS has been implemented at varying speeds across the country. NFIRS 5.0 brought major changes in the underlying logic of the system. It provides significant new data in terms of expanded incident types, human factors, and fire protection systems. Implementation practices have varied by state according to the state's needs and priorities. Consequently, the national NFIRS database from 1999 through at least 2003 contains data collected in Version 5.0 and data collected in older versions that have been converted to Version 5.0. Because data definitions and data elements in the versions are not identical, the conversion is not exact. This makes accurate analysis of the combined data more challenging. An understanding of both Version 5.0 and the older systems is required for accurate analyses of merged data.

COMPUTERS AND NFIRS

Computers have made it easier to enter and use the data. On-screen look-ups assist the fire officer in choosing the correct classification.

Quality Control

Quality control issues can become more complicated with computer-generated reports. Most programs do some error checking for allowable values and some checks to see whether the data make sense. Computers, however, have no common sense. As long as the data meet the criteria, they will pass through the system. It is often easier to spot inconsistencies or patterns of problems through a visual scan of paper forms than by working with coded electronic data. A detailed narrative is more important than ever with an automated or paper checkbox system. Before checkboxes and computers, a fire officer would write words describing the event witnessed. In many cases, one code covers multiple items such as "portable appliance designed to produce heat, other" or "storage area, tank or bin." "Electric foot warmer" or "500-gallon propane tank" would be more specific. If that information is not entered elsewhere, it will be lost. At least one vendor provides users with the ability to generate

a preliminary narrative based on the coded information in the incident report. To be meaningful, this narrative must be supplemented with the specifics of an incident.

To protect the integrity and data quality of the information collected from departments, standard NFIRS edit checks exist and are documented in the *NFIRS 5.0 Design Documentation* maintained by the USFA. The edits consist of both allowable and relational edit checks and must be implemented in a standard way by all developers of NFIRS 5.0 data collection software. System edits prevent many common data entry errors such as transposing the incident alarm time and the time that the department arrived at the incident scene. Software edit checks are typically done at the time of data entry, and the corrections are made at the department level. Incidents that fail validation are either corrected by the state NFIRS program manager or returned to the department for correction and resubmission.

NFIRS Software

The USFA has developed bare-bones software for Version 5.0 to enable states to manage their systems. If the state authority permits, local fire departments may also use this software. However, the state authority, not the USFA, is expected to provide the support, and some do not feel they have the resources to do so. Some states have purchased software or licenses for their fire departments from commercial vendors.

Data Retrieval and Analysis

In many fire-reporting systems, a great deal of effort is devoted to data collection, and then very little effort is given to making good use of the data. Data analyses should be of two kinds: (1) routine, periodic reports that summarize the fire problem and that provide management data and (2) special reports that answer queries about particular problems or evaluate programs, support budget requests, and the like.

Data analysis can begin with a simple tally of incident types or other data element. Data analysis should also consider the interrelationship between various data elements or various databases. For example, relating fire data to socioeconomic data by census tract shows the population groups that are most affected. Comparing fire losses over the years to inflation rates and increasing property values may show that fire protection is currently more effective, even though in raw numbers the total loss is greater.

Nearly all NFIRS reporting software comes with a suite of canned reports. USFA makes web-based NFIRS reporting available to all NFIRS users that have an account to use the browser-based reporting tool. Each NFIRS state reporting office determines who may use the reporting tool within each state. The USFA reporting tool provides many standard NFIRS reports with filtering capabilities that run against the data contained in the NFIRS database. States and departments may use the USFA tool exclusively or use it to supplement existing vendor reporting tools or other custom local reporting tools. Since getting answers from raw data can be difficult for those not trained in data analysis, canned reports ensure standard and accurate answers to commonly asked questions about the data. Many incident reporting software packages also include powerful data-filtering features so that the usefulness of the standard reports is greatly extended. For example, the standard Tally report counts the frequency of occurrence for each code within a data field. Running this report on the Incident Type field with no data filter results in a count for each type of run done by the department. By using a data filter, the department can also limit the report output to just fires, just arson fires, or just fires in single-family homes started with a candle. In this way, multiple questions can be answered with the same canned report. Several commercial vendors of NFIRS software include NFPA's annual fire department experience survey in their packages.

More information on data analysis can be found in Section 3, Chapter 4, "Use of Fire Incident Data and Statistics."

NFIRS Support Materials on USFA Website

The USFA's website (http://www.nfirs.fema.gov) has downloadable coding manuals for NFIRS 4.1 and 5.0, active vendors and procedures, and other relevant information.

GETTING THE BIG PICTURE ON FIRES

NFIRS can provide a great deal of information, but it is important to remember what it cannot do. Because of the time lag in compiling data, some time will pass before a new problem can be identified. NFIRS by itself cannot be used to determine risk. Denominators such as prevalence in the population are needed. As was mentioned earlier, different states have different reporting policies. NFIRS is not a census of all fires; it is not even a full listing of all fires reported to fire departments. Such a listing does not exist. How do we tell how big the fire problem is in the United States?

NFPA's Annual Fire Department Survey

Each January, NFPA sends its survey to all fire departments protecting 100,000 or more and a random sample, stratified by population, of the smaller departments. In 2004, NFPA sent out almost 13,000 surveys and received a total of 2,830 back, a response rate of 22 percent, with higher response rates from the larger communities. The departments that did respond protect about 36 percent of the U.S. population.[18] The data are used to develop national estimates of the fire problem. A press release about the number of fires and fire deaths is issued each summer. An abbreviated version of the full report *Fire Loss in the United States* is published in a fall issue of *NFPA Journal.* The report is also available on NFPA's website to all visitors.

NFPA's survey is not terribly detailed. It asks about fires by type and broad occupancy class, intentional structure and vehicle fires, and civilian and fire fighter deaths and injuries. NFIRS has far more detail, although it usually lags substantially behind the survey in terms of timeliness.

By comparing the totals from NFPA's survey to corresponding totals in NFIRS, analysts estimate what fraction of total U.S. fires and associated deaths, injuries, and property damage were captured by the NFIRS sample. These fractions are inverted into ratios that are used to "scale up" the NFIRS numbers on

specific fire problems to "national estimates" of the total size of these problems. Different ratios are used for residential structure fires, nonresidential structure fires, vehicle fires, and other fires. Within each group, analysts use different ratios for fires, injuries, deaths, and direct property damage.[19]

Many fire fighters have wondered why, if they faithfully complete their fire incident reports, they are also asked to complete NFPA's survey. The reason is that because different states have different reporting practices, NFIRS cannot estimate the total number of reported fires per year. Analysts need to use the survey results and NFIRS together to develop national estimates. In the older versions of NFIRS, nonfire responses (except for hazardous material incidents in Version 4.1) were not forwarded to the USFA. Until all fire departments around the country report using NFIRS 5.0 to states that are processing all incidents, the NFPA survey is the only national source of this data. Because the survey is completed by summer each year, it can produce numbers about a year earlier than NFIRS.

What Is Not Included in the Statistics

Neither the survey nor NFIRS captures data on fires that were not reported to fire departments. Consequently, fires that are handled by private brigades or individuals will not be counted. The NFPA survey samples only municipal fire departments, including career and volunteer departments. Fires reported to wildland fire agencies or military agencies will also not be captured. Figure 3.3.2 illustrates how fires in communities protected by municipal fire departments are or are not captured in the data.

If a fire is handled privately, with no fire department notification, as far as these two databases are concerned, it never happened. If the fire department responded but did not complete a report, the fire will not be counted. If the report was completed but not sent forward to the state, it will not become part of the state or national NFIRS database. If a fire report has a serious or fatal error or inconsistency, it will also be excluded from the NFIRS database. If the fire department was in the NFPA sample and it responded, then the fire will be counted by the survey. If the state does not collect or forward NFIRS data to the USFA, then that state's communities generally will not be in the NFIRS database. Exceptions have been made for large metropolitan fire departments reporting directly to the USFA with state permission.

Because of the large number of fires reported to NFIRS, reliable analyses can be done on most common types of problems even though many jurisdictions are not included. Difficulties arise, however, with unusual circumstances, such as nonhome fire deaths or fires in specific nonresidential occupancies. For example, North Carolina and Pennsylvania were not participating in NFIRS during the 1990s. National estimates based on NFIRS and the NFPA survey showed no fatalities in college dormitories or fraternity houses in the five-year period from 1993 through 1997, yet we knew from our Fire Incident Data Organization (FIDO) (see next section) that two fires in these properties had claimed five lives in each state. NFPA was aware of six other fatal fires in these properties during that time.[20] However, statistical projections can be footnoted, but not adjusted, on the basis of anecdotal data. Similarly, a fire with an unusually large dollar loss or number of casualties can also skew the data when projections are made.

These problems are not unique to fire data and are typical of any type of data collection effort. Even the U.S. Census Bureau considered using statistical projections to control for areas where undercounting was expected to be a problem.

OTHER SOURCES OF DATA

NFIRS and NFPA's annual fire department experience survey provide national estimates of fires reported to local fire departments. Other sources are needed to provide more detailed narrative accounts, international data, and arrest and injury data.

NFPA's Fire Incident Data Organization (FIDO)

NFPA designed and maintains the Fire Incident Data Organization (FIDO) to provide examples and details of specific types of fires. News clips, the Internet, word of mouth, and other sources

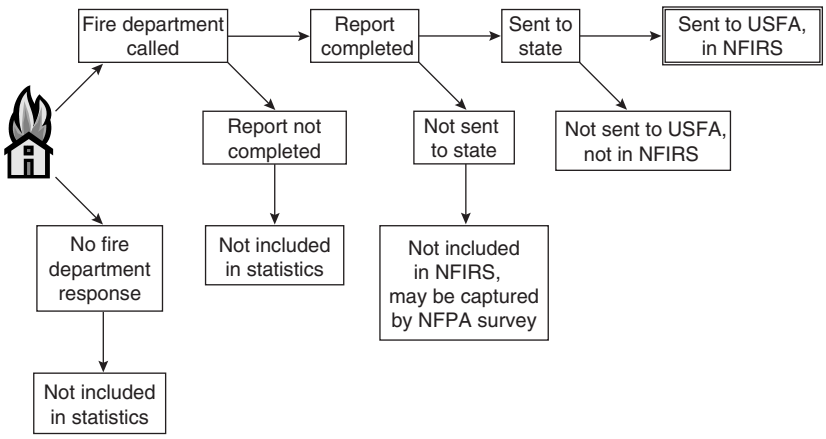

FIGURE 3.3.2 How a Fire Gets Counted

are used to identify fires of interest. Additional information is then sought from fire departments, insurance companies, and other federal and state safety agencies. FIDO is the source for the fires profiled in *NFPA Journal*'s "Firewatch" column. Because every effort, including surveying state fire marshals' offices, is made to track down reports of multiple death fires, large loss incidents, and fire fighter fatalities, we are confident of the completeness of the data and use FIDO as the source for these reports. Unsolicited fire department reports of fires with lessons learned are very welcome.

Most of the fires in FIDO are more serious than the usual. They show what can happen, not what is likely to happen. Anecdotal data such as FIDO cannot be the basis for statistical analysis. Incidents in FIDO have been entered by using codes very similar to the older versions of NFIRS, but additional fields have been added to capture other significant issues. NFPA does not release identifying information about a specific fire without the fire department's permission.

Uniform Crime Reporting System (UCR)

The Uniform Crime Reporting System (UCR) of the Federal Bureau of Investigation (FBI) collects standardized reports about crimes and offenders from nearly 17,000 law enforcement agencies around the country. Most contributing agencies are local police departments, but other agencies, including state fire marshals' offices, also make arrests. Agencies protecting about 94 percent of the U.S. population submit reports each year, but some agencies submit less than 12 months of data in a given year. As with NFIRS, UCR has a goal of complete participation.[21]

The UCR data provide information about the ages and genders of the arrestees. The FBI regularly publishes crime statistics in the Crime in the United States series.

Consumer Product Safety Commission (CPSC) Data

National Electronic Injury Surveillance System (NEISS). Through its National Electronic Injury Surveillance System (NEISS), the U.S. Consumer Product Safety Commission (CPSC) tracks injuries that were treated in a selected sample of emergency rooms. This information has been used to develop projections of injuries caused by products and to identify unsafe products or practices when using the products. Together with the Centers for Disease Control's (CDC's) National Center for Injury Prevention and Control, they have been expanding the scope of NEISS to include all types of injuries. Originally, only injuries involving consumer products were included, but in 2000, the system expanded to include all injuries treated at emergency rooms. Historically, it has been difficult to find information about nonfatal injuries. NEISS fills some of that void. Users may query the NEISS database directly from http://www.cpsc.gov/library/neiss.html. It is also possible to preview up to 30 cases that meet the search criteria or download the whole file. Although identifying information is removed to protect confidentiality, the comments provide very helpful information in understanding the injury scenarios.

Death Certificate File. The CPSC also maintains a death certificate database about deaths associated with consumer products. Victim data are removed before these data are released. Additional information may be obtained on the website for the National Injury Information Clearinghouse at http://www.cpsc.gov/about/clrnghse.html.

Phone: (301) 504-7921
Fax: (301) 504-0025

Other CPSC Data. CPSC's In-Depth Investigations (INDP) file contains summaries of investigations into product-related injuries or events. The agency's Injury/Potential Injury Incident File (IPII) contains summaries of product-related reports to the CPSC, newspaper accounts, letters, and medical examiners' reports. Although not incident based, CPSC's searchable database of recalls is a valuable tool for fire investigators.

Injury Facts

The National Safety Council compiles reports about deaths caused by unintentional injuries. *Injury Facts* (formerly *Accident Facts*) is published annually. This report provides data on death causes by age, state, home, vehicle or work, and long-term trends. A similar report, *International Accident Facts,* is updated less often but provides international comparisons from up to 50 countries.

International Fire Data Collection Organizations

NFPA is aware of two organizations engaged in collecting international fire data. Because each country collects data independently and has their own criteria for what is collected, it is difficult to make accurate comparisons.

World Fire Statistics Centre. The Geneva Association sponsors the World Fire Statistics Centre. Each year, the Centre collects data from about 20 nations on fire deaths, direct property damage, indirect fire losses, costs of fire-fighting organizations, costs of fire insurance administration, and costs of fire protection to buildings. When applicable, the data are presented as a percentage of the gross domestic product (GDP) or as per capita rates. Its annual report is presented each year to the U.N. Committee on Human Settlements. The October 2005 report noted that the European Union Fire Safety Network had been established the previous year, aiming to "interchange news, views, and statistics on fire safety matters. . . ."[22]

CTIF. The International Technical Committee for the Prevention and Extinction of Fire (CTIF) was formed in Russia in 1995. Its 2005 report[23] contains information collected from more than 50 countries, almost one-third of the world's countries with about two-thirds of the world's population. They collect information on the number of fires, structure fires, vehicle fires, arsons, false calls, and fire department staffing and equipment. They also have data from many of the world's largest cities. Their data include many of the former Soviet republics and other countries from Eastern Europe as well as elsewhere.

International Fire Data Collection

In some countries, fire data collection is a government function; in others, it is done by the insurance industry. Definitions vary from country to country, so comparisons should be made with caution.

Canada. In Canada, as in the United States, the system is three-tiered. Local fire departments report their data to the provinces. However, the provinces report the totals, not the incidents themselves, to the Human Resources and Social Development Canada (HRSDC). The Council of Canadian Fire Marshals and Fire Commissioners produces annual reports. These reports are available at http://www.ccfmfc.ca/stats/statsReports_e.html. A workshop to improve fire statistics and explore the possibility of establishing a national fire data center was held at the National Research Council of Canada in April 2005. The presentations are available online at http://irc.nrc-cnrc.gc.ca/fr/firestatisticsworkshop/nrc_fire_stats_workshop_april_2005_introduction.pdf.

Australia. The Australian Incident Reporting System (AIRS), used by most of the Australian fire service, uses a data classification standard based on the U.S. NFIRS system. However, the participating services have made their own modifications to some elements of the system.

Sweden. In Sweden, the insurance industry collects fire data. Only fire deaths are reported to the government. When the insurance industry collects the data, it is likely that fires in uninsured properties or fires that do not trigger a claim will be underreported.

United Kingdom. Fire brigades (departments) in the United Kingdom report their fires directly to the Office of the Deputy Prime Minister in London. In addition, the British Crime Survey includes questions about fire experience and provides some information about fires that were never reported. The national government manages these databases. However, the government does not collect dollar loss information; that task is left to the insurance industry. The British fire databases are described in *Fire Statistics: A User Guide for Research.*[24]

Japan. Fire departments in Japan also report their fires directly to a national government office.

SUMMARY

The data provided by NFIRS and other detailed national and international databases make it possible to monitor progress in fire prevention and protection. Almost all of the data come originally from fire services. Researchers must remember that completing incident reports is a small part of a fire officer's responsibilities and certainly not why someone joined the fire service. However, most fire officers understand that statistics can help them to manage a department more effectively, prepare and defend a budget proposal, and determine what types of fire problems their community faces.

Data collection will improve as the fire service uses the data itself and better understands the role of the data it provides in decisions elsewhere. Fire data analysis is more accurate when the analysts understand the system used and the conditions under which the data were collected.

When a fire officer completes an incident report, he or she is contributing data to a huge research effort in addition to preparing a local record of the event. NFIRS provides the ability to collect many specific details about a wide variety of incidents. NFIRS 5.0 provides the means for fire departments to document more of the concerns and activities of today's fire service. Modern computer technology makes it easier to complete and process the reports. When incident reports are compiled, the local department, the state, and the country can analyze the data to identify trends, new problems, progress solving old ones, and the effectiveness of different protective features. Between one-third and one-half of the fires reported to municipal fire departments are reported to NFIRS each year.

Projections about the total numbers of fires, fire casualties, direct property damage, and fire department calls are made from NFPA's annual fire department experience survey. Because it is smaller in scope, the results are available more quickly. Each fall, *NFPA Journal* runs *Fire Loss in the United States During . . .* for the previous year. This report is also posted on NFPA's website, free to all visitors. The sample-based survey collects summary data and lacks most of the detail collected by NFIRS. However, national estimates of specific fire problems can be obtained by developing scaling ratios from the relationship of the NFIRS totals to the totals from the NFPA survey.

Most of what we know about a country's fire experience, both in the United States and elsewhere, is based on reports filed by a fire officer. These reports are a small fraction of their responsibilities, but the data provided are critical to policy makers, regulators, life safety educators, inventors, the media, and others.

Chapter 4

Use of Fire Incident Data and Statistics

Revised by
Marty Ahrens ❑ Patricia Frazier ❑ Gayle Kelch

Chapter Contents

Using Data to Characterize the Fire Problem
Basic Tools for NFIRS Analysis
Data Source Issues
Approaches to Fire Data Analysis
Using Data in Program and Strategy Analysis
Comparing Estimates Using Different Databases or Analytic Approaches

Key Terms

Fire Incident Data Organization (FIDO), fire incident record, fire problem, National Electronic Injury Surveillance System (NEISS), National Fire Incident Reporting System (NFIRS), United States Fire Administration (USFA)

The previous chapter, Section 3, Chapter 3, "Fire Data Collection and Databases," provided a description of the sources used for analyses of fire experienced in the real world, as opposed to laboratory studies. In the United States, the key database for such analyses is the National Fire Incident Reporting System (NFIRS). Responsible data analysis requires the analyst to understand what is and is not included in the data and the impact of system upgrades on the data. The text in this chapter will be more meaningful if readers have a working knowledge of NFIRS or have at least read the previous chapter. Changes to NFIRS have generally been adopted gradually as different states incorporate them. Version 5.0, first introduced in 1999, was the most significant change. It is important to examine whether any trend shifts could be due to changes in NFIRS rather than the actual fire experience.

This chapter explores how data source issues impact the analysis process. Particular attention is paid to reporting policies and practices, differences between NFIRS 5.0 and earlier versions of NFIRS, and to issues that arise with data converted from the older NFIRS versions. Several approaches to fire data analysis are also described, including top-down and topic-driven analysis. This portion includes discussions of analysis by specific data elements; analysis of incidents with unknown or missing data; issues faced when working with small data sets; location-based fire data analysis; and rates and measures of risk, trend analysis, and data used for program and strategy analysis. The chapter concludes with a discussion of issues encountered when using data from different databases or analytic approaches.

Those familiar with the state of fire incident data prior to the late 1970s will realize that it is remarkable to see how much the quantity and quality of fire data available for analysis have grown. In the early 1970s, even the best fire departments typically had fire incident records only in narrative form. Neither the method of storage (in file cabinets, by incident number) nor the method of description (phrases selected by fire officers, without standardized coded descriptions or even a standard list of characteristics to be documented) facilitated analysis of the community's leading fire problems. At the state level, very few states had any fire incident database. At the national level, the National Fire Protection Association (NFPA) prepared estimates of U.S. incidents, deaths, injuries, and losses from its annual survey and provided analyses of fire causes and other detailed factors from its Fire Incident Data Organization (FIDO) anecdotal database. The Fire Reporting Committee of NFPA had developed NFPA 901, *Uniform Coding for Fire Protection* (now *Standard Classifications for Incident Reporting and Fire Protection Data*),[1] a standard fire incident reporting format, but few fire departments were using it.

In 1977, NFPA modified its survey techniques to take account of modern statistical design principles and, in the process, greatly improved estimates of the size of the national fire problem. Also in the 1970s, the new National Fire Prevention and Control Administration (now the U.S. Fire

Marty Ahrens is the manager of fire analysis services at NFPA.

Patricia Frazier is the director of the Center for Data Analysis at TriData Corporation. She is the lead data analyst and specializes in fire-related data.

Gayle Kelch is a statistician at the Department of Homeland Security's U.S. Fire Administration's National Fire Data Center.

Administration [USFA], which is now part of the Department of Homeland Security) launched the National Fire Incident Reporting System (NFIRS). Based on NFPA 901, the NFIRS system provided the framework for a large-scale, truly national fire incident database. Since 1980, NFIRS has had the participation, in whole or in part, of the majority of states. In 2003, more than 18,000 fire departments participated in NFIRS,[2] reporting a total of more than 930,000 fires.[3] This represents 59 percent of the estimated total of fires reported to local fire departments. (As sources of the principal fire databases, NFPA and USFA also have helped each other over the years, with USFA providing financial support and technical suggestions on NFPA databases and NFPA providing developmental work and analysis services on NFIRS for USFA.)

A parallel development has enlarged the capacity for analysis of the newly generated fire incident data. The advent of powerful personal computers and the increasing affordability and flexibility of computer power in general have made it increasingly possible for the fire service and other fire data users to perform meaningful analyses. Most readers of this handbook now have access to valid national or local databases in forms suitable for analysis and to the equipment and skills required to analyze that data. See Table 3.4.1 for a sample of the many potential data users and uses.

TABLE 3.4.1 Typical Users and Uses of Fire Experience Results

User	*Use*
Fire protection engineers	Supporting data needs of performance-based codes and standards Defining and quantifying fire scenarios Estimating probabilities of fire incidence and fire protection performance Evaluating fire protection alternatives
Technical fire safety standards committees	Supporting data needs of performance-based codes and standards Identifying needs for standards Keeping standards current Monitoring the performance of standards Analyzing the benefits and costs of standards
Local and state fire service	Showing value of proposed fire safety and fire protection programs and legislation Targeting fire prevention and suppression programs Backing up budget requests Enacting and enforcing fire codes Developing community fire safety education program Monitoring progress
Fire protection planners at national and state levels	Showing value of proposed fire safety and fire protection programs and legislation Comparing fire to other problems competing for resources Planning the most effective deployment of resources to make the greatest impact on the fire problem Monitoring fire protection progress
Communicators/educators	Reporting of fire problems Educating for fire safety
Committees developing fire fighter safety standards, individuals, fire departments working to improve fire fighter safety	Identifying reasons for fire fighter deaths and injuries Developing safety and training programs Designing protective equipment
Researchers	Establishing fire safety research priorities Designing research programs
Insurers	Loss prevention Risk selection and underwriting
Industry	Worker safety Loss prevention
Product developers	Identifying needed products and markets Modifying products to improve fire safety
Building designers, architects, managers	Ensuring a fire-safe design
Legislators, regulators, enforcers, courts	Effective and equitable fire safety laws and regulations

For related topics see the following chapters in Section 3: Chapter 2, "Fire Loss Investigation"; Chapter 3, "Fire Data Collection and Databases"; and Chapter 5, "Introduction to Fire Modeling."

USING DATA TO CHARACTERIZE THE FIRE PROBLEM

Table 3.4.2 lists 10 major findings on the nature of the fire problem that have emerged from analyses of the past decades. Many of these analyses could not have been conducted without the new and refined databases that emerged in the late 1970s. This list is not arranged in any order of priority, nor is it necessarily a list of what everyone would consider the 10 most important data-based findings. The list does, however, illustrate the ability of data and analysis to identify emerging problems, describe those problems in ways that can help the design of corresponding programs, and track the impact of those programs.

BASIC TOOLS FOR NFIRS ANALYSIS

Before attempting to analyze fire data, it is important to have the right tools and an understanding of what is in and not in the data. The following items will be needed in some or all circumstances.

NFIRS 5.0 Complete Reference Guide

The coding manual for Version 5.0 of NFIRS may be downloaded from http://www.nfirs.fema.gov/documentation/reference. Because many—if not most—of the people completing reports in NFIRS 5.0 are entering the data using pull-down menus instead of a coding manual, the analyst should check the data dictionary in the *NFIRS Version 5.0 Design Documentation* manual to see the code descriptions viewed by the people completing the form. The longer definitions found in the *NFIRS 5.0 Complete Reference Guide* (CRG) provide greater specificity about what should and should not be included in a specific code. People who use computer look-ups may miss these distinctions. The analyst should be guided by the definitions used by the fire service, the people who provide the data.

NFIRS Version 5.0 Design Documentation

Those working with the national NFIRS database from years in which data were collected in Version 4.1 and converted to Version 5.0 (1999 through at least 2004) will want to be familiar with the coding system and definitions used in the older system and how such data were converted to the Version 5.0 system. The codes used with Version 4.1 may be downloaded from http://www.usfa.fema.gov/nfirs/tools. The *NFIRS Version 5.0 Design Documentation* manual contains conversion tables, record layouts, edit checks, and the data dictionary. The data dictionary contains the standard codes plus codes used only for conversion of older data. These conversion-only codes are not listed in the *NFIRS 5.0 Complete Reference Guide,* so that users will not consider them valid when completing new reports. However, they are essential to analysts working with a database that contains any converted data. This document may be downloaded from http://www.nfirs.fema.gov/documentation/design.htm. Conversion tables and Version 5.0 forms may also be downloaded separately from the same site.

Anyone who is working with the national fire database or who wishes to use national numbers in his or her own analysis should be familiar with the article "The National Estimates Approach to U.S. Fire Statistics" by Hall and Harwood.[16] A free copy of this article may be obtained from NFPA's One-Stop Data Shop [Tel: (617) 984-7450; e-mail: osds@nfpa.org]. The results of NFPA's annual survey of fire department experience can be found in Mike Karter's report *Fire Loss in the United States,*[17] an abbreviated form of which is published each fall in the *NFPA Journal*®. This information is also available from NFPA's One-Stop Data Shop and on NFPA's website at http://www.nfpa.org.

Version 4.1 Coding Manual

Codes for the incident report, civilian casualty report, and fire fighter casualty report are available from the USFA and may be downloaded from the website at http://www.usfa.fema.gov/nfirs/tools. National data for 1998 and earlier were collected and released according to this coding structure. If the NFIRS 5.0 database contains converted data, it is important to know how the data were collected originally.

DATA SOURCE ISSUES

NFIRS is not a complete census of reported fires. When people are interested in the size of the national fire problem, they must look beyond NFIRS. Because NFIRS at the national level is not a complete census and not a random sample, it cannot by itself answer questions such as "How many fires were reported last year?" or "How many people died as a result of last year's fires?" NFPA's annual survey of fire department experience, described in the preceding chapter, is based on a stratified random sample. This allows projections to be made on the "big picture" numbers of fires, residential or home fires, fire deaths, and fire injuries. When the NFIRS totals are compared to the results of the survey, scaling ratios are derived that can be applied to NFIRS to develop estimates of the national fire problem. The procedures are described in Hall and Harwood.[16]

Reporting Policies and Practices

Voluntary State Participation in NFIRS. Each state may set its own requirements. Some states require all runs to be reported, some only require fires, some have a dollar loss threshold, and, in some states, reporting is voluntary.

Different communities within each state may have different practices or interpretations of the requirements. NFIRS was designed to capture fires reported to fire departments. If the fire department did not respond, no NFIRS report was generated. When fire reporting is voluntary or based on loss criteria, there may be differences in deciding which fires are worth reporting or should be reported.

Influence of Reporting Requirements on NFIRS Data. Different states have different reporting requirements for NFIRS.

TABLE 3.4.2 Ten Major U.S. Data-Based Findings of Recent Years

1. U.S. and Canadian fire death rates were, in the 1970s and 1980s, among the highest in the developed world. The gap has been steadily closing. In the late 1970s, U.S. fire death rates were double the rates in the United Kingdom, Japan, and Sweden. In the mid-1980s, U.S. fire death rates were roughly 50 percent higher. In the early 1990s, U.S. fire death rates were only one-fourth to one-third higher. By the late 1990s and early twenty-first century, the U.S. fire death rate was lower than the fire death rate in Japan and sometimes lower than in Sweden. The U.S. fire death rate has been higher than Canada's fire death rate since the mid-1980s, although the trend lines are similar.[4]

2. Within the United States, the states of the Old South still tend to have the highest fire death rates, but the gap is closing; for some years, the South has not been the highest region. In the early 1980s, fire death rates in the South were typically around 50 percent higher than those in the Northeast and North Central regions and double the rates in the West. Excluding the events of September 11, 2001, in 1997 to 2001, the South's fire death rates have averaged one-fifth higher than the rates in the North Central and Northeast regions. The West continues to do substantially better than any other region, having an average death rate half that of the South.[5]

3. Seven (28%) of the 25 U.S. fires with the largest property loss (adjusted for inflation) were wildland fires. NFPA maintains a list of the 25 costliest fires and explosions of all time, based on loss values adjusted for inflation. The September 11, 2001, attack on the World Trade Center in New York City heads the list with an estimated direct property loss of almost $36 billion in 2004 dollars. The 1906 San Francisco earthquake fire caused losses estimated at $350 million at the time, or more than $7 billion in 2004 dollars. Seven of the 25 costliest fires occurred in the 10-year period from 1996 through 2005.[6]

4. Rural areas have a higher rate of reported fires and fire deaths than do larger communities. During the 5-year period of 1997 to 2001 (excluding the events of September 11, 2001), rural communities with populations under 2500 had an average fire death rate of 30.9 per million population. This rate was at least twice that found in most other population intervals with the exception of communities with populations of 2500 to 5000, which had a rate of 18.4 fire deaths per million population. Communities with populations under 2500 averaged 12.0 reported fires per 1000 population, twice that of all population intervals except 2500–5000 (8.3) and 5,000–10,000 (6.9). These communities also have the highest per capita rate of reported fires.[7]

5. Sprinklers are a reliable and effective means of reducing loss of life and property from fire. In reported fires large enough to operate sprinklers, the sprinklers failed to operate in only 7 percent of the fires in which they were present in the fire area. In two-thirds of the failures, the system had been shut off before the fire. These statistics are based on NFIRS Version 5.0 data reported in 1999 to 2002. Due to the lack of a code for unknown automatic suppression system presence in NFIRS Version 5.0 until 2004, older data are used to demonstrate the lifesaving effectiveness of this equipment. The death rate in 1989–1998 residential fires with this equipment was 78 percent lower than in fires that lacked this protection.[8]

6. Home smoke alarms are nearly universal, but many aspects of the national use of home smoke alarms still need attention. According to a 2004 Fire Prevention Week telephone survey done for the NFPA, 96 percent of U.S. homes had at least one smoke alarm, a remarkable change from 30 years earlier when almost no one had these devices. The small portion of homes without smoke alarms accounted for 55 percent of the home fire deaths reported in 1999 to 2002.[9]

In 1992, the U.S. Consumer Product Safety Commission (CPSC) studied smoke alarms in all types of homes—not just those that had fires—and found that in 20 percent of the households with at least one smoke alarm present, none were operational.[10] Smoke alarms were present and operating in only 52 percent of reported home fires, assuming that no working smoke alarms were present in confined fires in which the device did not alert occupants. In 2004, only 23 percent of households had escape plans that they had rehearsed, so the extra warning time provided by detectors may often be wasted in real fires.[11]

7. Playing with fire, principally matches and lighters, is still the leading cause of fire death among preschoolers. The U.S. Consumer Product Safety Commission's requirement for child-resistant lighters took effect in 1994. Fire-play deaths involving lighters and matches have since declined sharply.[12]

8. Juvenile firesetters became even more dominant as the leading share of the arson problem. In the early 1980s, juveniles (those under age 18) typically accounted for around 40 percent of those arrested for arson, according to data from the Federal Bureau of Investigation's Uniform Crime Reports. Since 1994, roughly 50 percent of those arrested were under 18. During the same time, there was a growing recognition that many of the child-playing fires involved psychological or environmental problems similar to those common among juvenile firesetters classified as arsonists. These findings supported greatly expanded programmatic attention to the juvenile firesetter problem, which was reflected in fire safety initiatives in the late twentieth and early twenty-first centuries.[13]

9. The number of reported home candle fires stabilized from 2001 to 2002, after rising 15 percent from 2000 to 2001. Candle fires generally declined in the 1980s, hitting their lowest point in 1990. They started climbing again in 1991. The year 2002 was the first since 1995 that has not seen a new high. Partly because total home fires have declined so much since 1980 and partly because candle fires have increased in recent years, the share of fires started by candles has jumped from 1 percent in the early 1980s to 5 percent in 2001 and 2002.[14]

10. From 1995 through 2004, 44 percent of the on-duty fire fighter fatalities, on average, resulted from sudden cardiac death. Forty-four percent of the cardiac victims had a history of heart-related conditions. Another 31 percent had arteriosclerotic heat disease, but the victims may not have been aware of the condition. Thirty-five percent of the victims suffered cardiac symptoms during fireground operations; 25 percent were stricken while responding to or returning from an alarm. The median age of cardiac victims was 52. Volunteer fire fighters accounted for the vast majority of cardiac fire fighter fatalities over 60 years of age.[15]

These differing requirements impact the data in ways that cannot fully be controlled. States may differ not only in what reporting they require but also in what incident types they will accept. These differences pose larger issues with NFIRS 5.0 as the USFA now accepts all types of incidents in its database. For example, in older versions of NFIRS data, it was possible to identify fires in which smoke alarms and sprinklers operated. With the expanded incident types of 5.0, it is now possible to identify incidents in which smoke alarms or sprinklers were unintentionally activated. This would help in cost/benefit analyses. However, if several states are not routinely capturing nonfire incidents, the projection or estimation rules will need to compensate for that fact, or the number of unintentional activations will appear artificially low.

Even when complete reporting is required, a dislike of paperwork has occasionally influenced how incidents were coded. In the past, fire officers had to complete the full form for structure fires but provide nothing or only basic information for smoke scares. This may have resulted in some minor fires being called "smoke scares" or in some fires not reported at all.

These problems may have resulted in the undercounting of some minor incidents. Even on the NFPA fire experience survey, the fire department can only report incidents it has documented. Consequently, minor fires and nonfire incidents may not be documented if the state does not require the department to do so.

Many departments understand that they need to know the nature of their fire problems and activities and, therefore, document all incidents regardless of what is required. NFIRS software programs facilitate documenting and reporting by making the process easier. However, there is no systematic way to control for underreporting or changes in reporting practices.

Comparing Data from Different Jurisdictions. Any comparison of fire department experience across jurisdictions must begin with a detailed evaluation of each jurisdiction's reporting practices and policies. Because of the variations described earlier, results may be misleading.

To avoid misleading results, each jurisdiction's reporting practices and policies should be reconciled with one another. If the study is to use existing data, then a data set of common assumptions may be constructed through inclusion/exclusion of specific types of incidents. For example, if a jurisdiction that reports all incidents wishes to compare itself with another jurisdiction that employs threshold reporting, then the all-incident department may exclude incidents that would not have been reported by the threshold reporting department for comparison purposes.

Similar issues pertain to location-based analysis outlined later in this chapter. Intercity comparisons should only be made when each entity adheres to similar geocoding data quality standards. If Department A maintains a 95 percent valid location rate for all incidents, and Departments B and C are only at 80 percent, there will be a bias toward higher location-specific rates for Department A's reporting areas than the others for comparison purposes. Although this might not greatly affect percentage distribution of types of fires (unless there is a bias among nongeocoded incidents), rates of fires per capita would be affected.

Optional NFIRS 5.0 Modules. Version 5.0 requires the use of five modules under specific circumstances: Basic, Fire, Structure Fire, Civilian Fire Casualty, and Fire Service Casualty. The other modules, including EMS (emergency medical services), Hazmat (hazardous materials), Wildland Fire, Arson, Juvenile Firesetter, Apparatus or Resources, Personnel, and Supplemental, may or may not be required or even accepted at the state or local level. According to NFIRS, either the Fire Module or the Wildland Fire Module may be used for grass, crop, and wildland fires.

NFIRS 5.0 Wildland Fire Module. Although it might seem logical to assume that the number of wildland forms received by NFIRS equals the number of wildland fires in the reporting areas, it is not the case. Departments using earlier versions of NFIRS will not use the Wildland Fire Module. According to the NFIRS 5.0 CRG, "The purpose of the Wildland Fire Module is to document *reportable* (emphasis added) wildland fires." A reportable wildland fire is defined as "any fire involving vegetative fuels that occurs in the wildland or urban-wildland interface areas, including those which threaten or consume structures."[18] This module may—depending on state or local policy—be used for brush, forest, or grass fires; fires on cultivated land; or unauthorized, controlled, or prescribed burning. Normally, only hostile fires are counted as fires. This means that Wildland Fire Module reports may be present for incidents that are not counted as part of the fire problem. It is generally good practice to restrict queries by incident types.

Some states, such as Kansas, encourage the use of the Wildland Fire Module for all grass fires. Some of these fires would not normally be considered wildland.[19]

Cause Categories in the NFIRS 5.0 Wildland Fire Module. The fields in the Wildland Fire and Fire Modules overlap, but there are differences in the broad cause categories (Table 3.4.3). Although the Wildland Fire Module was designed to document reportable wildland fires, local and state authorities may require or encourage its use with fires of specific incident types that have not reached the status of what would normally be called "wildland fires." If an analysis of NFIRS 5.0 data of intentionally set fires is based only on the causes from the Fire Module, incendiary fires documented on the Wildland Fire Module will be omitted.

Although similar, the cause "Failure of equipment or heat source" on the Fire Module and the cause "Equipment" on the Wildland Fire Module are not exactly equivalent. If a lantern placed on the ground ignited some leaves or pine needles, the equipment played a role, and "equipment" might reasonably be listed as the cause. However, if the Fire Module was completed instead, "Unintentional" would probably be the more appropriate code because the equipment did not really fail, except in terms of not protecting against likely misuse. "Equipment" on the Wildland Fire Module includes equipment that was operating properly as well as defective equipment. Consequently, the "Equipment" causes on the two modules cannot confidently be combined.

Impact of Abbreviated Reporting. With the older versions of NFIRS, some states allowed abbreviated reporting of the so-called no-loss outside fires—the brush, rubbish, or grass fires

TABLE 3.4.3 Cause of Ignition Codes in Fire and Wildland Fire Modules

Fire Module Cause	*Wildland Fire Cause*
1. Intentional	1. Natural source
2. Unintentional	2. Equipment
3. Failure of equipment or heat source	3. Smoking
4. Act of nature	4. Open/outdoor fire
5. Cause under investigation	5. Debris/vegetation burn
O. Other	6. Structure (exposure)
U. Cause undetermined after investigation	7. Incendiary
	8. Misuse of fire
	O. Other
	U. Undetermined

Source: Adapted from NFIRS-2, Fire Module, Revision 0/01/05 and NFIRS-8 Wildland Fire Module, Revision 01/01/04.

and the outside trash, rubbish, or waste fires. Abbreviated reporting generally captured dispatch-type information and the occupancy class or fixed property use. Ignition factor was requested but often left blank or coded as undetermined because cause investigation was not a priority in these incidents. For analysis, the uncollected fields were treated as "unknowns."

Abbreviated Reporting and the Analysis of Structure Fires. Abbreviated reporting for structure fires was generally not allowed in the older versions of NFIRS. Items such as area of origin, fire causal factors, and alarm and sprinkler performance were always required fields. Version 5.0, however, allows for abbreviated reporting of certain confined structure fires (and outside rubbish fires), including fires confined to the chimney, incinerator, trash receptacles, or fuel burner, or confined cooking fires. In NFIRS 5.0, confined structure fires are defined as small fire incidents that are generally confined to noncombustible containers and where flame damage does not spread beyond the container. Losses, such as property and contents losses, and deaths and injuries rarely occur as a result of such fires. In fact, deaths are not an expected result of confined fires.

With the introduction of Version 5.0, it was believed that causal factors were so similar for confined fire incidents that it was redundant to ask for completion of the Fire and Structure Fire Modules. When fires from the older NFIRS versions are converted, data from the Fire and Structure Fire Modules will be present for these types of fires. However, the older incidents do not have the specific confined fires incident-type codes.

Abbreviated reporting may not be allowed in some jurisdictions. In those jurisdictions, it may be a requirement that the NFIRS Fire Module and Structure Fire Module also be completed for confined fires resulting in more detailed information being reported for small fires. For the data analyst, this inconsistency has posed interesting challenges regarding assumptions about the distribution of unknowns. In 2002, approximately 20 percent of confined fire incident reports provided data beyond that of the Basic Module. Some national analysts have opted to disregard the fact that these incidents have additional information and to simply treat these fires as abbreviated, confined fires.

The USFA has investigated the topic of confined fire incidents in a report entitled *Confined Structure Fires.*[20] From this report, it was determined that structures other than buildings as well as fires that incur damages beyond their noncombustible containers are being included as confined fires. According to the NFIRS 5.0 CRG, the confined fire incident types are to be used only for fires in buildings that are confined to noncombustible containers when there is no flame damage beyond the noncombustible container.[21] The CRG also notes that "contained, no-loss fires are simply reported using only the Basic Module."[22] From USFA's analysis, it is clear that the container itself is often damaged, implying that it may be beneficial to modify the NFIRS reporting requirement to change "no-loss" to "low-loss" and define a reasonable loss threshold.

The *Confined Structure Fires* report also suggests that the confined fire incident types should not be used to code fire incidents resulting in deaths, property loss, or high content losses. Instead, it should be required that more detailed information be provided through the completion of the Fire and Structure Fire Modules. Training on the proper NFIRS conventions and requirements as well as tighter data entry controls are tools that may be explored as avenues to achieve more consistent data quality. To download a copy of the report, please visit: http://www.usfa.fema.gov/downloads/pdf/publications/confined-structure-fires.pdf.

With the advent of abbreviated reporting in Version 5.0, fire data analysts have recognized the need for new analytic approaches. Several national analysts have decided to analyze the nonconfined fires separately, including the confined fires only after any unknown data were allocated across the nonconfined fires. This approach is especially needed in the analysis area of the presence and effectiveness of smoke alarms. Further investigations into the appropriate methodologies for smoke alarm analyses are currently being pursued.

Possibility of Artificial Increase in Fires. The ease of recording abbreviated fire incidents may lead to an artificially created statistical increase in these types of incidents and in their share of the total fire problem. It will be necessary to carefully examine the breakdown of incident types to determine if the increase is real or a result of the new reporting system. Some states continue to accept older versions of NFIRS from at least some of their departments. This means that system-driven changes in the data will continue for a number of years. However, USFA is currently exploring the possibility of sunsetting NFIRS Version 4.1.

Number of Expected Entries per Data Element. Analysts working with Version 5.0 data need to understand which combinations of data elements must be completed under which circumstances. Certain data elements allow multiple entries. For example, two entries are allowed for factors contributing to ignition. Depending on how the file is structured, it may be necessary to query multiple fields for one data element. This issue also exists for other data elements such as actions taken, human factors, on-site materials, and fire suppression factors. Because only the Basic Module is required for specific confined structure fires and outside rubbish fires, data collected from the Fire Module (or Structure Fire Module, as appropriate) are not captured for all fires.

NFIRS Versions and Converted Data

Analyses are cleaner when working with data collected in only one version of NFIRS. However, it is not possible for trend analyses or for analysts who must work with data collected in two or more systems. The differences between Versions 3, 4.0, and 4.1 were not that extreme. A few new fields, such as the number of stories, were added to Version 4.0. The fire fighter casualty report was also added and required conversion of fire fighter injury reports collected on the old injury report. In Versions 4.0 and 4.1, the original injury report was used for civilian and non–fire fighter injuries only. None of the fields in the fire incident report required conversion. Version 4.1 added the Hazardous Material Module but did not change any of the elements on the other forms. With the advent of NFIRS 5.0 and its new coding scheme and data structure, the issue of converted data becomes prominent. The proportion of native 5.0 data has steadily increased since the introduction of NFIRS 5.0 in 1999. Table 3.4.4 shows NFIRS data reporting by version for 1999 to 2003. As more native NFIRS Version 5.0 data become available each year, some analysts choose to use only native NFIRS Version 5.0 data in fire data analyses.

TABLE 3.4.4 Data Collection Version of NFIRS, 1999–2003

Year	*NFIRS 4.1 Percentage*	*Native NFIRS 5.0 Percentage*
1999	93	7
2000	79	21
2001	52	48
2002	32	68
2003	18	82

Comparing Version 5.0 with Older Versions of NFIRS. The structure and the coding system of NFIRS 5.0 are significantly different from those of Versions 3, 4.0, and 4.1. Conversion tables were developed, but the conversion is not one-to-one. Code definitions differ between the systems, and conversions are often not exact. For some analyses, it would be prudent to exclude converted data.

Data collected in the older versions during the transition years are converted to the Version 5.0 format. The version in which the data were collected is recorded, enabling analysts to include or exclude the older data.

Structure and Vehicle Fires. Most analysts agree that structure fires include all the fires in the 110 and 120 series, including fires in or on structures and fires in mobile properties used as fixed structures. It is important to note that not all structure fires are building fires—structure fires also include such items as bridges, towers, tanks, and so on. Table 3.4.5 shows the categories of structure fires in Version 5.0 of NFIRS and the modules required. Vehicle fires are captured in the 130 series in Version 5.0.

Residential Fires. Residential properties are identified by the 400 series in Version 5.0 of NFIRS. NFPA and some other organizations separate homes from other residential properties. Homes include one- and two-family dwellings, manufactured housing, and apartments. These are identified by property use codes 419 (detached one- and two-family dwellings, including manufactured homes, mobile homes not in transit, and duplexes) and 429 (multifamily dwellings, including

TABLE 3.4.5 Version 5.0 Structure Fires and Required Modules

Code	*Description*	*Comments*
110	Conversion code only for older structure fires (Situation Found 11), excluding those with mobile property used as a structure	Associated data will be converted or incomplete
111	Building fire	Basic, Fire, and Structure Fire Modules
112	Fires in structures other than buildings	Basic, Fire, and part of Structure Fire Modules
113	Cooking fire, confined to container	Abbreviated report okay
114	Chimney or flue fire, confined to chimney or flue	Abbreviated report okay
115	Incinerator overload or malfunction	Abbreviated report okay
116	Fuel burner/boiler malfunction, fire confined	Abbreviated report okay
117	Commercial compactor fire, confined to rubbish	Abbreviated report okay
118	Trash or rubbish fire, contained	Abbreviated report okay, but full report encouraged when fire may have been intentionally set
121	Fire in mobile home used as fixed residence	Basic, Fire, and Structure Fire Modules
122	Fire in motor home, camper, recreational vehicle (used as fixed structure)	Basic, Fire, and Structure Fire Modules
123	Fire in portable building with a fixed location	Basic, Fire, and Structure Fire Modules
120	Fire in mobile property used as a fixed structure, other	Basic, Fire, and Structure Fire Modules

apartments, condominiums, townhouses, row houses, and tenements).

Outside and Other Fires. Outside and other fires were said to include outside fires involving property of value; brush, tree, grass, or forest fires; outside rubbish or trash fires; explosions with no after-fire; outside spills or leaks with ensuing fire; unclassified fires; and unknown-type fires (situation found 12, 14, 15, 16, 17, 19, and 10, respectively). Version 5.0 codes capture similar incidents with more specific codes for various types of natural vegetation fires, outside rubbish fires, special outside fires, cultivated vegetation or crop fires, and unclassified fires (incident type 140–173, and 100). In Version 5.0, an explosion that does not result in a fire (incident type 240s series) is no longer grouped with fires or counted as a fire.

Incendiary, Suspicious, and Intentional Fires. For statistical purposes, analysts generally grouped ignition factors for incendiary and suspicious from older versions of NFIRS together as arson, much to the chagrin of many fire investigators who concur with NFPA 921, *Guide for Fire and Explosion Investigations,* which does not consider suspicious to be a valid cause. Although there is broad consensus that "suspicious" is never a valid final cause determination after investigation, it was considered appropriate for fires that are likely to never be fully investigated or for reports that may not have been updated after an investigation. Version 5.0 added a new field, "Cause," to the Fire Module (see Table 3.4.3). Intentional nonwildland fires are identified in this field. The choices of *incendiary* and *suspicious* have been dropped from the Fire Module in Version 5.0.

The ignition factors of incendiary and suspicious both convert to the cause of intentional, so the distinction between the two is lost. Incendiary and suspicious both imply an illegal act; "intentional" does not carry that implication as strongly. For example, a crisis-type juvenile firesetter may be below the age of legal responsibility but may intentionally start a fire.

Smoke Alarm Information. Analyzing smoke alarm data is considerably more complicated with Version 5.0 of NFIRS than it was in the past. Detailed information on smoke alarm presence and operation is not collected for confined or contained fires, which comprise 13 percent of the reported home fires in 1999 to 2002. The percentage of these fires will increase as more of the data is originally collected in Version 5.0. Because the confined or contained fires are almost all minor, many of the minor fires are removed from the pool of data with details on smoke alarm effectiveness. The only information captured for these confined fires concerns whether the detection equipment did or did not alert occupants. Information on whether detection equipment was present, whether it operated, and whether occupants were present is generally not collected for these incidents.

If the detection equipment in a confined fire was coded as "alerted occupants," for this analysis it was assumed that a smoke alarm was present and operated. When this equipment did not alert occupants, it was assumed to have not operated or to not have been present. This approach was used to create Table 3.4.6.[23] Because a fire may be discovered before a smoke alarm operates, a smoke alarm may operate in the absence of occupants, or a confined fire may have been too small to activate detection equipment, "smoke alarm alerted occupants in confined fire" should be considered a lower bound of operating smoke alarms whereas "smoke alarms did not alert occupants in confined fire" should be considered the upper bound of possible fires with no working smoke alarms. Again, due to conversion issues, it is advisable to use data collected originally in Version 5.0 only.

Automatic Extinguishing Systems. Analyses of the effectiveness and reliability of automatic extinguishing systems should control for whether the system was actually in the fire area. Ex-

TABLE 3.4.6 Smoke Alarm Status in Homes, Version 5.0 Data Only, 1999–2002 Annual Averages

Smoke Alarm Status	*Percentage of Fires*	*Percentage of Civilian Deaths*	*Death Rate per 100 Fires*	*Percentage of Civilian Injuries*	*Injury Rate per 100 Fires*
Smoke alarm operated in nonconfined fire	25	26	0.7	41	6.9
Smoke alarm alerted occupants in confined fire	18	0	0.0	5	1.2
Subtotal—operating smoke alarm	43	26	0.4	46	4.5
Smoke alarm present but failed to operate in nonconfined fire	9	19	1.5	17	8.1
No smoke alarm present in nonconfined fire	32	55	1.2	31	4.0
Smoke alarm did not alert occupants in confined fire	11	0	0.0	4	1.7
Subtotal—no operating smoke alarm	52	74	1.0	52	4.2
Fire too small to operate in nonconfined fire	5	0	0.0	2	1.8
Total	100	100	0.7	100	4.2

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire.

Source: NFIRS and NFPA survey.

cluding fires with no reasons or unknown reasons, in 47 percent of the fires in which the system failed to operate, the reason given was "Fire not in area protected by system." The additional detail collected in Version 5.0 provides valuable information about types of systems, heads operating, and effectiveness. Unfortunately, a code for presence undetermined was not included in Version 5.0 until 2004.[24] If fire fighters were unsure if such a system was present, they were instructed to code it as "not present." The conversion from older versions has also been problematic. Consequently, statistical comparisons of the life and property savings with and without these systems have been limited to data collected prior to 1999 and will be updated after the 2004 data are released.

Equipment Involved in Ignition. The equipment involved in ignition field has been expanded to three characters, with a corresponding increase in number of choices. A separate field indicates if the equipment was portable or stationary. When working with data that include incidents collected in older versions, it is important to remember that specific equipment that was first identified separately in Version 5.0 will be undercounted. The sheer number of codes makes some form of grouping desirable; grouping can also compensate for the different code choices in the two systems. Limiting analysis to Version 5.0 data can provide the appropriate percentages for specific types of equipment.

APPROACHES TO FIRE DATA ANALYSIS

The discussion to this point has focused on how the data and the data collection system impact analysis. The remainder of the chapter will focus on approaches to fire data analysis.

Top-Down and Topic-Driven Analysis

Most characterizations of the fire problem begin with some measures of the problem's size. Why? Implicit in these measurements is the idea that fire is a problem big enough to justify concern and attention. Each year, fire kills thousands of people, injures tens of thousands more, and destroys billions of dollars of property. When the fire community wishes to pursue a program that requires the cooperation of others, that community must first attract attention. The big numbers on fire—incidents, deaths, injuries, and property damage—accomplish this goal.

Top-down analysis is an approach that begins with a summary of the big numbers and then subdivides the totals into their major parts. A top-down analysis might begin with the number of runs. Several types of subsections are possible, including types of runs (i.e., fires, EMS, false calls, etc.). These subsections may be broken down further: for example, separate profiles can be created for each time period, occupancy class, or fire cause. At the local level this breakdown might also include profiles by station or company. A top-down look at U.S. fire department runs over the past 25 years reveals a steady drop in fire calls but an increase in EMS calls and false alarms. Although the decrease in fires is encouraging, the total of reported fires and false alarms has averaged about 3.6 million since 1980. The combined total has not fallen below this average since 1993.[25] These statistics are shown in Figure 3.4.1. Fire departments cannot presume a call is a false alarm and must respond as they would to a fire. If only the statistics for fires were examined, this pattern would be missed.

The top-down approach provides the broadest perspective on the overall fire problem or a fire department's activity. It differs from topic-driven analysis, which begins with interest in certain issues involving only certain types of fires. For example,

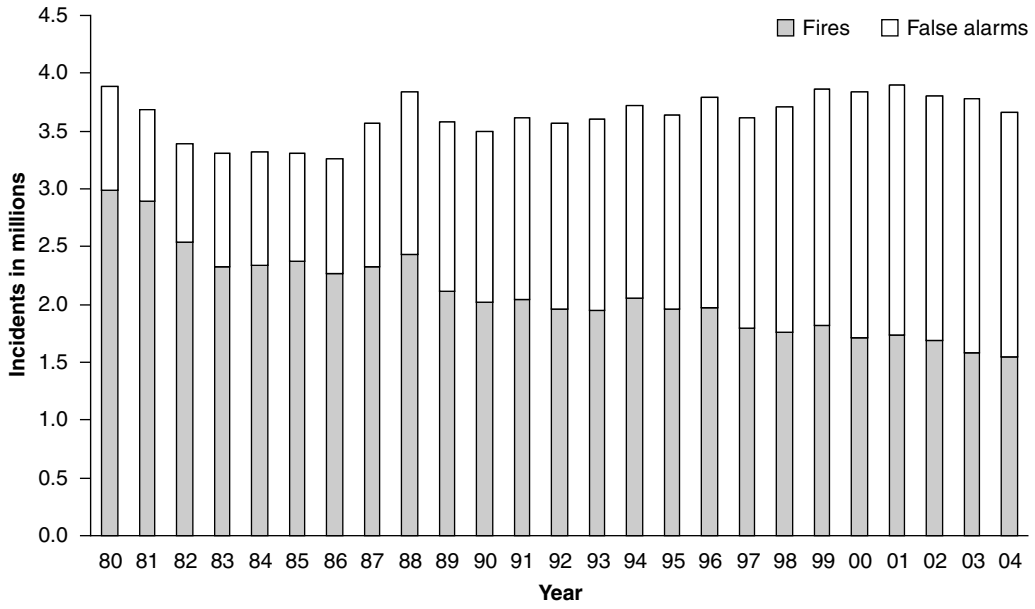

FIGURE 3.4.1 Reported Fires and False Alarms, 1980–2004 (Source: The U.S. Fire Problem Overview Report: Leading Causes and Other Patterns and Trends)

a top-down analysis of fires in residences might identify smoking materials as the leading factor in civilian fatalities in homes, accounting for roughly one-fourth of the fires for which the cause was reported. On the other hand, a topic-driven analysis focused on smoking-material fires—for example, a study of the likely impact of a self-extinguishing cigarette or of a public education program aimed at smokers—would involve more than just homes. Although both topic-driven and top-down analyses might be interested in the role of smoking-related fires in home fire deaths, topic-driven analysis might also be interested in the involvement of smoking materials in nonhome fire fatalities or in property damage in home fires. Even though smoking-related fires do not account for the largest shares of the latter two problems (intentional causes lead in both cases), they are still part of the overall smoking-related fire problem; any change that affects the smoking-related fire problem may affect all smoking-related fires.

In a top-down analysis, the basic rule is to look for the biggest parts of the problem. Why bother subdividing the problem? Resources usually are too limited to permit an attack on the whole problem and choices must be made. At times, however, important pieces of information are missed if only totals are examined. For example, home structure fires account for only one-quarter of reported fires but four-fifths of all fire deaths. The use of data to identify the largest manageable parts of the problem is the first step in making those choices. Whereas totals are used to show the overall size of the problem, percentages are used to indicate the largest parts.

Use of percentages to identify the largest parts of the fire problem is not as easy as it sounds. Judgment is involved in selecting the categories for which percentages will be calculated. For example, suppose an analysis showed the biggest subgroup of a particular occupancy group's fire problem consisted of fires involving electrical short circuits. This finding does not fit well into most strategies for attacking the fire problem. If one is going to examine every piece of equipment that could be subject to short circuits, one might as well also check for other electrical faults in that equipment. The available strategy may dictate a broader category, covering fires involving all electrical equipment faults. Or maybe it is easier to design strategies around particular types of electrical equipment (e.g., fixed wiring, heating systems, ranges, and ovens) and address all fires involving such equipment, whether the equipment or the user was at fault.

Take another example. Which of the following findings is more useful: (1) 34 percent of all reported home fires begin in the kitchen; or (2) 28 percent of reported home fires involve cooking equipment?[26] The latter finding identifies a smaller part of the problem and uses a completely different categorization (area of origin vs. equipment involved in ignition), but it locates the problem much more specifically. In a kitchen, there could be dozens of fire hazards to check out; most homes have only a few types of cooking equipment.

Finally, suppose a categorization includes equipment involvement, material ignited, and the human elements that brought them together. Such a categorization will produce detailed scenarios, but the "leading" category might account for only 2 to 4 percent of all fires. It would be necessary to develop strategies for several dozen scenarios to make any noticeable impact on the total fire problem. If that is so, it may make more sense to select scenarios that fit together logically and can be addressed by variations of the same strategy (i.e., use of less specific categories) than to select several dozen distinct scenarios and tackle each one separately. To put it another way, the scenario technique of analyzing several fire characteristics simultaneously is most useful as a second-stage analysis, performed after one characteristic has been used to establish basic clustering.

Therefore, in selecting categories for calculating percentages, it is important to match the structure of the categories to the structure of the strategies available to attack the fire problem. Remember that the size of the problem being attacked is no more or less important than the anticipated leverage on the problem; for example, a 7 percent reduction in a problem that causes 500 deaths a year is worth just as much as a 70 percent reduction in a problem that causes 50 deaths a year. (This is discussed at greater length later in this chapter under the heading "Using Data in Program and Strategy Analysis.") So be sure when you pick out the biggest parts of the problem that they collectively account for a sizable share of the total, but also remember that some parts of the problem may be much more preventable than others.

Figures 3.4.2 and 3.4.3 illustrate the effective use of percentages (presented in Figure 3.4.3 through the display of numbers) to describe patterns in the 2004 fire fighter fatality problem. (These figures also illustrate the effective use of graphics to summarize numerical data in a more comprehensible manner.) Figure 3.4.2 shows that only 28 percent of the fire fighter fatalities resulted from fireground duties. Response/return from alarm, which should involve only controllable dangers and relatively little risk, accounts for 34 percent of all fire fighter deaths. Figure 3.4.3 shows that deaths from heart attacks ac-

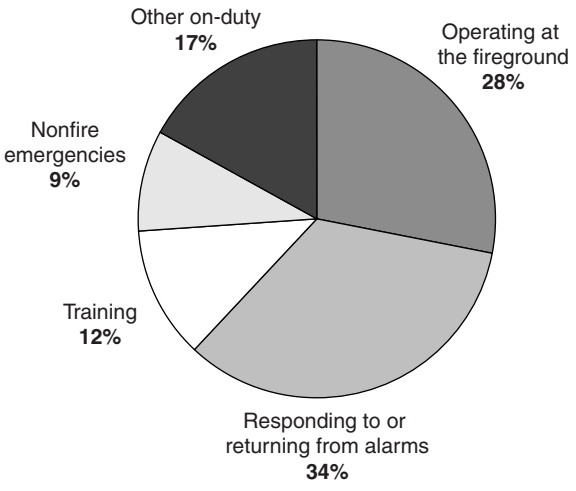

FIGURE 3.4.2 Fire Fighter Fatalities in 2004 by Type of Duty (Source: P. R. LeBlanc and R. F. Fahy, *Full Report: Firefighter Fatalities in the United States,* National Fire Protection Association, Quincy, MA, 2005)

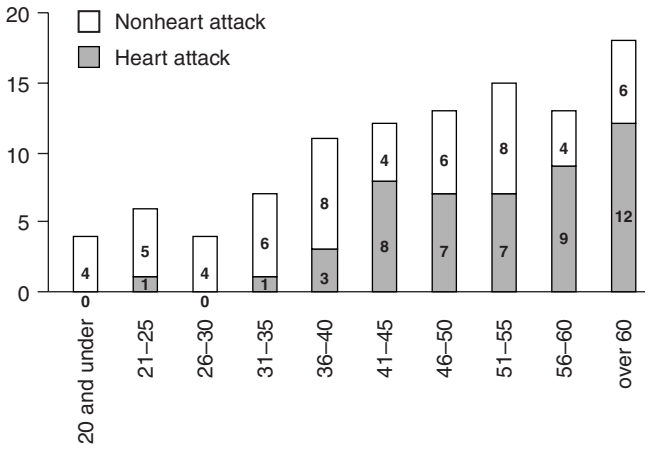

FIGURE 3.4.3 On Duty Fire Fighter Fatalities in 2004 by Age and Cause of Death (Source: P. R. LeBlanc and R. F. Fahy, *Full Report: Firefighter Fatalities in the United States,* National Fire Protection Association, Quincy, MA, 2005)

count for two-thirds of the fatalities in the two oldest age-groups but only a small share of the fire fighter fatalities in those 35 or younger.[27] Such patterns have direct implications for targeting of physical fitness programs.

Analysis by Fire Cause and Property Type

The dimensions most frequently chosen for top-down and topic-driven analyses are fire cause and property type, because most fire prevention strategies are structured along those lines. "Analysis by cause" actually refers to a variety of analyses addressed to different aspects of the causal factors. The question of how to categorize, already discussed in general terms, becomes especially difficult in analyses of cause-related information.

Even the question of how to refer to cause-based descriptions can be a problem. For example, suppose one observes that roughly one-fourth of all civilian fire fatalities in homes with fire cause reported were smoking related. Does this mean that cigarettes (the principal smoking material involved) were to blame for all those deaths? Not necessarily. If the smokers in question had been careful not to smoke in bed and always to place cigarettes in sturdy ashtrays, few of the deaths would have occurred. Or if the upholstered furniture, bedding, mattresses, and pillows that are the first items ignited in most fatal smoking-related fires had been more ignition resistant, many or most of the deaths would have been avoided. If the cigarettes used had been designed to self-extinguish more quickly, many or most of the deaths might have been prevented. A decision on which dimension to use in categorizing fire causes—the source of heat, items ignited, or the behaviors that brought them together—should be made in a way that supports analyses of workable prevention strategies. Assessments of blame are tasks for lawyers or philosophers; they do not help in the search for ways to reduce fire problems.

NFIRS contains six fire-cause-related elements of information: (1) a general cause category (intentional, unintentional, failure of equipment or heat source, or act of nature); (2) the heat source; (3) equipment involved in ignition, if any; (4) the item first ignited (e.g., chair, floor covering, structural beam); (5) type of material ignited (e.g., wood, plastic, fabric); and (6) factors contributing to ignition—the human or equipment failures that brought together the ignition heat and ignited material. Together, these six dimensions and their subsections can define billions of distinct fire-cause categories, a clearly unworkable partitioning of the problem. In the face of all this detail, several approaches have been developed to extract major patterns. These approaches include the following:

- Emphasis on intentional versus not intentional
- Emphasis on equipment
- Emphasis on behavior
- Emphasis on heat source
- Emphasis on item ignited
- Emphasis on leading causes summarized from multiple data elements

Table 3.4.7 shows how different approaches can affect the description of leading causes of home structure fires reported during 1999 to 2002. Note that confined fires are included as entries in each table. In future years, these fires are expected to account for an even larger share of the incidents. The percentages include a proportional share of fires with unknown data. This allocation will be discussed later in the section. It is important to remember that each of these data elements contributes to a fire scenario and that they often overlap. For example, some "playing with fire" incidents are intentional; most "playing with fire" incidents involve matches or lighters, but candles, cigarettes, and cooking equipment may also be factors.[28]

In the single-digit cause codes used in NFIRS 5.0, a distinction is made between "cause under investigation" and "cause undetermined after investigation." Both are considered unknown for analysis purposes, although it is possible that many incidents of "cause under investigation" are intentional. In the absence of causal information, "cause under investigation" seems the best choice.

A report by the U.S. General Accounting Office (GAO) raised a number of issues about the analysis of fire statistics concerning upholstered furniture.[29] Because of that report, the U.S. Consumer Product Safety Commission (CPSC) has excluded fires in which the ignition factor was incendiary or suspicious in older versions of NFIRS or intentional in Version 5.0. For its analyses, NFPA generally includes these fires but performs further analyses when necessary to identify causes or the number of intentional fires associated with a particular product.

Analyzing by One Data Element. Any one of the causal dimensions can be used to describe the fires. Because the coding structure used for many data elements is generally grouped into "decades" and "centuries," one can often use the first digit alone to create 10 categories, or two digits to create nearly 100 categories for each dimension. This approach often proves frustrating, however, because the structure of the coding elements often does not coincide with the issues to be analyzed.

Scenario Groupings. A third approach has been to use scenarios based on two or three of the causal dimensions. This

TABLE 3.4.7 Leading Causes of Structure Fires in Homes with Different Emphases, 1999–2002 Annual Averages

Description of Cause	*Percentages*	
Emphasis on Intentional Versus Nonintentional Based on Cause of Ignition		
Unintentional	47	Note that all known causes other than intentional could be described as unintentional.
Failure of equipment or heat source	25	
Intentional	9	An intentional fire may not be arson in the legal sense.
Unclassified	3	
Act of nature	2	
Confined fire	13	A causal determination cannot be inferred for some types of confined fires, particularly rubbish fires.
Emphasis on Equipment Based on Equipment Involved in Ignition, with Some Subgrouping Done by NFPA		
No equipment involved	39	
Range or cooking surface	14	More often than not, the equipment involved in ignition was used improperly.
Confined cooking fire	8	One can infer that some type of cooking equipment was involved in confined cooking fires; the type of cooking equipment is unknown.
Fixed wiring, switch, or outlet	4	
Clothes dryer or washer	4	
Oven or rotisserie	3	
Fireplace or chimney	3	
Confined chimney fire	3	One can infer that some type of chimney was involved in confined chimney fires.
Emphasis on Behavior Based on Factor Contributing to Ignition Originally Collected in Version 5.0 of NFIRS		
Short circuit or other electrical malfunction	18	
Heat source too close to combustibles	12	
Abandoned or discarded materials or products	8	This often refers to smoking materials.
Confined cooking fire	8	
Equipment unattended	7	
Unclassified misuse of material or product	6	
Unclassified factor contributed to ignition	6	
Exposure fire	5	
Unclassified mechanical failure or malfunction	4	
Playing with heat source	4	
Confined chimney fire	3	
Emphasis on Heat Source		
Radiated or conducted heat from operating equipment	27	Equipment power source is a separate field.
Arcing	12	
Confined cooking fire	8	Although the exact heat source is generally not captured for confined fires, some heat sources can largely be ruled out for the confined equipment fires.
Unclassified heat from powered equipment	7	
Smoking materials	7	Statistics on open flame and smoking materials, including matches, lighters, and candles, include a proportional share of fires in which the heat source was coded as "heat from other open flame or smoking material."
Candle	5	
Spark, ember, or flame from operating equipment	5	
Unclassified hot or smoldering object	4	
Match	4	
Unclassified heat source	3	
Lighter	3	
Confined chimney fire	3	

TABLE 3.4.7 Continued

Description of Cause	*Percentages*	
Emphasis on Item First Ignited		
Cooking materials, including food	16	
Confined cooking fire	8	It seems reasonable to infer that confined cooking fires began with food or cooking materials.
Structural member or framing	8	
Electrical wire or cable insulation	6	
Mattress or bedding	5	NFPA generally groups mattresses and bedding together because they function as one system.
Rubbish, trash, or waste	5	
Unclassified	4	
Exterior wall covering or finish	4	
Interior wall covering, excluding drapes	4	
Clothing	3	
Confined chimney fire	3	One could also infer that these confined chimney fires started with creosote.
Flammable or combustible liquid or gas, filter, or piping	3	This also represents a grouping of codes as some of the specific choices were not available in earlier versions of NFIRS.
Multiple items first ignited	3	
Upholstered furniture or vehicle seat	3	
Multidimensional Summary of Causes from Different Data Elements		
Cooking equipment fire	28	Note that subcategories can be nested below the main category.
Identified cooking equipment	20	Identified cooking equipment and heating equipment include fires with unclassified kitchen and cooking equipment and unclassified heating and air-conditioning equipment.
Confined cooking fire	8	
Heating equipment	14	
Identified heating equipment	11	
Confined chimney or flue fire	3	
Confined fuel burner or boiler malfunction or fire	1	
Intentional	9	
Electrical distribution or lighting equipment	9	
Smoking materials	7	
Candle	5	
Exposure to other fire	4	
Playing with heat source	4	
Clothes dryer or washer	4	

Note: Percentages represent national estimates of fires reported to U.S. municipal fire departments and, therefore, exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections.

Source: NFIRS and NFPA survey.

approach avoids the tendency, in the one-dimensional scenario, for major problems to be mixed together or disguised. The use of even two dimensions from NFIRS, however—or the use of three dimensions with the first digit only, where appropriate—can create thousands of cause categories, and again one is faced with the likelihood that even the largest parts of the total will not represent a very large share of the total.

Broad Cause Categories. The fourth approach has been to use a small number of major, easily recognizable categories based on the causal data elements but not necessarily grouped along the lines laid out in the NFIRS coding structure. Historically, the most widely used scheme based on this approach was a set of 13 categories developed at the USFA. This scheme used a hierarchical process to sort fires into categories. Priorities were established to assign each fire to one of the specific cause categories. For example, an incendiary fire started by a cigarette was counted as incendiary and not counted as caused by smoking materials. If cooking equipment were involved in a fire with heat source of radiated heat, the fire was counted as caused by cooking equipment. Fires resulting from radiant heat that did not fit into other cause categories were counted as exposures. When some type of equipment is said to be involved in ignition or the cause of fire, it means that the equipment provided the heat to ignite the fire. More often than not, human error was involved. Unattended cooking is a far more frequent cause of cooking equipment fires than defective equipment.[30]

Criticisms of this or any other hierarchical sorting approach focus on the reasonableness of the sorting priorities and the usefulness of the categories produced. If a fire is caused by a child playing with cigarettes, should that be categorized as a child playing with fire or a smoking-related fire? A revised cause hierarchy was developed for the transition years of Version 5.0 of NFIRS. As larger shares of the data were originally collected in Version 5.0, it became increasingly clear that the new hierarchy was no longer as effective. NFPA has started to produce tables showing a summary of the leading causes extracted from multiple data elements. However, these causes are not all mutually exclusive and some double counting does occur. Table 3.4.8 shows the leading causes of structure fires in homes during 1999 to 2002.[31]

Top-Down Refinement Along Causal Factors. Another approach, which can be used as a refinement of any of the others, applies the top-down approach to one dimension. Table 3.4.9 shows this approach applied to item first ignited in 1999–2002 home structure fires, including confined structure fires. Inferences were made about the item first ignited in these confined fires (organic materials for confined cooking fires; general materials for contained trash fires, confined incinerator fires, and confined commercial compactor fires; and liquids, gases, filters, or piping for confined fuel burner or boiler fires). Sums were calculated for the broad categories—organic materials, structural component or finish, general materials, and so on. Specific items within each category are shown if they accounted for at least 1 percent of the fires. This approach can be used with

TABLE 3.4.8 Leading Causes of Structure Fires in Homes, 1999–2002 Annual Averages

Cause	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*		*Civilian Deaths per 100 Fires*	*Average Dollar Loss per Fire*
Cooking equipment fire	105,400	(28%)	270	(9%)	4,230	(28%)	519	(10%)	0.3	4,900
Identified cooking equipment	75,600	(20%)	270	(9%)	3,750	(25%)	509	(9%)	0.4	6,700
Confined cooking fire	29,800	(8%)	0	(0%)	470	(3%)	10	(0%)	0.0	300

Smoking materials	24,800	(7%)	850	(29%)	1,900	(12%)	455	(8%)	3.4	18,300
Candle	18,200	(5%)	160	(5%)	1,640	(11%)	392	(7%)	0.9	21,500
Exposure to other fire	15,800	(4%)	30	(1%)	90	(1%)	319	(6%)	0.2	20,200
Playing with heat source	14,000	(4%)	220	(8%)	1,360	(9%)	249	(5%)	1.6	17,800
Clothes dryer or washer	13,400	(4%)	10	(0%)	280	(2%)	98	(2%)	0.1	7,300

Note: These are the leading causes, obtained from the following list: intentional (from the NFIRS field "cause"); playing with fire (from factor contributing to ignition); confined heating (including confined chimney and confined fuel burner or boiler fires), confined cooking, and contained trash or rubbish from incident type; identified heating, identified cooking, clothes dryer or washer, torch (including burner and soldering iron), electrical distribution and lighting equipment, medical equipment, and electronic, office, or entertainment equipment (from equipment involved in ignition); smoking materials, candles, lightning, and spontaneous combustion or chemical reaction(from heat source), and mobile property involved (from mobile property involved in ignition). The statistics on smoking materials and candles include a proportional share of fires in which the heat source was heat from an unclassified open flame or smoking material. Exposure fires include fires with an exposure number greater than zero, as well as fires identified by heat source or factor contributing to ignition when no equipment was involved in ignition and the fires were not intentionally set. Because contained trash or rubbish fires are a scenario without causal information, they are shown at the bottom of the table if they account for at least 2 percent of the fires. Causal information is not routinely collected for these incidents. The same fire can be listed under multiple causes, based on multiple data elements.

These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest ten, and direct property damage is rounded to the nearest million. Property damage has not been adjusted for inflation.

TABLE 3.4.9 Structure Fires in Homes by Item First Ignited, 1999–2002 Annual Averages

Item First Ignited	*Fires*		*Civilian Deaths*		*Civilian Injuries*		*Direct Property Damage (in Millions of Dollars)*	
Organic materials	93,700	(25%)	150	(5%)	3,650	(24%)	355	(7%)
Cooking materials, including food	59,600	(16%)	140	(5%)	3,110	(20%)	296	(6%)
Confined cooking fire	29,800	(8%)	0	(0%)	470	(3%)	10	(0%)
Light vegetation, including grass	2,000	(1%)	0	(0%)	20	(0%)	25	(0%)
Structural component or finish	87,700	(24%)	580	(20%)	2,090	(14%)	2,219	(41%)
Structural member or framing	29,300	(8%)	210	(7%)	610	(4%)	917	(17%)
Exterior wall covering or finish	14,900	(4%)	30	(1%)	190	(1%)	281	(5%)
Interior wall covering, excluding drapes	13,100	(4%)	140	(5%)	510	(3%)	321	(6%)
Floor covering, rug, carpet, or mat	8,100	(2%)	110	(4%)	350	(2%)	159	(3%)
Insulation within structural area	5,200	(1%)	10	(0%)	90	(1%)	71	(1%)
Exterior roof covering or finish	3,700	(1%)	0	(0%)	40	(0%)	118	(2%)
Exterior trim, including doors	3,400	(1%)	10	(0%)	40	(0%)	51	(1%)
Interior ceiling cover or finish	2,500	(1%)	10	(0%)	60	(0%)	56	(1%)
Unclassified structural component or finish	7,500	(2%)	60	(2%)	200	(1%)	245	(5%)
General materials	78,500	(21%)	400	(14%)	1,750	(11%)	923	(17%)
Electrical wire or cable insulation	23,500	(6%)	90	(3%)	480	(3%)	297	(6%)
Rubbish, trash, or waste	17,400	(5%)	50	(2%)	360	(2%)	135	(3%)
Confined chimney fire	10,600	(3%)	0	(0%)	10	(0%)	7	(0%)
Multiple items first ignited	10,500	(3%)	190	(6%)	480	(3%)	350	(6%)
Magazine, newspaper, or writing paper	4,600	(1%)	60	(2%)	230	(2%)	71	(1%)
Contained trash or rubbish fire	4,600	(1%)	0	(0%)	20	(0%)	1	(0%)
Dust, fiber, lint, sawdust, or excelsior	4,300	(1%)	0	(0%)	70	(0%)	26	(0%)
Soft goods or wearing apparel	42,400	(11%)	710	(24%)	3,430	(22%)	683	(13%)
Mattress or bedding	18,000	(5%)	410	(14%)	2,000	(13%)	358	(7%)
Clothing	13,000	(3%)	200	(7%)	780	(5%)	160	(3%)
Curtains, blinds, drapes, or tapestry	3,600	(1%)	20	(1%)	280	(2%)	57	(1%)
Linen other than bedding	3,400	(1%)	20	(1%)	140	(1%)	33	(1%)
Unclassified soft goods or wearing apparel	3,900	(1%)	60	(2%)	200	(1%)	66	(1%)
Furniture or utensils	30,300	(8%)	770	(26%)	2,360	(15%)	634	(12%)
Upholstered furniture or vehicle seat	10,200	(3%)	560	(19%)	1,130	(7%)	283	(5%)
Cabinetry, including built-in	6,900	(2%)	40	(1%)	400	(3%)	136	(3%)
Appliance housing or casing	4,900	(1%)	20	(1%)	180	(1%)	50	(1%)
Unclassified furniture or utensils	6,000	(2%)	130	(5%)	530	(3%)	136	(3%)
Liquid, gas, filter, or piping	13,400	(4%)	170	(6%)	1,000	(7%)	246	(5%)
Flammable or combustible liquid or gas, filter, or piping	10,500	(3%)	170	(6%)	980	(6%)	244	(5%)
Confined fuel burner or boiler fire	2,900	(1%)	0	(0%)	10	(0%)	2	(0%)
Storage supplies	6,500	(2%)	40	(1%)	260	(2%)	90	(2%)
Box, carton, bag, basket, or barrel	4,300	(1%)	30	(1%)	190	(1%)	64	(1%)
Adornment, recreational material, or signs	3,800	(1%)	30	(1%)	220	(1%)	63	(1%)
Unclassified	16,700	(4%)	120	(4%)	550	(4%)	171	(3%)
Total	372,900	(100%)	2,960	(100%)	15,300	(100%)	5,383	(100%)

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, civilian deaths and injuries are rounded to the nearest ten, and direct property damage is rounded to the nearest million dollars. Property damage has not been adjusted for inflation. Nonconfined and noncontained structure fires in which the item first ignited was unknown or not reported have been allocated proportionally among fires with known item first ignited. Totals may not equal sums due to rounding errors.

Source: NFIRS and NFPA survey.

any data element or element combination structured to provide greater or lesser detail, including property use (occupancy), heat source, equipment involved in ignition, area of origin, and factor contributing to ignition. Individuals interested in fires in home properties may be interested in all of these properties, or they may prefer to focus on fires in one- and two-family dwellings and to omit apartments. Nesting represents the top-down approach at its best—it provides usable levels of detail without sacrificing an overview of the largest parts of the total.

Handling Fires with Unknown or Unreported Data

Another matter to consider when analyzing fire data is how to handle incidents for which some data were unknown or unreported. A sizable share of fires is reported with missing or incomplete information. In the nonconfined home structure fires in Table 3.4.9, the item first ignited was undetermined or not reported in 21 percent of the nonconfined fires, 39 percent of the civilian deaths, 18 percent of the civilian fire injuries, and 30 percent of the direct property damage. Severe fires, particularly those that result in fatalities or unusually large losses, tend to have larger shares of unknown data. A calculation of percentages based only on cases with known data implicitly assumes (in the absence of contrary evidence) that the profile of the fires reported with unknown or missing data would look the same (if the data were known) as the profile of the fires reported with known causes. This assumption was made for Table 3.4.9.

Why is it desirable to allocate unknowns? Suppose two neighboring states have relative profiles that look the same, except that fire deaths due to unknown data appear as 14 percent in one state and 43 percent in the other. Table 3.4.10 shows the results. State B seems to be doing better than State A with respect to every known cause, but if unknowns are allocated, both states have the same problems to the same degree. If it is necessary or desirable to compare two groups, differences in the proportions of the unknowns need to be taken into consideration.

Why is it difficult to allocate unknowns? There are many reasons. One reason is that no one particular method of allocating the unknowns has been shown to be the "best." Fire data analysts have generally chosen to allocate unknowns over known data, as it is a simple solution to this potentially difficult problem. And, in the absence of another methodology, it has been generally accepted as reasonable. A study underway by the USFA to investigate the causes of unknown-cause fatal fires may shed light on the validity of this method of allocation. Moreover, this methodology is not without its detractions as some fire data analysts maintain that there is often enough information provided by the data to make other equally reasonable assumptions on how to allocate the unknown: time of day, size of fire, and property type are examples of data items that can be used to allocate the unknown across causes. Regardless of the method of allocation, it is the analyst's responsibility to both specify the allocation scheme and support the rationale behind it.

TABLE 3.4.10 The Problem of Comparisons with Unallocated Unknown Cause Fires

	Percentage of Home Fires	
Cause	*State A*	*State B*
Intentional	9	6
Unintentional	50	33
Failure of equipment or heat source	21	14
Act of nature	3	2
Other	3	2
Undetermined, under investigation, or not reported	14	43

Handling Fires with Unknown Causal Factors. As mentioned previously, NFIRS does not require causal information for certain types of confined structure fires and for outdoor rubbish fires. Table 3.4.11 shows the numbers and percentages of confined fires by incident type for the years 1999 to 2003. The percentage of structure fires that are confined increased from 2.8 percent in 1999 to 34.2 percent in 2003. A large portion of the increase is attributed to the increase of fire departments reporting incidents using NFIRS Version 5.0. In the future when all departments are reporting incidents using only NFIRS Version 5.0, it is expected that the percentages of structure fires that are confined each year will eventually plateau. The number of confined fires is large enough that they cannot be ignored.

Although these incidents generally lack causal data, some information can reasonably be inferred based on the incident types. NFPA had initially inferred information for several data elements, treating the inferred values as "known." This approach had problems. No other scenario was without unknown data. Treating them as known and adding a proportional share of the completely unknown data to them resulted in artificially large estimates. In addition, analysis of confined fires with causal data showed more variation than expected. Many analysts now use a three-step process for structure fire data that are not collected for confined fires. First, unknown data are allocated proportionally across the known nonconfined data. Second, the confined fire categories are added to the list of categories (individually or as a group) in each data element. And, third, percentages are calculated based on the total of confined and nonconfined fires.

A further observation on allocation is offered: Causal information can be more difficult to obtain in the largest fires, as more of the evidence of fire origin is destroyed. Known-cause fires indicate that cause profiles are different for larger versus smaller fires. For example, Table 3.4.8 shows that intentionally set fires, fires started by candles, and electrical distribution or lighting equipment fires result in the largest average property loss per fire, and fires started by smoking materials, intentional fires, and fires started by someone (usually a child) playing with a heat source result in the highest rates of civilian fire death per 100 fires. Therefore, if unknowns are to be allocated, the allocation ideally should take into account the cause profiles for fires of comparable size. This isue is another fire data analysis issue around which no consensus has yet formed. The ideal solution would be to find ways to reduce the rate of unknowns, but there also may be better ways to arrive at estimates in the face of the unknowns that do exist.

In the single-digit cause codes used in NFIRS 5.0, a distinction is made between "cause under investigation" and "cause undetermined after investigation." For analysis purposes, both of these may be considered unknown.

Allocating Partial Unknowns. Many data elements have categories that can be considered "partial unknowns." Equipment involved in ignition codes includes choices such as "other heating or air-conditioning equipment"; "other electrical distribution, lighting, or power transfer equipment"; "other kitchen and cooking equipment," and so on. Some of these "other" entries are true "others" with no appropriate code choice. The "other" codes tend to also include fires for which incomplete information was known. A fire official may have known that a cooking or heating appliance was involved in the ignition but be uncertain about the exact type of equipment. If these "others" are not allocated proportionally among the equipment category, the share of each equipment involved would be undercounted. Proportional allocation of these "other" codes may result in a somewhat inflated estimate. Some analyses include the allocation of these partial unknowns. NFPA now routinely uses this approach with heat source code 60, "other open flame or smoking material." Without this secondary allocation, intentional overtakes smoking materials as the leading cause of home fire deaths. Prior to Version 5.0, open flame and smoking materials were in separate categories. The trend line seems more consistent with this approach, but it is also clear that some incidents were allocated that were, in fact, unclassified or "other."

The data element, "factor contributing to ignition," has a code for "none." This code seems to be used as an alternative to "undetermined." For this multiple-entry field, NFPA treats "none," "undetermined," and "not reported" as unknowns. Because multiple entries are allowed, the scaling ratio to allocate unknowns is total/(total-none-undetermined-not reported). The known values are multiplied by this ratio to obtain allocated estimates. The nested Table 3.4.12 shows this approach used for highway vehicle fires. Due to conversion issues, it is advisable to use only data collected originally in Version 5.0 when working with this data element. When this approach is used with structure fires, nonconfined fires should be analyzed separately from the confined fires.

"Skip patterns" or blanks in nonrequired data elements also pose challenges when allocating unknowns. Factor contributing to ignition is not required for intentional fires but is sometimes completed. Type of material ignited is not required when organic or general materials (item first ignited codes 70–99) were the items first ignited, but information may be entered. To allocate unknown data across the type of material ignited in nonconfined structure fires, NFPA calculated the scaling ratio as (total – fires with organic item or general item first ignited and no type of material ignited reported)/(total – fires with type of material ignited reported undetermined or not reported – fires with organic item or general item first ignited and no type of material ignited reported).

Extreme Values. Any discussion of total fire fatalities and fire losses that encompass 2001 must indicate whether the events of September 11, 2001, are included. If included in an analysis of office building fires, losses from other causes would seem insignificant. Many analysts elect to exclude incidents with exceptionally large losses from the calculations but discuss them in the text and notes. NFPA's tables usually include this statement in the notes: "Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire." With projections, an extreme value is multiplied.

Coding Inconsistencies and Errors. The quality of any analysis is dependent on the quality of the data used. Sometimes analysts decide to exclude values that seem obviously inconsistent or unlikely. An analysis of response times might exclude any response times longer than an hour. An analysis of upholstered furniture might exclude fires in which the item first ignited was upholstered furniture, but the type of material first ignited was paper or gasoline. The type of material first ignited is intended to provide more detail about the item first ignited.

TABLE 3.4.11 Confined Structure Fires Reported to NFIRS by Incident Type, 1999–2003

	1999 Fires		2000 Fires		2001 Fires		2002 Fires		2003 Fires	
Incident Type	*Number*	*Percent*	*Number*	*Percent*	*Number*	*Percent*	*Number*	*Percent*	*Number*	*Percent*
113 Cooking	804	0.9	5,049	3.0	18,576	9.8	29,706	14.2	56,453	20.4

Failure to clean	1	0	0	0
Unclassified or unknown-type operational deficiency	2	1	3	1
Fire spread or control	**6**	**5**	**4**	**11**
Exposure fire	6	3	3	11
Design, manufacturing, or installation deficiency	**1**	**0**	**1**	**2**
Installation deficiency	1	0	1	0
Natural condition	**0**	**1**	**1**	**1**
Unclassified factor contributed	**6**	**12**	**7**	**10**

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. More than one factor contributing to ignition could be entered. Fires, in which the factor contributing to ignition was undetermined, not reported, or coded as "none" were allocated proportionally among fires with known factor contributing to ignition. Although this field is not required for fires that were coded as intentionally set or attributed to a cause of "other," the share of incidents with unreported data (fires, 17%; deaths, 22%; injuries, 10%; property damage, 27%) or fires with "none" (fires, 28%; deaths, 16%; injuries, 19%; property damage, 27%) generally exceeded those for undetermined (fires, 11%; deaths, 11%; injuries, 10%; property damage, 13%) suggesting that this type of allocation would be most appropriate. Except for the group headings, only factors contributing that accounted for at least 1 percent of the fires are shown. Groups are shown in descending order, and within groups, factors exceeding 1 percent are also shown in descending order. Unclassified type factors are shown last. Group sums include all factors within the group, even when the factors were under 1 percent and, consequently, not shown.

Source: NFIRS and NFPA survey.

It is important to remember that the NFIRS report generally serves as the fire department report of an incident. From a purely descriptive sense, the inconsistent coding may better serve the fire department's needs. It is also important to remember that errors seldom go in one direction only. To get a fair picture of a product's fire experience, if one omits the fires that seem to have been incorrectly included, one should also add the fires that were incorrectly excluded.

Analysis of Small Data Sets

A problem can arise in the size of the database available for analyses aimed at particular property uses. In 2004, according to NFPA, all nonresidential structures combined accounted for 115,500 fires, 80 civilian deaths, 1350 civilian injuries, and $2.4 billion in property damage.[32] Typically, roughly half to two-thirds of all fires are represented in the NFIRS, which has individual incident reports and can be used to analyze patterns by specific property use. For some property uses, the number of reported fires is low enough to make detailed analysis difficult or, in some cases, pointless. Often information is needed about some part of, or problem in, a particular occupancy, such as prison cells, hospital operating rooms, auditorium areas in theaters, or school hallways. In some cases, it may be possible to include other similar occupancies or related causal factors to expand the pool of incidents. It may be prudent to provide a less detailed analysis. In other cases, it may be more appropriate to extend the length of time studied.

Some fluctuations occur normally; one large incident can artificially inflate the casualties or dollar loss. It may seem logical to use the number of fire deaths as a measure of success for a public fire education program. However, the numbers at the state and local level are generally not big enough to do so with confidence. To minimize the year-to-year variability, NFPA produces annual averages for most analyses. The USFA also uses multiyear data in its analyses for the same reason.

Introduction to Location-Based Fire Data Analysis

As mentioned earlier in this chapter, the increase in computing power has enabled sophisticated analysis of fire incident data at the local level in ways that would have been impractical, if not impossible, just a few years ago. One of the most exciting new approaches now accessible to many jurisdictions is the use of geographical information systems (GIS) for location-based analysis.

Previous efforts at a more targeted, location-based description of the fire situation have centered on fire station or district-level groupings of data. However, this tends to blur differences among neighborhoods of differing characteristics. By geocoding fire incident data, one is able to examine groups of incidents at the census tract (approximately 500–3500 people), block group, or even block levels.

What is meant by geocoding data? For our purposes, geocoding is the process of assigning an absolute location to a fire incident report. This information could be as simple as street address or zip code or as detailed as high-resolution latitude/longitude. This location can then be associated with a variety of other location-based data sets, including census tracts, fire districts, or political boundaries.

The process of geocoding incidents is fairly straightforward. For most structure fires, simply an accurately entered address will be all the information needed for processing with off-the-shelf geocoding software. The software will assign any of a number of attributes to the incident, including latitude/longitude and census tract/block group data. The types of data could include demographics such as age distribution, race/ethnicity, education level, income, residential occupancy rates, and information on the housing stock. Once this has been accomplished, the number of fires, types of fires, casualties, and any other type of incident that is collected can be identified for each census area.

Grouping these data at various levels paints different pictures of a city's fire experience. Combined with the all-incident reporting of NFIRS 5.0, location-based, rather than fire station–based, reporting may be of great interest. With well-scrubbed data, local analysis as fine as the census track/block group may be possible.

By doing this, area-specific trends and issues can be identified. Are false alarms a problem in a neighborhood? Is one area of the city experiencing a higher rate of arson? What is the expected rate of fire for a particular city? How does it vary across the city? How do neighborhoods of certain demographic attributes compare with other neighborhoods within the city and even across different cities?

It is possible to identify high densities of at-risk populations, such as the very young and very old. Limited prevention resources can be targeted at the areas where they will do the most good instead of a broad approach to public education.

Although many of these issues are intuitively obvious, in the current arena of backing dollars with facts, it is imperative that the fire service quantify the needs for its services, both for response and prevention. This approach makes it possible to say more than "Arson is a problem in poor areas of the city." The data could justify or refute statements such as "People in these sections of the city are at twice the risk for residential arson as the rest of the city."

For this approach to work, it is necessary to implement and maintain quality control procedures when entering location data. Some departments have location data (latitude/longitude) automatically associated with each dispatch. This method simplifies matters greatly and facilitates analysis of nonstructure incidents for which there might not be suitable address data.

Resources necessary for location-based fire data analysis include the following:

- Good-quality fire incident data
- Census data
- GIS application
- Locally produced data sets
- Good PC/spreadsheet-type skills

Many municipalities have GIS shops already working in offices such as transportation, planning, and zoning. It may be possible to dovetail fire-location-based analysis with existing GIS efforts. Otherwise, a reasonably literate computer user can be trained on introductory-level GIS skills in a relatively short time.

Rates and Measures of Fire Risk

The use of rates is another means to provide a context or make comparisons across groups or time. A rate is a ratio consisting of a measure of the size of a fire problem divided by a measure of the size of the group affected by that problem.

In 2004, the United States suffered 13 civilian fire deaths per million population. That is a rate consisting of the estimated number of civilian fire deaths (3900) divided by the estimated resident population, or number of people who live in the United States (293,655,000), divided by 1 million. In 2004, the average fire-related property loss in rural communities was $82 per person per year.[32] That is a ratio consisting of the total property damage in rural communities divided by the number of people living in those communities.

Rates provide measures of fire risk. They can be used, therefore, in any analysis where the size of the group affected by a problem may change. For example, as has been said, the United States suffered 13 civilian fire deaths per million population in 2004. Because the total population growth adds almost 3 million people to the population each year, the number of civilian fire fatalities will be about 33 deaths higher each year unless increased fire safety lowers the rate.

NFPA estimates that annual fire deaths fell 40 percent from 1980 through 2004. During the same time, the resident population grew 29 percent. The resulting change in deaths per million population was a decrease of 54 percent. Increased fire safety may be best measured by the decline in the fire death rate, as this rate takes into account both changes in the absolute number of fire deaths and changes in the population.

Risk measures do the best job of bringing the fire problem down to a personal level. Rural communities do not account for a majority of the country's fire deaths, but they have by far the highest fire death rates compared to communities of larger size.[32] Person for person, their citizens are in the most danger from fire. People 65 years of age or older face twice the risk of dying in a fire as do members of the general population.[33] An individual wants to know his or her own risk, not the risk to an average American. Barring that, he or she wants to know the risk for people as much like him or her as possible. Risk measured for specifically defined groups provides that information.

Risk measured by rates is of particular interest if there is the potential for large-scale shifts from one group to another of substantially higher or lower risk. In the early 1980s, analysts determined that solid-fueled heating devices, principally wood-burning stoves, accounted for an unusually high risk; that is, there was a high ratio of fires involving those devices divided by homes using those devices.[34] At the time, it appeared that the generation-long decline in use of these devices was about to be reversed, under the pressure of higher prices for oil and natural gas. This was an ideal opportunity to use data to guide action; at a time when decisions were being made, most people did not know the unusual dangers posed by their choices. As an example of risk moving in the other direction, analysts using fire incident data from the early growth years of smoke-alarm usage were able to demonstrate that the rate of deaths per home fire was just over half as great for homes with smoke alarms as for homes without them.[35] Here again, decisions with substantial impact on risk were being made regarding equipment; therefore, it was possible to get people's attention and encourage the move toward smoke alarms.

Getting Information Needed to Calculate Rates. For some analyses, it may be difficult or impossible to obtain the information needed to construct the appropriate rate. One example is an analysis comparing the dangers of fire fighting with risks of other professions. The ratio should be number of on-duty fire service deaths to number of hours of exposure by fire fighters. The latter number cannot be easily calculated, however, because no one has national statistics on how many hours volunteer fire fighters serve. Also, differences in workweek need to be considered for career fire service personnel.

Another example is a comparison of fire fatality risks in homes versus those in hotels. Numbers of persons cannot be used for both, because length of stay is obviously much shorter for hotels than for homes. Numbers of units might work better if one could obtain those data and if occupancy rates could be addressed by a single parameter estimate. The problems of selecting the right denominator and obtaining data for it usually can be solved to some degree of acceptability, but the process is often complex and challenging.

Another problem in constructing rates can occur if the group of interest is defined too narrowly. A household, for example, might like to be able to calculate a risk index that reflects its smoking and drinking habits, its number of children, the ages of its members, its types of equipment and how they are fueled or powered, and many other characteristics. Today this would pose an insoluble problem. There are not enough data to calculate the numbers of households with all those characteristics (so there can be no denominator), and the list of descriptors defines a class so narrow that the number of fires experienced by households of that precise type would be very small and subject to considerable statistical uncertainty. One could separately measure the effects of some of these characteristics and then combine the results, but such a calculation would involve modeling assumptions that are already known to be false. Considerable statistical modeling and research will be needed to make progress on questions of this type.

Risk of Fires by Occupancy. Many analyses focus on fires or incidents in specific types of occupancies (i.e., homes, health care, educational, manufacturing, etc.). By combining NFIRS data with the NFPA survey, an estimate for the number of fires in these occupancies can be obtained. These sources do not, however, reveal anything about the risk of fires in these occupancies. A denominator, based on the number of units or establishments, is required to calculate risk. NFIRS users from outside the fire service may be more familiar with the North American Industry Classification System (NAICS) codes, released in 1997 and updated in 2002, or the older Standard Industrial Classification (SIC) codes.[36] Data on the number of establishments of a certain occupancy type would most likely be collected according to the NAICS codes. Table 3.4.13 shows the sectors that are included. Each sector is further divided into subsectors, industry groups, the NAICS industry, and the national industry.

Challenges abound when two data sources are combined, and the users must remember the differences in original goals for each of the data sources. The property use codes in NFIRS describe the setting the fire department encountered; the NAICS codes describe businesses or related entities. Consequently, many of the codes will not line up neatly with each other, particularly when one business has multiple property uses, such as a parking lot, storage shed, and an office building.

TABLE 3.4.13 NAICS Codes Compared to NFIRS Property Use Codes

NAICS Sector	*NAICS Name*	*NFIRS Code*	*NFIRS Property Use*
11	Agriculture, forestry, fishing, and hunting	655	Crop or orchard
		659	Livestock production
		669	Forest, timberland, woodland
21	Mining	679	Mine or quarry
22	Utilities	610	Other energy production plant
		614	Steam or heat generating plant
		615	Electric generating plant
		642	Electrical distribution
		647	Water utility
		640	Other utility or distribution system
23	NA	NNN	None
31	Manufacturing	700[a]	Manufacturing or processing[a]
		984	Industrial plant yard area not used for storage
42	Wholesale trade		No separate category for wholesale—see retail
44–45	Retail trade	500[a]	Other mercantile or business[a]
		511	Convenience store
		519	Food and beverage sales
		529	Textile or wearing apparel sales
		539[a]	Household goods, sales, repairs[a]
		549	Specialty shop
		559	Recreational stores
		569[a]	Sale of specialized professional supplies, art supplies, home maintenance services[a]
		571	Service or gas station
		579[a]	Motor vehicle or boat sales, services, or repair[a]
		581	Department or discount store
		580	Other general retail
48–49	Transportation and warehousing	171	Airport passenger terminal or heliport
		173	Bus station
		174	Rapid transit station
		170	Other passenger terminal
		596[a]	Post office or mailing firm[a]
		644	Gas distribution or pipeline
		645	Flammable liquid distribution or pipeline
		816	Grain elevator or silo
		819	Livestock or poultry storage
		839	Refrigerated storage
		849[a]	Outside storage tank[a]
		891	Warehouse
		899[a]	Residential or self-storage units[a]
		800[a]	Other storage[a]
		921	Bridge or trestle
	Transportation and warehousing *(continued)*	922	Tunnel
		941[a]	Open waters, including ports[a]
		972	Aircraft runway
		973	Aircraft taxiway
		974	Aircraft loading area
		982	Pipeline, powerline, or other utility right-of-way[a]
51	Information	151	Library
		183	Movie theater
		185	Radio or television studio
		186	Film or movie production studio
		180[a]	Other studio or theater
		635	Computer center, including computer laboratories
		639	Communications center
		700[a]	Manufacturing (e.g., printing and publishing)
52	Finance and insurance	592[a]	Bank, including ATMs when not part of other structure[a]
		599[a]	Business office[a]
53	Real estate and rental and leasing	599[a]	Business office[a]
			See also Retail section 500–580[a]
54	Professional, scientific, and technical services	593[a]	Veterinary or research office
		599	Business office[a]
		629[a]	Laboratory or science laboratory
55	Management of companies and enterprises	592[a]	Bank, including ATMs when not part of other structure[a]
		599[a]	Business office[a]
56	Administrative and support services	599[a]	Business office[a]
		648	Sanitation utility
		919	Dump or sanitary landfill
61	Educational services	213	Elementary school, including kindergarten
		215	Middle, junior, and high school
		210	Other nonadult school
		241	Adult education center or college classroom
		200[a]	Other educational
62	Health care and social assistance	211	Preschool, not in same facility with other grades
		254	Day care in commercial property
		255	Day care in residential property, licensed
		256	Day care in residential property, unlicensed

Analysts calculating risk trends by occupancy will need to remember that the older SIC code data have been converted to the extent possible. With conversions in both the numerator and denominator, analysts should proceed cautiously.

Using Data to Identify Trends

Although most of the analyses described previously provide a "snapshot" of the fire problem, some questions need a "moving picture." Is a part of the fire problem getting better or worse? Is the character of the fire problem changing? If changes are occurring, do they track with corresponding changes in product use, property use, fire service practices, fire prevention activities, codes and regulations, or other elements of the environment? (For this last question, one may need a full-fledged strategy or program analysis, as described later in this chapter, under "Using Data in Program and Strategy Analysis.")

All trend analyses must address the question of whether or not the past is a consistent guide to the present, let alone the future. It would be nice to be able to say that a trend indicates whether fire risk is going up or coming down. However, a simple trend calculation may not provide this information if the base of comparison has been shifting during the years covered. For example, start with a calculation of the number of fire deaths per year in manufactured homes. If the number dropped over time, that might mean that manufactured homes were becoming safer or it might mean that fewer people were choosing to live in manufactured homes. A trend calculation based on the number of fire deaths per million people living in manufactured homes would factor out the latter possibility and do a better job of showing whether manufactured homes were becoming safer. This is an example of how rates (discussed earlier) are also effective measures when examining trends.

Another problem in trend calculations might be a shift in the sampling technique used to create the database. Suppose that while analyzing fire deaths per million population, as in the previous paragraph, another state was added to the database in the middle of the trend period. The increase in the number of persons would not by itself bias the results because, all other things being equal, numbers of deaths and persons would rise together. But all other things may not be equal. If that state has an unusually large percentage of households living in manufactured homes, it could exert a sizable influence on the result. Similarly, any major differences in climate, income, educational levels, and other such factors could have an impact. There would be no way to know how much of any change was due to changes in manufactured home fire safety and how much was due to the addition of a new state to the database.

As mentioned previously, trend analysis involving data collected by NFIRS 5.0 and earlier versions may be misleading. The change from SIC codes to the NAICS codes affects some of the establishment counts. These changes necessitate extreme caution in occupancy class risk analysis.

Trends in Fire Fatalities and the Protection of Life. Figure 3.4.4 shows the trend in NFPA's estimates of civilian fire deaths, starting with 1977 when the NFPA survey was upgraded. The National Safety Council (NSC) has been using a consistent estimating procedure based on state health department records of death certificates for a longer period. Its definition has, however, in the past included nonfire burn deaths and still excludes some fire deaths, most notably those involving vehicle accidents, arson, or self-immolations. Their longer trend line (Figure 3.4.5) shows an even longer decline, although there were periods of backsliding. Figure 3.4.6 shows the generally steady decline in the rate of fire deaths per million population from both sources.[37] Although the fire death definitions used by NFPA and the NSC vary slightly, the two trend lines are quite similar. The death certificate data shown by the NSC indicate that unintentional fire deaths in 2004 were roughly three-fifths (56%) lower than in 1913, whereas the 2004 fire death rate was 86 percent lower than the 1913 rate. Although these percentages should be considered rough estimates because of the definitional changes, the percentages show both the dramatic drop in fire deaths and how different progress can appear if measured by actual numbers or by rates.

Table 3.4.14 shows another approach to tracking by way of the deadliest of the big fires. Not being a graph, it lacks visual impact. Instead, the sense of progress is stated more subtly, as the table shows how much less severe the worst fires of the decade had become until the past 15 years. Figure 3.4.7 shows this relationship graphically with death counts from each of the three fires marked.

By focusing on specific fires, Table 3.4.14 can also serve as an introduction to the kind of extended discussion of turning-point fires (i.e., incidents that triggered changes in our approach

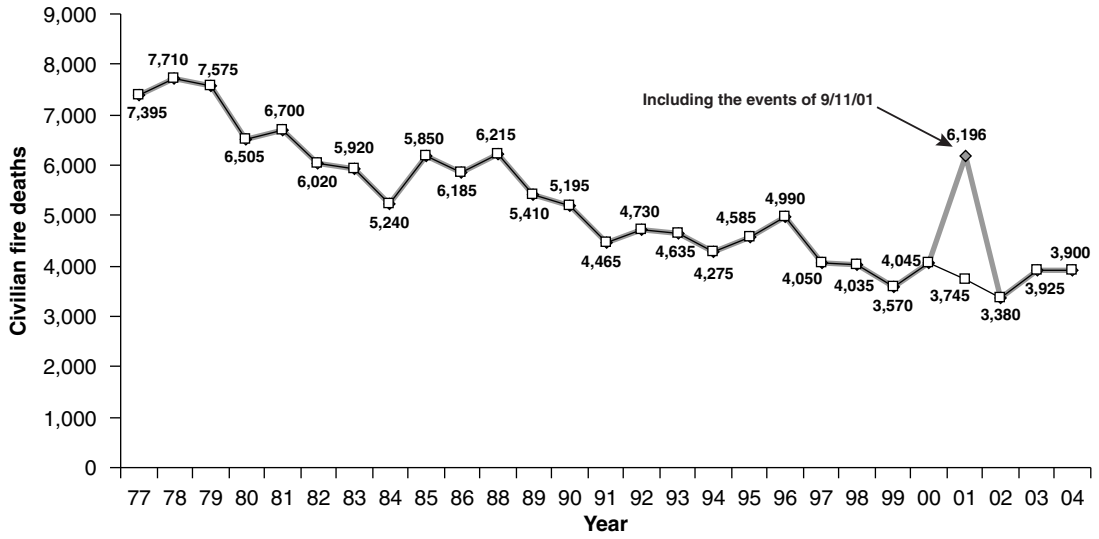

FIGURE 3.4.4 National Estimates of Civilian Fire Deaths (Source: NFPA National Experience Survey)

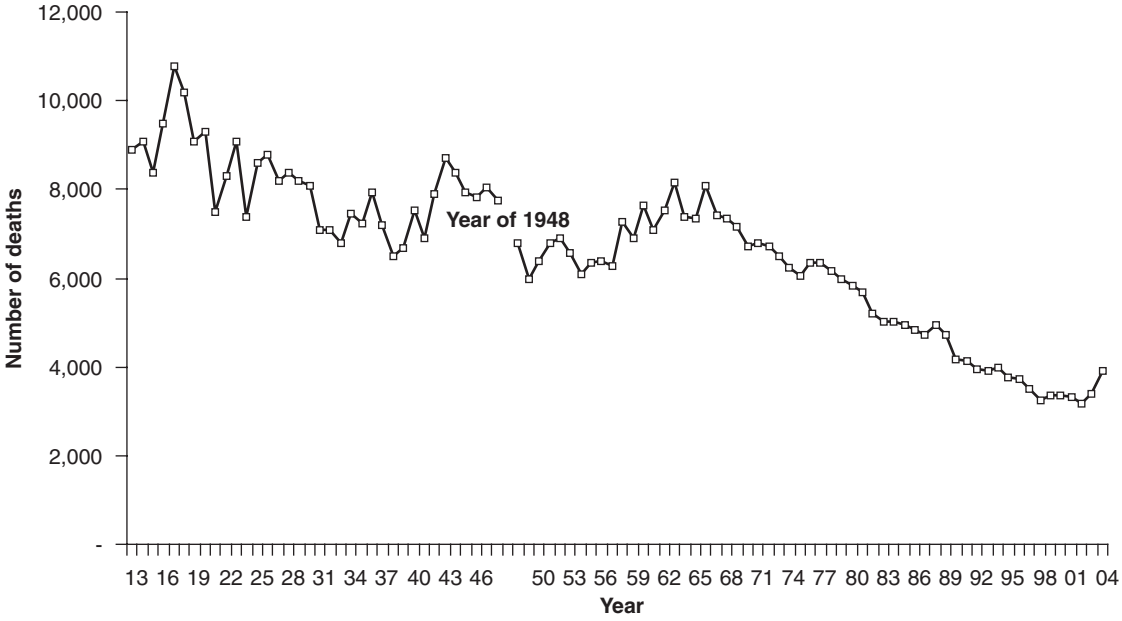

FIGURE 3.4.5 Unintentional Injury Fire Deaths per Year (Death Certificate Data), 1913–2004. Note: Two figures are given for 1948 to reflect old and new methodologies. These are reflected by a break in the graph. Other methodology changes occurred in 1958 and 1968, but different numbers were not provided. (Source: National Safety Council analysis of death certificate data, pp. 42–43[37])

to fire safety that significantly and permanently altered our loss experience, provided in Section 3, Chapter 1, "An Overview of the Fire Problem and Fire Protection"). From a statistical standpoint, it is striking that in almost every decade the deadliest fires tend to include fires that are not building fires, ranging from the ship fires at the start of the century to the airline fires at the end of the century, with forest fires and mine fires occurring throughout the century.

The purpose of statistics is to answer important questions that will help indicate what is needed for fire safety. An interest in major fires is justified by the view that fire codes and standards ought to be able to prevent any really large incidents from occurring. This view is what leads to the phenomenon of one bad fire leading by itself to a set of code changes, because it only takes one fire of sufficient severity to indicate that an objective as stringent as preventing all very large fires has not been met.

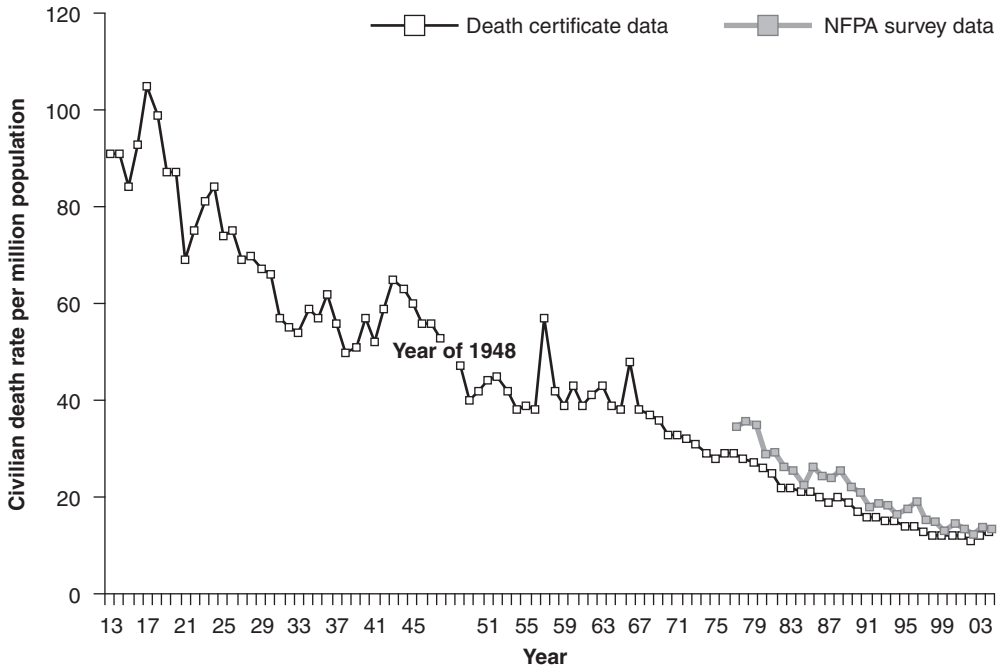

FIGURE 3.4.6 Fire Death Rates per Million Population. Note: Two figures are given for 1948 to reflect old and new methodologies. These are reflected by a break in the graph. Other methodology changes occurred in 1958 and 1968, but different numbers were not provided. Events of September 11, 2001, are not included in this graph. (Source: National Safety Council analysis of death certificate data[29] and NFPA National Fire Experience Survey, pp. 44–45)

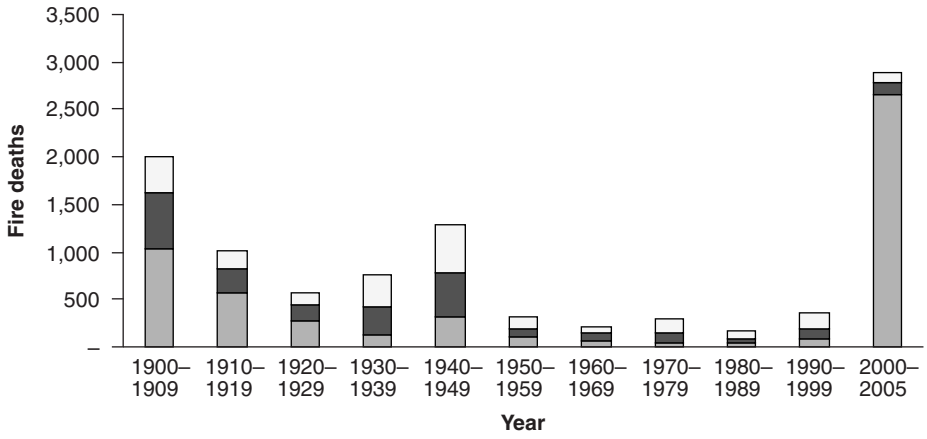

FIGURE 3.4.7 Sum of Fire Deaths from Three Largest U.S. Fatal Fires per Decade (Sources: NFPA archive files; NFPA Fire Incident Data Organization; NFPA 1984 *Fire Almanac;* J. Cornell, *The Great International Disaster Book,* Pocket Books, New York, 1976)

This sequence of events is especially likely to occur if the one bad fire occurs in a place or under circumstances never previously associated with really bad fires, because, in that case, the one bad fire will serve as a sign to many that a particular class of properties, equipment, or activities is not as safe as everyone thought it was.

Because this kind of logic is so common and seems so plausible, it is useful to introduce some cautions. First, fire protection engineering may be thought of as deterministic solutions for a probabilistic world. To put it another way, risk can never be reduced to zero, and it is important that realistic fire safety designs recognize that even the most determined enforcement of

TABLE 3.4.14 Deadliest U.S. Fires and Explosions of the Past Century, Since 1900

Fire	*Number Killed*
2000–2005

the most stringent requirements will not eliminate all possibility of a serious fire.

Second, most fire deaths and other fire losses do not occur in big fires or even in the kinds of places and situations where big fires occur. Big multiple-death fires occur in high-occupancy places, such as large office complexes, hotels, or nightclubs, whereas most fire deaths occur in low-occupancy places, such as dwellings or individual apartment units, and occur as single-fatality fires. Big multiple-death vehicle fires may involve high-occupancy vehicles such as commercial airliners or large ships, whereas most vehicle fire deaths occur in small private vehicles such as cars and trucks.

Finally, it should be obvious from a casual glance at the deadliest fires in the past few decades that the problem often is not that the codes are not tough enough but rather that the adoption is not universal or the enforcement is not effective.

Event-driven changes in fire codes primarily involve the fire community. However, getting those changes adopted into law and backing the law with strong enforcement programs require the cooperation of elected officials and the public, most of whom are concerned about many subjects in addition to fire. Recognizing this, some fire chiefs have prepared legal packages targeted at particular problems in advance, holding them in reserve until a major fire provides the visibility and sense of urgency required for adoption.

In view of this strategy, it is worth noting that "newsworthiness" is not always synonymous with incident severity. Two examples will suffice. The third most deadly fire of the 1960–1969 decade was the Golden Age Nursing Home fire, which killed 63 persons; it occurred, however, on the day after President John F. Kennedy was assassinated. This coincidence of timing sharply reduced the visibility of the fire. By contrast, the 1937 *Hindenburg* zeppelin fire killed "only" 36 persons, a death toll barely a fourth the size of even the third-largest fire of that decade and only one-eighth the size of the New London, Texas, school fire in the same year. The zeppelin fire, however, was broadcast "live" and occurred in full view of newsreel cameras and, therefore, it was probably the most widely heard and seen fatal U.S. fire until the *Challenger* space shuttle explosion in 1986. The *Hindenburg* fire meant the end of the rigid-airship industry.

These examples also have a lesson for analysis of trends in fire deaths, injuries, or incidents. For fires as severe as those discussed in the last few paragraphs, only decade-by-decade comparisons suffice to separate real trends from random ups and downs. For total U.S. civilian fire deaths, year-to-year tracking is generally meaningful. For a single large city, however, year-to-year tracking of fire deaths will be subject to considerable statistical noise; for town and rural areas, there is no good way to track fatality trends except as part of a larger aggregation, such as the state or the rural portion of the entire region.

Trends in Property Damage Due to Fire. The first fire protection standards promulgated by NFPA were directed principally at property protection, reflecting the association's founding by men in the business of insuring property against loss due to fire. Assessments of the success of strategies for property protection are more difficult than for life protection, however, because data on fire damage are subject to several gaps and quirks that do not affect data on fire deaths. Although all indicators of fire—incidents, deaths, injuries, and property damage—are clouded by the absence of information on fires not reported to local fire departments, property damage is the only indicator of severity that is left unreported in a significant minority of reported fires. Estimates of property damage involve more guesswork than estimates of people killed or injured. Some very-large-loss fires are never reported to local fire departments, because the affected firms are able to handle them with on-site resources. No comparable omissions occur among multiple-death fires.

Trend analysis must take into account the effect of inflation. Table 3.4.15 shows NFPA's estimates for total national property damage due to fire during 1994 to 2004, both as published and as recalculated in terms of 2004 dollars, using the U.S. Bureau of Labor Statistics' consumer price index to remove the effects of inflation.[38] Without adjusting for inflation, the direct property damage resulting from fire in 2004 was 20 percent higher than that reported in 1994. After adjusting for inflation, the 2004 property losses were actually 6 percent lower than were reported in 1994. Also significant is the effect of changes in the number of fires, because total damage figures involve the total number of fires and the average dollar loss per fire. The average loss per fire, unadjusted, was 58 percent higher in 2004 than in 1994; the average 2004 loss was only 24 percent higher after adjusting for inflation.

This inflation makes it difficult to compare large-loss experience over several years. In the early 1930s, the NFPA defined a large-loss fire as one involving at least $250,000 in direct property damage. In 1978, a large-loss fire was redefined as one involving at least $500,000, and in the early 1980s the amount became at least $1,000,000 in direct property damage. Each minimum represented the cutoff point for the largest several hundred fires of its time. In the late 1980s, it was decided to shift the large-loss study to a more detailed treatment of a smaller number of fires and, therefore, the threshold was raised to $5,000,000.

Table 3.4.16 lists the costliest fires in U.S. history, sorted by loss in 2004 dollars. Note that the unadjusted losses for four of the top 10 fires—the San Francisco Earthquake and Fire in 1906 (#2), the Great Chicago Fire of 1871 (#3), the Great Boston Fire of 1872 (#5), the Baltimore Conflagration of 1904 (#9)—were below the threshold for inclusion in 2004 dollars. In studying the table, one might note that 12 of the 25 fires on the list occurred since 1990, 7 of the 25 were wildland or forest fires, and 6 of the 25 were in California.

Difficulties in comparison become more pronounced when points even further back in history are considered. The 1947 chemical plant fire in Texas City, Texas, had a reported loss of $67 million. Using the consumer price index, that translates into $567 million in 2004. The 1906 earthquake and fire in San Francisco had a reported loss of $350 million. That means $7.3 billion today—or more than half the loss attributed to all reported fires in the United States in a typical year. At this point, comparisons can become very sensitive to assumptions. Was the property lost in the Texas City fire sufficiently similar to the items covered by the consumer price index? Or should a more industry-specific price index be used? Were the estimates of loss

TABLE 3.4.15 U.S. Trends in Property Damage Due to Fire, 1994–2004

Year	Fires	Direct Property Damage (in Billions of Dollars)		Average Loss per Fire	
		As Reported	*In 2004 Dollars*	*As Reported*	*In 2004 Dollars*
1994	2,054,500	8.2	10.4	4,000	5,100
1995	1,965,500	8.9	11.0	4,500	5,600
1996	1,975,000	9.4	11.3	4,800	5,700
1997	1,795,000	8.5	10.0	4,700	5,600
1998	1,755,500	8.6	10.0	4,900	5,700
1999	1,823,000	10.0	11.3	5,500	6,200
2000	1,708,000	11.2	12.3	6,600	7,200
2001	1,734,500				
w/ 9/11/01		44.0	46.9	25,400	27,100
w/o 9/11/01		10.6	11.3	6,100	6,500
2002	1,687,500	10.3	10.8	6,100	6,400
2003	1,584,500				
w/ So. CA wildfires		12.3	12.6	7,800	8,000
w/o So. CA wildfires		10.3	10.5	6,500	6,700
2004	1,550,500	9.8	9.8	6,300	6,300

for the San Francisco fire made to the nearest $10 million or even the nearest $50 million? Then the 2004 version of that loss might be accurate to only the nearest $200 million or $1 billion, which would mean its range of uncertainty would be higher than the total loss of almost any recent fire.[38–40]

The lesson here is that trend analysis of loss figures can be very tricky and needs to be done with an eye toward the effects of inflation and population growth (which also affect trends in numbers of fires, deaths, and injuries). Keep in mind that loss trends have a tendency to look bad even if real progress is being made.

USING DATA IN PROGRAM AND STRATEGY ANALYSIS

Earlier in this chapter, techniques were described for using data to analyze the present (size and characteristics of the fire problem) and the past (trends in the size and nature of the fire problem). Program and strategy analysis is the most decision-relevant use of data because it tries to project the future and, in particular, the ways in which the future will be different if a particular program or strategy is or is not adopted.

The most fundamental question to be answered in using data for program or strategy analysis is whether past fire experience is a good guide to future fire problems. Sometimes it is; sometimes it is not. However, intelligent use of data with other sources of information is an essential part of the best possible projection of the future. After all, what will we use if not data? Models are tied to reality by validation, which is based on experience of the past. Expert judgment is formed, at least in part, by the experience of the past. The issue is not whether to use the past as a guide; it is how best to characterize the important changes that will occur in the future.

Often the most important aspect of the future will be a different mix of the elements already in place in the present. For example, home smoke-alarm usage has grown at a phenomenal rate in the past 25 years, with most of the growth occurring in or after 1976. Fire incident data from the early years of growth in alarm usage showed that smoke alarms reduce by nearly half the risk (measured by the number of deaths per 1000 fires) that a person will die if he or she has a fire. At that point, there were uncertainties about the applicability of this finding to the future. Would the lifesaving impact of smoke alarms remain the same when the devices were installed in poorer households with less-educated occupants?[41]

The answer turned out to be yes, although there was some erosion in the estimated benefit from smoke alarms that coincided with adverse trends in the estimated fraction of smoke alarms that were operational. But the form of the question shows how data can be used intelligently to try to project the future. Start with the future predicted by a simple projection of recent trends. Using judgment, creativity, and brainstorming, try to identify what aspects of the present environment might be changing in ways that would modify the simple projection. Try to obtain data on the speed of those changes. Try to analyze the fire data in hand to determine the sensitivity of your conclusions to those changes. Combine these results to produce a revised projection.

Most analyses to date have found that environmental changes relevant to fire occur slowly and so produce relatively modest changes in what are called baseline projections (i.e., projections of the size and character of the fire problem if no new strategies are adopted). For example, the average age of the U.S. population is rising. This means a drop in the percentage of the population in the high-death-rate years of infancy, a rise in the percentage in the high-death-rate elderly years, and other shifts along the age spectrum. By the end of the century

TABLE 3.4.16 The 25 Largest Fire Losses in U.S. History

	Loss in Year Fire Occurred (in Dollars)	*Adjusted Loss (in 2004 Dollars)*
1. The World Trade Center New York City, New York September 11, 2001	33.4 billion	35.6 billion
2. San Francisco Earthquake and Fire San Francisco, California April 18, 1906	350 million	7.3 billion
3. Great Chicago Fire Chicago, Illinois October 8–9, 1871	168 million	2.6 billion
4. Oakland Fire Storm (wildland/urban interface) Oakland, California October 20, 1991	1.5 billion	2.1 billion
5. Great Boston Fire Boston, Massachusetts November 9, 1872	75 million	1.2 billion
6. Polyolefin Plant Pasadena, Texas October 23, 1989	750 million	1.1 billion
7. Wildland Fire (wildland/urban interface) Los Alamos, New Mexico May 4, 2000	1.0 billion	1.1 billion
8. Wildland Fire (Cedar) Julian, California October 25, 2003	1.1 billion	1.1 billion
9. Baltimore Conflagration Baltimore, Maryland February 7, 1904	50 million	1.0 billion
10. Wildland Fire (Old) San Bernardino, California October 25, 2003	975 million	1.0 billion
11. Los Angeles Civil Disturbance Los Angeles, California April 29–May 1, 1992	567 million	763 million
12. Power Plant (auto manufacturing complex) Dearborn, Michigan February 1, 1999	650 million	736 million
13. "Laguna Beach Fire" (wildland/urban interface) Orange County, California October 27, 1993	528 million	689 million
14. Textile Mill Methuen, Massachusetts December 11, 1995	500 million	619 million
15. USS *Lafayette* (formerly SS *Normandie* ocean liner) New York, New York February 9, 1942	53 million	613 million
16. SS *Grandcamp* and Chemical Co. Plant Texas City, Texas April 16, 1947	67 million	567 million
17. Petroleum Refinery Norco, Louisiana May 5, 1988	330 million	526 million
18. Cargo Plane In-Flight Fire Near Newburgh, New York September 5, 1996	395 million	475 million
19. Great Fire of New York New York, New York December 16, 1835	26 million	474 million
20. Wildland Fire Florida May–June 1998	395 million	456 million
21. One Meridian Plaza (high-rise office building) Philadelphia, Pennsylvania February 23, 1991	325 million	450 million
22. Forest Fire Cloquet, Minnesota October 12, 1918	35 million	437 million
23. *Apollo* Spacecraft Cabin Cape Kennedy, Florida January 27, 1967	75 million	424 million
24. Chemical Company Plant Pampa, Texas November 14, 1987	215 million	357 million
25. Nuclear Power Plant Near Decatur, Alabama March 22, 1975	100 million	351 million

Note: Loss estimates are from NFPA records and are adjusted to 2004 dollars by using the consumer price index, including Census Bureau estimates for historical times. The list is limited to fires that have a reliable dollar-loss estimate and that occur in or over the United States.

the cumulative effect will be large, but on a year-to-year basis it produces only a small, predicted change in the national fire death rate.

An analysis of the projected impact of a strategy or program involves the following five steps:

1. Identify the part of the fire problem that the strategy can affect and measure the size of that problem. For example, a change in the flame resistance of upholstered-furniture-covering materials would affect only fires involving those materials. Keep in mind the need to address both fires that begin

with upholstered furniture and fires that begin elsewhere and become severe primarily because of spread to upholstered furniture. A change to self-extinguishing cigarettes would affect only fires whose form of heat of ignition was cigarettes, and so on.

2. Estimate the likely percentage reduction in this target fire problem if the strategy or program were adopted, and prepare estimates for each of the measures of fire severity (deaths, injuries, property loss) because the impact probably will be different for each measure. If the strategy or program is already in use (as was true for smoke alarms), then fire incident data analysis may produce these estimates. If the strategy or program is not in use or is in very limited use, as is true for home sprinklers, then some combination of modeling, laboratory tests, and expert judgment will be needed to produce the estimates. In either case, it makes sense to develop a range of estimates from optimistic to pessimistic.

3. Estimate how much of the target population will adopt the program or strategy and how quickly. This typically is a marketing question, and the results can be surprising. Most analyses of the growth in smoke alarm coverage were too pessimistic on both how much and how fast. At the same time, most analyses were too optimistic about the installation of smoke alarms in homes most likely to have fires. Although 96 percent of U.S. households called in a 2004 Fire Prevention Week survey done for NFPA reported having at least one smoke alarm, no smoke alarms were present in roughly one-third of the nonconfined home fires reported in 1999 to 2002. Additionally, smoke alarms did not alert the occupants in 11 percent of the reported confined home fires. It is assumed that in the majority of this number, either no smoke alarm was present or it did not operate.[42] This discrepancy is not unusual for strategies that work through the marketplace. The first purchasers tend to be more affluent and better educated; these people traditionally have lower fire rates than the rest of the population do. Also, speed of adoption will reflect the normal life of a product. Changes in cigarettes can be implemented for all cigarettes in months, whereas changes in the upholstered furniture ignited by cigarettes may take decades to work their way through the whole population.

4. Estimate how often the strategy will be defeated in practice. For example, what proportion of home smoke alarms will have had the batteries removed, disconnected, or not replaced on schedule? Note that if the method in step (2) involved the use of actual fire incident data, the estimate already may include the effects of defeating or attenuation. (The latter is a term that does not have the connotation of deliberate sabotage that *defeating* may have for some people.)

5. Combine the measures of fire problem size from step (1) and the percentages from steps (2) through (4) to produce estimates of the net percentage reduction in the fire problem and of the new size of the fire problem. With these results, decide how valuable this strategy or program would be and whether to press for its adoption. In some forums, this decision will require a parallel calculation of the cost of the strategy or program, followed by some kind of comparison of the costs and loss reductions.

The important point is the use of analysis to narrow the target of a program or strategy in order to maximize impact and conserve scarce program resources. Another consideration in analysis is the need to identify clearly which of many important objectives are to be given priority. For example, is it more important to reduce the fire loss actually being suffered, thereby targeting properties where most loss now occurs? Or is it more important to reduce the potential for catastrophic fire loss, thereby targeting properties with sizable numbers of lives or property value at risk, even if their actual loss has been relatively small? Also, is it most important to reduce numbers of fires, numbers of deaths and injuries, or numbers of dollars in direct property loss? In home fires, for example, a focus on fires might mean targeting cooking and heating-related fires, a focus on deaths might mean targeting smoking-related fires, and a focus on property loss might mean targeting intentional fires.

Finally, remember that tracking analysis continues to be useful even after a decision has been made and a strategy or program has been implemented. As noted earlier, most of the estimates used in an analysis involve uncertainty; therefore, it may be useful to see whether the future unfolds as projected. If not, some further refinements in the design of a strategy or program may be warranted. Even early termination of a program might be indicated.

COMPARING ESTIMATES USING DIFFERENT DATABASES OR ANALYTIC APPROACHES

The previous chapter, "Fire Data Collection and Databases," details how NFIRS, the NFPA fire experience survey, NFPA's Fire Incident Data Organization (FIDO), and other databases not exclusively dedicated to fire, such as the death certificate database, collect and categorize fires.

Occasionally a situation arises for which two different numbers exist, derived from different sources or different analytical approaches. For nonanalysts who may not know the source of either number, such a situation can prove frustrating and can encourage a cynical attitude about the arbitrariness of all fire statistics. Even analysts familiar with the sources of both numbers may have difficulty pinning down the precise reasons for any discrepancies and deciding how important the differences are and which number is best. It is very important, therefore, for all data users—and others who expect to confront arguments based on fire statistics—to understand how and why estimates can differ. For the most part, variations involve the ways different data sources and estimates deal with the inevitable gaps in coverage that affect all sources of fire incident information.

No fire database can possibly capture all instances of unwanted fires. Few databases—and none discussed in this section—cover fires that are not reported to fire departments. (Special studies, such as one done on residential fires for the CPSC in 1984[43] and the British Crime Survey's regular reports on domestic fires,[44] do provide some estimates of the size and composition of the unreported fire problem.) No fire database even captures all the fires reported to fire departments, but some databases, notably the NFPA survey, are built on sam-

ples designed to be representative of all municipal or local fire departments.

By their nature, fire databases are biased in favor of "failures" rather than "successes." The fire that is controlled so quickly that it does not need to be reported to a fire department is not captured by the databases that cover reported fires. Analyses of the impact of devices and procedures that provide early detection or suppression also need to allow for the phenomenon of missing "success" stories. Moreover, anecdotal databases such as FIDO, which provide the most detail on building features and their performance, tend to be limited to the largest of the reported fires.

There is also the issue of quality control for a database. For databases with limited depth of detail (e.g., the NFPA survey) or limited breadth of coverage (e.g., FIDO, which is confined mostly to large fires), it is possible to invest considerable effort in ensuring that each report is as complete and accurate as possible. Follow-up calls can be used to fill gaps and check possible odd answers. For a database with the depth and breadth of NFIRS, however, the same level of quality control effort has not been possible. Consequently, NFIRS is missing more entries and has more that are dubious. The trade-off between data quality and data quantity is never easy; an analyst needs to be aware of the strength and dependability of the sources before conducting an analysis.

Different sources provide different estimates of fire deaths and injuries. The CPSC's National Electronic Injury Surveillance System (NEISS) obtains estimates of the number of injuries treated at hospital emergency rooms. According to NEISS estimates, more than 48,000 nonarson civilian fire injuries were seen at hospital emergency rooms from July 1, 2002, through June 30, 2003. More than 21,000, but still less than half, of these injuries occurred at fires attended by the fire service.[45] This is higher than NFPA's estimates of civilian fire injuries reported to U.S. fire departments. In some cases, private individuals or nonfire ambulance companies may transport patients without notifying the fire service.

The fire death statistics, discussed earlier, provide another example of differing results based on different data classifications using different definitions. NFPA's estimates are sample-based statistical projections derived from the fire department survey. Fire deaths from all types of fires, including arson, self-immolations, and vehicle fires, are included. In the death certificate database, fire deaths resulting from these three causes might be classified as homicide, suicide, and vehicle accidents, respectively. In NFPA's report on fire deaths by state,[46] the National Safety Council's analysis of the death certificate database was used because of the more complete and consistent coding done with death certificates. As mentioned earlier, the National Safety Council's definition of unintentional fire deaths excludes some fire deaths, most notably those involving vehicle accidents, arson, or self-immolations. Because of these differences, discrepancies will occur. However, the trends and patterns are consistent.

Analysis decisions on matters such as how to combine codes or categories, which codes should be considered unknowns and allocated, and how extreme values are handled will impact the results obtained. Such decisions should be clearly documented.

SUMMARY

Analysis of national NFIRS data has been in transition for the past several years as an increasingly large share of each year's data is originally collected in Version 5.0. NFIRS 5.0 is significantly different from earlier versions in its structure and in much of the data collected. The NFIRS database for 1999 through at least 2004 contains a mixture of data from different versions. Trend analyses need to compensate for the changes in the data itself. The data users—fire service, insurers, industry planners, educators, and policy makers—still need the same types of information they had in the past as well as the new information that is now available. Analysts must be sensitive to the differences introduced by changes in the data collection system, but the principles of analysis remain the same.

This chapter has illustrated several techniques for analysis with data collected by NFIRS and other incident data. These techniques include the selection of appropriate data elements for consideration, the combination of data elements, dealing with unknown or missing data, trend analysis, and determining when and how risk of fire can be calculated. Geocoding and the use of other databases with NFIRS are also discussed.

Types of Fire Models
Zone Fire Models
Computational Fluid Dynamics (CFD) Models
Probabilistic Fire Models
Fire Modeling Trends

Key Terms

computational fluid dynamics (CFD) model, computer fire model, deterministic model, field model, fire model, lumped-mass model, mathematical fire model, Navier-Stokes equations, network model, physical fire model, probabilistic model, simulation model, statistical model, validation, zone fire model

Modeling is an inherent part of research in science and engineering, and its application to fire is as old as scientific research into fire behavior itself. The first book devoted solely to modeling in fire research was published in 1959.[1] Modern fire research, coupled with the ever-increasing power of computers, has given rise to highly complex models that can only be implemented as computer fire models. Although computer fire models have popularized fire modeling, these computer-based models do not differ substantially from earlier fire models; they are simply more complex and possess greater capabilities.

Computer models are simply computer programs that implement a mathematical model simulating a process or phenomenon. Computer models have been used for some time in the design and analysis of fire protection systems, like sprinkler or gaseous agent suppression systems. Computer models, commonly known as design programs, have become the industry's standard method for designing water supply, automatic sprinkler systems, and gaseous agent systems. These programs perform large numbers of tedious and lengthy calculations and provide the user with accurate, cost-optimized designs in a fraction of the time required by manual procedures.

In addition to the design of fire protection systems, computer models may be used to evaluate the effects of fire on people and property. These computer fire models can provide a faster and more accurate estimate of the impact of a fire and the measures used to prevent or control the fire than many of the methods previously used. Although manual calculation methods provide good estimates of specific fire effects (e.g., prediction of time to flashover), they are not well suited for comprehensive analyses involving the time-dependent interactions of multiple physical and chemical processes present in developing fires.

Perhaps the most important attribute of computer fire models is their ability to predict the relevant fire behavior within their stated limitations. The predictive capability of a model depends on both the underlying scientific understanding of the processes being modeled and the translation of that understanding into a calculation methodology. There remain substantial shortcomings in the scientific understanding of fire and related processes. However, our current level of understanding supports the development of calculations with enhanced predictability. It is not necessary to understand a phenomenon fully in the pure scientific context in order to exploit a lower level of understanding for design and practice purposes. In fact, current models take great advantage of "imperfect" knowledge to yield useful results.

In recent years, increasing attention has been given to the development and use of computer fire models. They have been used by engineers and architects, building officials, the fire service, investigators, building and fire code developers, materials and systems manufacturers, fire researchers,

Craig L. Beyler, Ph.D., is technical director, Hughes Associates, Inc., and section editor of the *SFPE Handbook of Fire Protection Engineering.*

John M. Watts, Jr., Ph.D., is director of the Fire Safety Institute, a not-for-profit information, research, and educational corporation located in Middlebury, Vermont. He also serves as editor of NFPA's quarterly scientific journal, *Fire Technology,* and section editor of the *SFPE Handbook of Fire Protection Engineering.*

and educators. The importance of modeling in its application to fire safety design has been recognized and has grown over the decades; with this widespread application comes a critical need for detailed understanding of the applicability of models to specific problems. There are ongoing issues with the application of modeling to problems for which the selected model is neither appropriate nor validated. The key challenge in the expanded use of modeling is to limit the application to appropriate and validated modeling tools.

The state of the art in computer fire modeling is changing rapidly. Understanding of the processes involved in fire growth is improving and, thus, the technical basis for the models is improving. The capabilities, documentation, and support for a given model can change significantly over a short period of time. In addition, computer technology itself (both software and hardware) is advancing rapidly. In the past, a large mainframe computer was required to use most of the computer fire models. Today, the models can be run on personal computers. Rather than providing an exhaustive discussion of the rapidly changing state-of-the-art computer models, the following discussion will focus on the general capabilities of each of the model types and brief summaries of representative models of each type.

TYPES OF FIRE MODELS

The wide range of types of fire models is illustrated in Figure 3.5.1. Models can be classified into two broad types: (1) physical models and (2) mathematical models. Physical models attempt to reproduce fire phenomena in a simplified physical situation. Scale models are a widespread form of modeling, as full-scale experiments are expensive, difficult, and sometimes wholly infeasible. Insights can often be gained by studying fire phenomena at reduced physical scale. Mathematical models are sets of equations that describe the behavior of a physical system. Often the goal of physical models is to uncover laws governing the behavior of physical/chemical systems. The resulting mathematical model can then be used to predict the behavior of real physical systems. Thus, physical and mathematical models are interrelated and complementary.

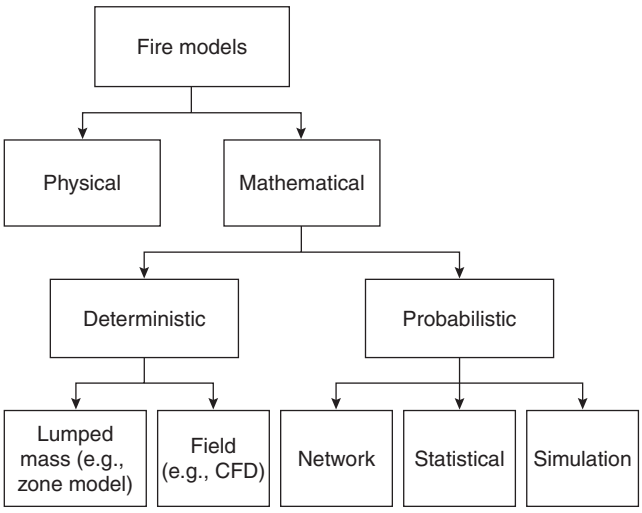

FIGURE 3.5.1 Classifications of Types of Fire Models

Mathematical Models

Mathematical models can be further classified into two classes: (1) *deterministic models* and (2) *probabilistic models.* Probabilistic models attempt to deal with the random nature of fire behavior, whereas deterministic models presume no random variation and, therefore, provide a fixed and precisely reproducible result associated with fire growth and behavior. Both approaches are valuable in understanding fire. Indeed, some probabilistic models include some deterministic modeling algorithms. In most modeling situations, the variability and multiplicity of conditions and scenarios require some form of probabilistic treatment. This may take the form of multiple deterministic modeling runs reflecting the range of conditions and scenarios, or it may explicitly include probabilistic treatment via a risk model.

Deterministic Mathematical Fire Models. Deterministic fire models can range from simple one-line correlations of data to highly complex models requiring weeks of computing time using dozens of computers. The unifying aspect of these models is that the course of a fire is fixed by the variables that establish the environment in which it occurs. The physical conditions that determine the progress and outcome of the fire are called the fire scenario. The fire scenario includes fuels involved, arrangement of the fuels, characteristics of the building and its fire protection systems, location of the ignition, location and capabilities of occupants, and any other variables that affect the fire's outcome. Thus, for all deterministic fire models, formulation of the fire scenario is of critical importance.

An example of a simple mathematical model is an equation describing the relationship shown in Figure 3.5.2.

$$L/D = 0.2(Q^{2/5}/D)$$

where L is the average flame height in meters, D is the diameter of the fire in meters, and Q is the heat release rate in kW. This equation is the result of applying Froude modeling principles. Other equations are available that are applicable at even lower values of L/D.

At the other end of the scale of complexity are models that describe the behavior of fire in one or more rooms (i.e., compartment fire models). These models may be complex because they include many physical/chemical processes or because a few processes are modeled in great detail. These complex models can be further classified into two classes: (1) *lumped-mass models* and (2) *field models.*

The most identifiable lumped-mass model is the *zone fire model.* In this type of modeling a compartment is idealized as containing one or more fire sources and the fire environment

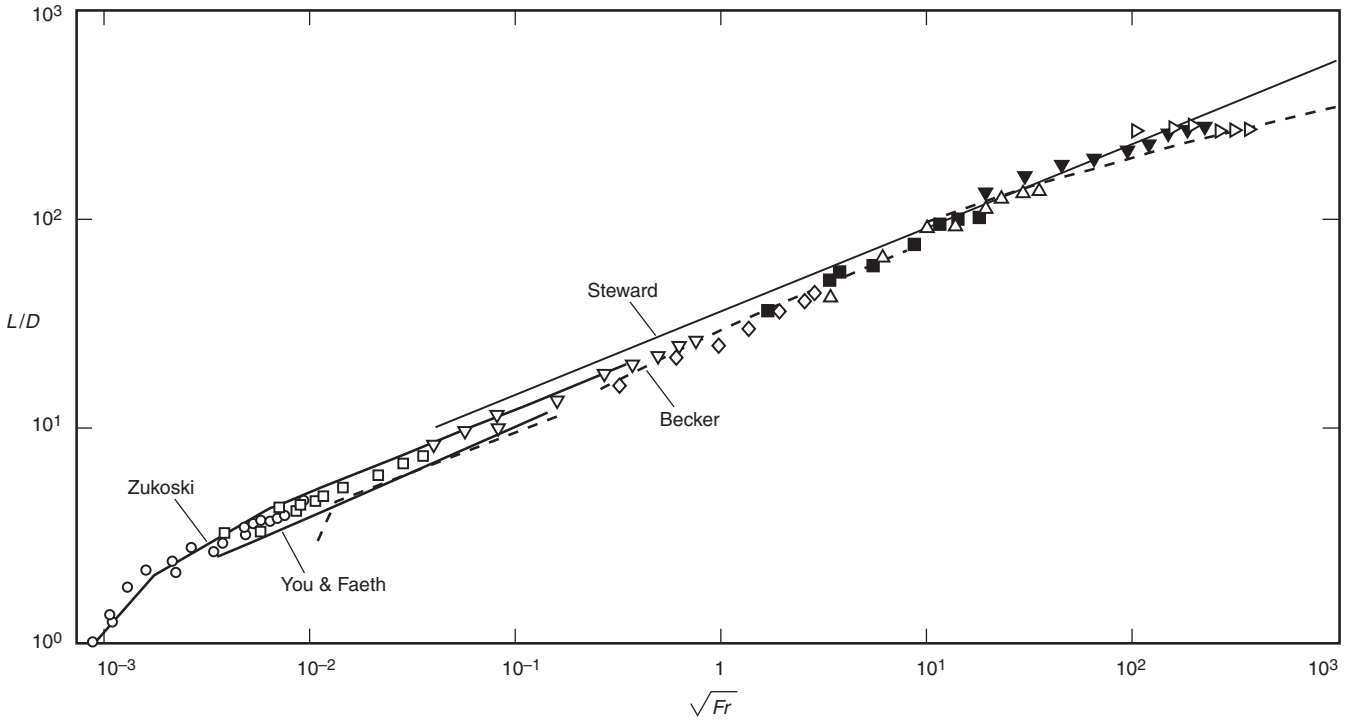

FIGURE 3.5.2 Flame-Height Correlation Model Based on Froude Modeling (Source: McCaffrey[2])

is modeled as one or two discrete volumes or zones. In single-zone models, the fire environment is characterized by a single average temperature and compartment-wide average smoke and gas concentrations. In two-zone models, the fire environment is modeled as an upper layer and a lower layer, each layer characterized by the average temperature and smoke and gas concentrations. These models can incorporate our empirical knowledge of fire phenomena and the calculations focus on the interaction of objects, such as fire sources and layers through equations describing conservation of mass and energy. These models are relatively simple so that very large buildings can be modeled using these techniques.

The most identifiable field model is the *computational fluid dynamics (CFD) model.* The key aspect of field models is the modeling of the structure of objects rather than simply the interaction of objects. So, in a CFD model the structure of the fire environment in terms of temperature and concentrations is spatially resolved throughout the compartment rather than being treated as average quantities as they are in zone models. Because the detailed structure is calculated based on detailed fluid mechanics equations, the CFD solution is more fundamentally based than zone models. However, because our fundamental knowledge of many fire phenomena is absent or at least very limited, the fire phenomena that can be modeled via CFD are also limited. Thus, the choice of model types involves trade-offs in capabilities that must be weighed when facing a specific modeling problem.

Probabilistic Fire Models. Probabilistic fire models can be categorized into three classes: (1) network, (2) statistical, and (3) simulation. Each of these deals with the uncertainties associated with fire growth processes. Network models are fire growth models in which the transition from one fire stage to another and the effectiveness of fire suppression systems, manual fire fighting, passive fire protection, and so on are governed by user-assigned probabilities that are based on historical data, engineering evaluations, or both. In some cases, these probabilities are single values, and in other models, the probabilities are time dependent. Statistical models represent the probability of an occurrence as it is determined from historical data. A classic example of a statistical model is the occurrence of fire alarms. Fire alarms are random events that are, within certain constraints, uniform in nature. That is, a fire or fire alarm might occur at any time with equal probability. Clearly, one of the constraints on this behavior is that the time of day must be controlled. It is well known that fires are a function of the time of day, and so one must restrict attention to a single time of day. Such a statistical model can be very useful in fire protection resource planning. Simulation methods try out different sets of conditions to see how they affect the outcome. Probabilities are often used to weigh outcomes for each set of conditions and produce an overall expected outcome. Simulation models may predict outcomes for a given set of conditions by using other physical, probabilistic, or deterministic models. In the latter case, simulation models regard fires as deterministic once the fire is fully defined. However, the inputs to the models are assumed to follow probabilistic models. Thus, the inputs to the deterministic model are treated as random variables. Such variables might include which furniture item is ignited or how far open the door is when the fire starts. A large series of runs is performed by

selecting inputs from the probabilistic models, and the range and frequency of different outcomes are examined. Such modeling combines elements of both probabilistic and deterministic models. Probabilistic models are taking on increased importance in the fire community in the assessment of risk. Various risk-based methods are under continuing development, most notably in Australia and Canada. These have been applied to building classes, individual buildings, and ships.

Physical Fire Models

Physical models attempt to reproduce fire phenomena in a simplified physical situation. The simplification can involve the scope of the model or the physical scale of the model. Even full-scale fire models are simplifications of the actual scenarios in which the experimenter seeks to include the important aspects of the scenario without introducing unimportant details or aspects. These unimportant details are removed because of the costs of being fully realistic and also because the experimenter seeks to provide findings with some generality. The design of such physical models is critical to the ultimate applicability of the findings.

Scale Modeling. Scale modeling does not simply mean conducting experiments at reduced physical scale. Reducing the linear dimensions of a physical situation and conducting experiments with the reduced-scale model is not sufficient. In addition to geometric scaling, it is necessary to maintain mechanical, thermal, and chemical similarity in the reduced-scale model. The scaling laws required to maintain these similarities can be determined from dimensional analysis or from the fundamental equations describing the physical/chemical phenomena. Like full-scale physical models, reduced-scale models also include simplifications of the physical arrangement to those elements of importance to the goal of the modeling effort.

The most widespread physical scaling laws in fire are known as "Froude modeling," which is applicable to buoyant flows associated with fires. Froude modeling requires that the ratio of buoyant forces to inertia forces be maintained. The Froude number, *Fr,* can be expressed as

$$Fr \sim Q^{2/5}/D \sim V/\sqrt{D}$$

where Q is the fire heat release rate, D the physical scale of the experiment, and V the characteristic velocity of the flowing medium. Thus, if a half-scale experiment is to be performed, the heat release must be reduced to 18 percent of the full-scale heat release in order to maintain the same Fr number and ensure that the flow velocities scale in the half-scale and full-scale models. The velocities themselves scale as the square root of the scale at constant Fr.

Froude modeling has been used successfully to understand plume flows, ceiling jet flows, and flame heights. Flame-height correlation models based on Froude modeling have been successful over a wide range of physical scales. An example is shown in Figure 3.5.2 , which was developed by McCaffrey.[2] The flame height to fire source diameter, L/D, is shown as a function of the $\sqrt{Fr}$. This flame height correlation based on Froude modeling has been successful over 12 orders of magnitude of Froude number, an amazingly wide range of applicability for any correlation or model.

Because different fire phenomena scale differently, it is not generally possible to study complex fires on a small scale. These differences in scale limit the use of scale modeling principles. It is notably difficult to scale convective flows and radiation at the same time. Thus, Froude modeling cannot be applied readily to fire problems where radiation is important, for instance.

Scale modeling using Froude scaling laws has been most successful in addressing smoke movement issues. Two techniques have found important applications: (1) reduced-scale gas-phase modeling and (2) saltwater modeling. The principles of these modeling techniques have been reviewed by Quintiere.[3] Saltwater modeling uses the discharge of high-density saltwater into freshwater as an inverse simulation of buoyant flows. This technique has been used successfully in both single compartments and multiple-compartment enclosures. The use of scale modeling in the design of smoke management systems is embraced by NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces.*

Non–Scale Modeling. Physical modeling does not always involve major reductions in physical scale. Physical models may simply seek to simplify complex phenomena into a manageable and understandable problem. Examples of this type of physical modeling can be found as far back as the ASTM E119 fire resistance test. The ASTM E119 time-temperature curve shown in Figure 3.5.3 was selected as a representative time-temperature curve for testing structural assemblies. The E119 fire resistance test is a form of physical modeling. The furnace environment is intended to model the fire environment experienced by structural members in a fire. The portions of the building structure exposed in an E119 furnace are intended to model the fire behavior of the

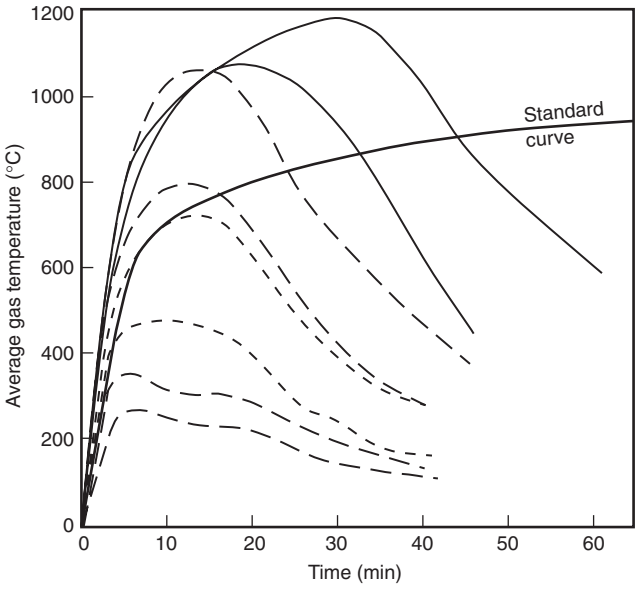

FIGURE 3.5.3 Representative Time-Temperature Curve (Source: ASTM E119)

building structure in a fire. No single time-temperature exposure can represent all fires, and testing portions of building structures does not fully represent the behavior of the structure, but the results of the simplified E119 test are useful nonetheless. Over the decades the value and the limitations of this widespread physical model have been learned.

In addition to physical models of systems, physical models of material behavior or response are available. The most identifiable example of such a physical model is the cone calorimeter.[4] This test method provides a well-controlled and well-known heating environment to which a material is exposed. The response of the material in terms of time to ignition, mass loss rate, heat release rate, smoke production, and gas generation rates are measured. This provides material data that can be employed as a relative measure of the fire performance of a material or can be used as inputs to mathematical fire models.

All standard fire tests are physical models of fire behavior. The adequacy of these physical models varies widely. There is a trend in the development of modern fire test methods to consider explicitly the adequacy of the test method as a physical model of actual fire behavior and response to fire.

Surveys have been conducted that provide a summary of the available fire models.[5,6] The most widely used lumped-mass models are known as zone models, whereas the most widely used field models are CFD models. These widely used model types are discussed in more detail in the following sections.

ZONE FIRE MODELS

Fire environment in a room is quite complex. Major insights into fire behavior have been achieved by a simple conceptual construct called zone modeling. In essence, a zone model assumes that the compartment may be idealized as consisting of uniform conditions in single or multiple regions or zones. In a two-zone model, these regions are (1) an upper region, filled with hot combustion gases, and (2) a lower region, filled with cooler, more nearly ambient air. Each region or zone is idealized to have uniform temperatures and gas concentrations. The plane dividing the two zones is the hot layer interface that may move vertically during a fire. Figure 3.5.4 shows a comparison of the temperature profile in a room fire with the idealized zone model equivalent. In one case, the zone model concept matches reality quite well; in the other, differences are clearly seen. Gas concentrations are idealized in the same way.

The two-zone model concept simplifies the room fire thermal environment to two temperatures and an interface height rather than a three-dimensional temperature field. Major simplifications are realized both mathematically and computationally. These simplifications have made many fire problems tractable and have allowed significant progress to be made.

In addition to two-zone models, there is widespread use of single-zone models in large buildings or ships. These models represent a large building with each compartment as a zone and model the movement of smoke between compartments throughout the structure. These models are designed to model complex ventilation systems that two-zone models have great difficulty modeling reliably. Smoke management systems in large buildings are routinely designed using such models. These models are also being developed to include many of the fire phenomena included in two-zone models with the goal of allowing modeling of the spread of smoke, heat, and fire through a complex building or ship.[7]

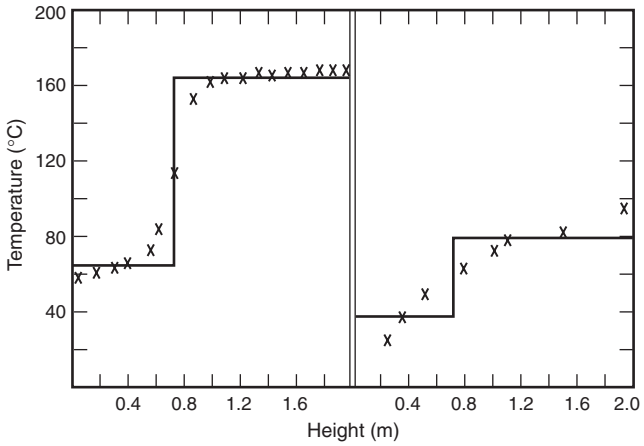

FIGURE 3.5.4 Comparison of the Temperature Profile in a Room Fire with the Idealized Zone Model Equivalent

Of course, in all zone models additional components are needed to specify fully the fire environment. Vent flows, plume entrainment, heat transfer, and combustion models are needed. Even if each of the component submodels is fairly simple, the result when coupled together is a complex model requiring computers for efficient, practical calculations.

Zone models by definition will always be approximate. The key is whether the predictions are "close enough" to yield significant insight for the situation under study. Zone modeling yields useful insight into many fire problems. There is a reasonable amount of validation test data available for comparison to models with one or with up to six compartments with length scales of 10 ft (3.05 m) connected via a corridor and modest (less than 1055 Btu/sec [1000 kW]), well-characterized fire. An excellent summary of the underlying assumptions of zone modeling is given by Quintiere.[8]

The following discussions attempt to briefly describe the current status and near-term possibilities for modeling some important phenomena. No one model is assumed; rather, the discussion summarizes the integrated capability of common zone models.

Ignition

Both piloted and unpiloted ignition due to radiative heating can be approximated. Small-scale ignition test data can be used.[4]

Burning Behavior

The burning behavior of a single fuel item cannot currently be predicted. The treatment of this obviously important subphenomenon in models is done through empirical correlations and/or large-scale test data. Approximations using small-scale tests

are possible. A more fundamental treatment is currently available for modeling the fire growth on interior finishes,[9] but these have yet to be generalized to other combustible objects found in compartments. Empirical methods, small-scale and large-scale data, and "design basis" fire assumptions will continue to form the basis of most zone models.

Flame Spread

Flame spread modeling on interior surfaces has recently been a very active area of model development. Flame spread models use the inputs from small-scale tests, such as the cone calorimeter and the LIFT apparatus, to predict the spread of flame and heat release rate in wall and corner fires. These models are beginning to be incorporated as submodels into zone fire models.[9] It is expected that the concepts developed in this work will be used in tackling the more difficult problems of flame spread and heat release rate prediction for individual fuel items.

Compartment Effects

Energy Balance. Zone-type approximations are being improved with the inclusion of plumes or ceiling jets as subzones. Heating of a ceiling in the vicinity of a flame or plume can be calculated. Enhanced radiation levels can be estimated, but it is not generally possible to predict the effect on the behavior of burning materials throughout the volume of a compartment fire.

Walls and Corners. Current methods used in most zone models to approximate the impact of walls and corners on plumes, flame heights, and ceiling jets are limited. Most available zone models do not include the full scope of our understanding of plumes in corners or against walls that is available in the *SFPE Handbook of Fire Protection Engineering.*[10]

Oxygen Starvation. The role of oxygen concentration is currently treated by use of heuristics involving a minimum oxygen concentration required for burning.

Multiple Room Fire and Smoke Spread

There are several models that treat smoke spread through multiple compartments using either a one-zone or two-zone approximation. Depending on the problem under analysis, this approach may yield acceptable results. The available validation data for multiple-room scenarios are limited.

Fire spread is currently limited to remote ignition of remote objects by heating from flames and the hot layer. Fire spread to multiple compartments is in principle predictable, though most zone models do not predict room-to-room fire spread.

Forced Ventilation

Several two-zone models have attempted to treat forced ventilation under simple vent configurations. There appear to be major unresolved technical issues in modeling forced ventilation in multicompartment two-zone models, which preclude effective modeling for many cases. Single-zone models are able to model complex forced ventilation systems.

Postflashover Predictions

The onset of flashover in a compartment poses a difficult prediction problem. Major unresolved technical problems include prediction of a radiation-enhanced burning rate; prediction of CO production in underventilated conditions; ignition of hot layers; burning at vents; and flame spread down corridors.[11,12]

There is one area where postflashover fires are well characterized. The prediction of temperature as a function of time for calculating the fire resistance of a structure is well developed. Design approaches using postflashover models are accepted alternatives to prescriptive fire resistance requirements in several countries. However, these successes are in single-zone models. Two-zone models, such as CFAST, tend to overpredict temperatures in postflashover compartment fires, especially for large vent openings.[11] The model is capable of producing predicted layer temperatures in excess of any experimentally measured layer temperature found in the literature.

Detection System Activation

Procedures exist for estimating the response of ceiling-mounted heat detectors via heating by a plume or ceiling jet. These calculations have been relatively well established for flat, smooth ceilings, with more limited validation for compartments with high ceiling heights or nonsmooth, nonflat ceilings.

Methods also exist for estimating smoke detector response to flaming fires.[13] The use of these models has been limited by the unavailability of the detector-specific parameters. Calculation methods exist for detector activation where a layer has formed. No procedures currently exist for estimating the activation of detectors in situations where the detector responds before a well-developed plume or ceiling jet forms or where mechanical ventilation appreciably perturbs the flow. Incremental progress is expected in this area in the near and moderate term.

Suppression Modeling

Fire suppression with a total-flooding gas system and with a water mist system has been successfully modeled.[14,15] Although there is research in modeling the suppression of fires by sprinklers,[16] no generally applicable design or analysis procedures are expected in the near future.

Fire Effects Modeling

Heat Damage. If the temperature threshold of a piece of equipment or material is known, standard heat transfer calculations can be used in conjunction with fire models to estimate the time dependence or degree of damage.

Smoke Damage. Estimates of smoke damage that reflect the sensitivity of the equipment exposed and type of smoke or fire involved are not generally available. Such calculations involve uncertainties associated with cold smoke transport and deposition, prediction of smoke production and properties, wide variability of smoke properties, and sensitivity of equipment to this wide variation of smoke types.

Human Interaction

Visibility. Limited experimental data on visibility combined with small-scale, constant-yield smoke concentration and optical property measurements enable rough estimates of human visibility in smoke. Using the results of computer models for smoke, layer depth, and smoke properties, approximate visibility estimates can be made.

Temperature/Radiation. Effects of heat and radiation can be estimated using empirical human tenability data.

Toxicity. Toxic effects of CO, CO_2, HCN, and oxygen depletion can be reasonably predicted using N-gas modeling approaches.[17] The effects of gases such as HCl, HF, or HBr can be estimated, but with a lower level of confidence. Bioassay methods can be used to screen for so-called paper-toxicant fire products where their existence is suspected.

The legitimate application of models to problems outside of the relatively narrow ranges discussed previously is possible and occurs frequently. If the results of the calculations do not require great accuracy (e.g., ±50%), the important physics of the problem is reflected in the model, and/or the results are used for approximate comparative purposes, these tools can be used in a much broader range of problems.

Overview of Selected Zone Models

ASET. ASET (Available Safe Egress Time) is a program for calculating the temperature and position of the hot smoke layer in a single room with closed doors and windows.[18] ASET can be used to determine the time to the onset of hazardous conditions for both people and property. The required program inputs are the heat loss fractions, the height of the fuel above the floor, criteria for hazard and detection, the room ceiling height, the room floor area, a heat release rate, and a species generation rate of the fire (optional). The program outputs are the temperature, thickness, and (optional) species concentration of the hot smoke layer as a function of time and the time to hazard and detection. ASET can examine multiple cases in a single run. ASET-B is a compact version of ASET designed to run on personal computers. Species concentrations and time to hazard and detection calculated by ASET are not calculated in the compact ASET-B version.

CFAST. CFAST (Consolidated Model of Fire Growth and Smoke Transport) is a multiroom fire model that predicts the conditions resulting from a user-specified fire within a structure.[12] The required program inputs are the geometrical data describing the rooms and connections; the thermophysical properties of the ceiling, walls, and floors; the fire as a rate of mass loss; and the generation rates of the products of combustion. The program outputs are the temperature, species concentrations, and thickness of the hot upper layer and the cooler lower layer in each compartment. Also given are surface temperatures, heat transfer, and mass flow rates. CFAST has very limited mechanical ventilation capabilities and can accommodate multiple fires, sprinklers, and detectors. FAST provides the data-editing and reporting tools for the CFAST model.

LAVENT. LAVENT (Link-Actuated VENT) is a two-zone model developed to simulate the environment and the response of sprinkler links in compartment fires with draft curtains and fusible-link-actuated ceiling vents.[19] The model used to calculate the heating of the fusible links includes the effects of the ceiling jet and the upper layer of hot gases beneath the ceiling. The required program inputs are the geometrical data describing the compartment, the thermophysical properties of the ceiling, the fire elevation, the time-dependent energy release rate of the fire, the fire diameter or energy release rate per area of the fire, the ceiling vent area, the fusible-link response time index (RTI) and fuse temperature, the fusible-link positions along the ceiling, the link assignment to each ceiling vent, and the ambient temperature. A maximum of five ceiling vents and ten fusible links are permitted in the compartment. The program outputs are the temperature, mass and height of the hot upper layer, the temperature of each link, the ceiling jet temperature and velocity at each link, the radial temperature distribution along the interior surface of the ceiling, the radial distribution of the heat flux to the interior and exterior surfaces of the ceiling, the fuse time of each link, and the vent area that has been opened.

CONTAM. CONTAM[20] is a single-zone model originally designed to track the movement of nonfire contaminants through a building. In includes extensive HVAC system model components and includes stack effect flows. Fire smoke sources can be modeled, though the temperatures in the building are set solely by the user, rather than being calculated as is done in most fire models. This modeling approach has been applied to the tallest buildings in the world to evaluate the potential for smoke movement and to design smoke management systems. Calculations are quite rapid, even for the largest buildings.

FSSIM. FSSIM[7] is a single-zone model originally designed for fire hazard analysis of ships. It includes most of the features of the popular two-zone models but within a single-zone fire environment description. It includes extensive HVAC system model components, stack effect, prediction of compartment temperatures, smoke and gas concentrations, as well as compartment-to-compartment fire spread, detection, and suppression. It has been applied to ships and buildings with several thousand compartments. Calculations are slower than CONTAM but still much faster than two-zone models and CFD models.

COMPUTATIONAL FLUID DYNAMICS (CFD) MODELS

Computational fluid dynamics (CFD) models avoid the simplifications inherent in zone models. The physical aspects of any fluid flow are governed by three fundamental principles: (1) mass is conserved; (2) Newton's second law [force = (mass) × (acceleration)]; and (3) energy is conserved. These fundamental principles can be expressed as generalized mathematical equations in the form of integral or partial differential equations and are generally referred to as the Navier-Stokes equations. Anderson[21] provides an excellent discussion of the governing equations for those who have no prior knowledge of CFD.

The Navier-Stokes equations are a coupled system of nonlinear partial differential equations and are difficult to solve analytically. To date, there is no general closed-form solution for the fully turbulent, time-dependant Navier-Stokes equations. Thus, the solution to these equations requires appropriate numerical methods. CFD is the technique of replacing the integrals and partial derivatives with discretized algebraic forms, which are solved to obtain numeric values at discrete points in time and/or space. Using an appropriate solving technique, the CFD model solves the fundamental equations of mass, momentum, and energy at each grid point in the computational domain that has been divided into a number of grid points that produce small elements. Imagine an enclosure filled with a three-dimensional grid of tiny cubes; a CFD model will calculate the physical conditions in each cube as a function of time. The CFD model program uses an iterative solver to calculate the physical changes in the cube at the current time step as a result of physical changes in the surrounding cubes from the previous time step. Depending on the size of the cubes, this model permits the user to determine the conditions (e.g., temperature, velocity, gas concentrations) at almost any point in the computational field.

CFD programs require substantial computational effort. More importantly, they require sophisticated users due to the complexity of defining initial and boundary conditions. CFD modeling programs have direct and immediate potential application to problems driven largely by fluid mechanics. Such problems include far-field smoke flow, details of flow and heat transfer to complex geometries, and impact of fixed ventilation flows on buoyancy-driven flows. Although the general problem of flame spread cannot yet be predicted with existing CFD models, significant progress has been made. At this time, modeling of combustion and the resulting heat fluxes seem to be the most difficult aspect of the problem. Applications of CFD models to fire problems have included aircraft terminals and atria, air-supported structures, power plants, aircraft cabins, tunnels, hospital wards, high-rack storage, and shopping malls.[22–30]

CFD and Turbulence Modeling

For turbulent and time-dependent flows, the generation and decay of turbulent energy within the fluid flow must be included in the model. The turbulent transport process cannot be calculated with an exact method in practical applications since the governing equations cannot account for turbulence at length scales smaller than the length scale of the computational cells; thus, it must be approximated. Various approaches for the modeling of turbulence using the CFD technique are described next.

Direct Numerical Simulation (DNS). By definition, DNS captures all of the relevant scales of turbulent motion, so no model is needed for the smallest scales. This approach is extremely computationally expensive, if not intractable, for complex problems on modern computing machines, hence, the need for models to represent the smallest scales of fluid motion that are less than the scale of the computational domain.

Reynolds-Averaged Navier-Stokes (RANS). RANS is the oldest approach for simulation of turbulent flows. In this approach, transport equations are solved for time averaged flow variables along with (zero, one, two, or more) transport equations for turbulence variables such as turbulent kinetic energy and its dissipation rate. All RANS models make the assumption that the time-varying velocity components can be represented by the sum of a mean and a fluctuating component. These equations are averaged over a time scale. This methodology is appropriate only when capturing unsteady flow behavior occurring over time scales at least an order of magnitude larger than the scales of the turbulent fluctuations. This modeling approach is not generally the most suitable for buoyant flows, which most often dominate in fire problems.

Large Eddy Simulations (LES). LES is a technique in which the smaller eddies are filtered and are modeled using a subgrid scale model, whereas the larger energy-carrying eddies are directly simulated. LES modeling involves resolving the time and space variations of the largest of the turbulent structures or eddies. With this approach the time averaging of the large eddies is not introduced, so transient behavior can be captured more faithfully. This method generally requires a more refined mesh than a RANS model but a far coarser mesh than a DNS solution.

CFD model calculations can be executed on desktop personal computers or a network of processors. From a practical standpoint, more extensive model domains may require multiple computer processors configured for parallel processing. Figure 3.5.5 shows an example of a CFD model prediction for the gas velocity in a compartment fire. The figure shows the cross section of a compartment with the door to the right of center and a fire near the floor to the left. The arrows represent the predicted gas velocity with the arrows pointing in the direction of gas flow and the speed of the flow indicated by the length of the arrows. The prediction shows air entering the lower level of the compartment to the right, rising in the fire, and flowing under the soffit as it leaves the compartment.

Overview of Selected CFD Models

Fire Dynamics Simulator (FDS). FDS allows for "Direct Numerical Simulation" or "Large Eddy Simulations (LES)" of fire effects.[31,32] The LES approach most readily lends itself to solving the types of fire problems typically found in fire engineering design and forensic applications. LES uses a low Mach number approximation for the Navier-Stokes equations and a formulation of the complex governing equations to provide a very efficient solution. Under the LES mode, the user inputs the parameters of the fire in terms of heat release rate and species generation. Although FDS includes algorithms for flame spread, burning rate, and suppression, these have not been developed and validated so as to allow their application to problems in these areas. FDS calculates the temperature, pressure, species concentrations, and flow field in relation to the prescribed fire. FDS provides for calculating the activation of heat detectors and sprinklers. In addition, the sprinklers can dispense droplets, which yield evaporative cooling and prewetting. The model supports prediction of multiple sprinkler activations. FDS also has the built-in capability of predicting the response of smoke detectors[31] based on the work of Desouza et al.[33] The major

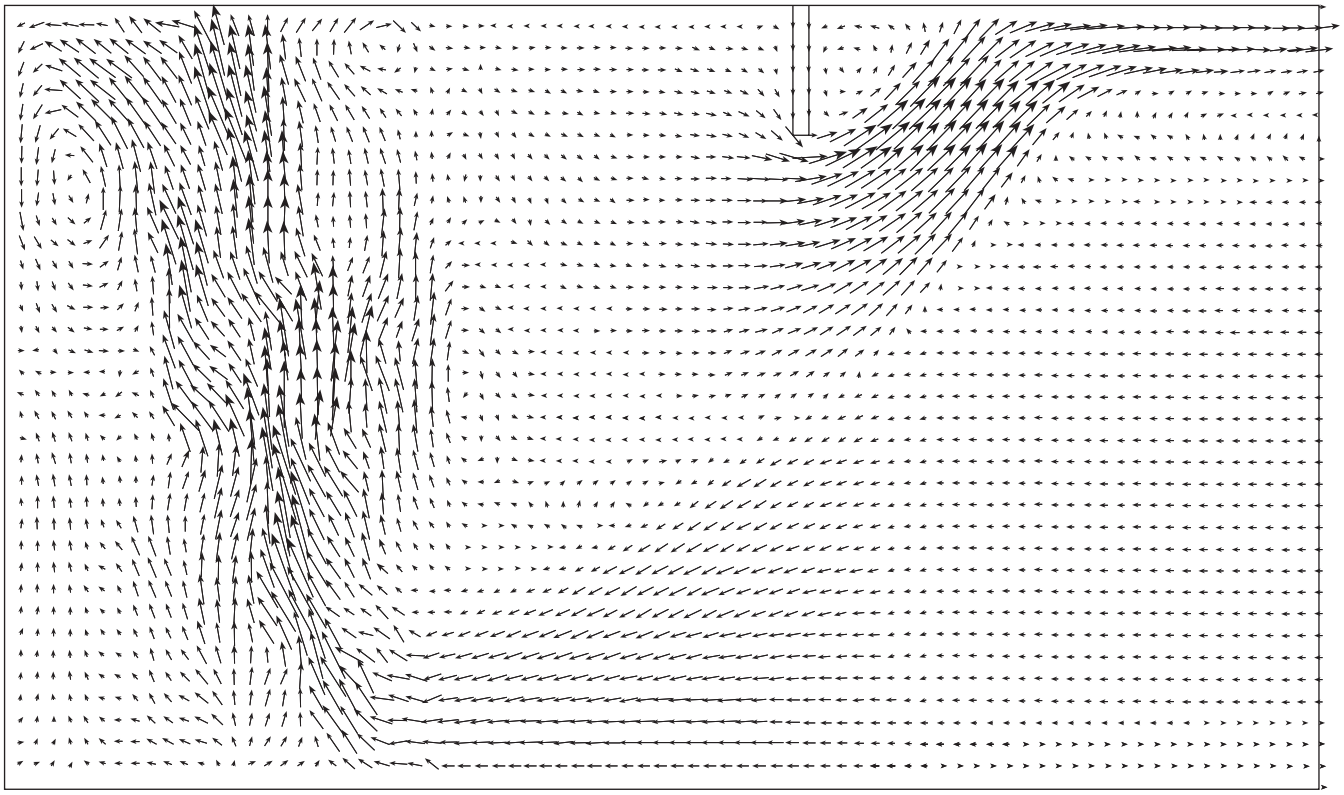

FIGURE 3.5.5 CFD Model Prediction of Gas Velocity in a Compartment Fire

geometric limitation of FDS is its exclusive use of rectilinear computational meshes, which effectively limits the model to "stair stepped" approximations for curved or sloped geometries. Although there are commercial CFD packages that allow better definition of realistic geometries, these are much less efficient and there has been limited validation of commercial CFD codes for use in fire applications. Heat transfer is treated as one-dimensional and is calculated by using thermally thin or thermally thick elements, but heat is not conducted through wall portions to other parts of the domain. The model also supports heat-activated vents that "open," allowing flow through the vent. Smokeview[34] is the companion software that is designed to visualize the numerical predictions generated by FDS.

Reynolds Averaged Navier-Stokes (RANS) Models. There are many commercially available CFD models. These general-purpose CFD models are designed to solve a wide range of flow phenomena including steady and transient, laminar and turbulent, and incompressible and compressible. Model features include heat transfer (convection, conduction, and radiation), mass transfer and chemical reaction (including combustion), porous media, scalar transport equations, discrete particle transport, multiple fluid streams, and multiphase flows. Commercial codes include graphical user interfaces (GUI) to aid the user in mesh generation, variable input, and postprocessing of results. These codes allow for body-fitted coordinates, structured and unstructured grids, as well as adaptive and moving grids. Output displays of variables include perspective views, contour mapping, vector diagrams, particle tracks, and gradients. The most widely used commercially available and general-purpose CFD codes for the simulation of combustion and fire include STAR*CD, Fluent, and CFX.

Special-Purpose Models

Fire Dynamics Tools (FDT). FDT is a suite of spreadsheets developed by the Nuclear Regulator Agency to support first-order field evaluations of potential hazards in commercial nuclear power plants. Calculations range from simple correlations to models to predict heat detector operation and the heating of bare steel.[35] The spreadsheets are available online at http://www.nrc.gov.

DETACT. DETACT-T2 (DETector ACTuation-Time squared) is a program for calculating the actuation time of thermal devices below unconfined ceilings.[36] It can be used to predict the actuation time of fixed-temperature and rate-of-rise heat detectors and of sprinkler heads subject to a user-specified fire that grows as the square of time. DETACT-T2 assumes that the thermal device is located in a relatively large area; that is, only the fire ceiling flow heats the device, and there is no heating from the accumulated hot gases in the room. The required program inputs are the ambient temperature, the response time index (RTI) for the device, the activation and rate-of-rise temperatures of the device, the height of the ceiling above the fuel, the device spacing, and the fire growth rate. The program outputs are the

time to device activation and the heat release rate at activation. DETACT-QS is a program for calculating the actuation time of thermal devices below unconfined ceilings.[37] It can be used to predict the actuation time of fixed-temperature heat detectors and sprinkler heads subject to a user-specified fire. DETACT-QS assumes that the thermal device is located in a relatively large area; that is, there is no accumulated hot gas layer in the room so only the fire ceiling flow heats the detection device. The required program inputs are the height of the ceiling above the fuel, the distance of the thermal device from the axis of the fire, the actuation temperature of the thermal device, the response time index (RTI) for the device, and the rate of heat release of the fire. The program outputs are the ceiling gas temperature at the device location and the device temperature both as a function of time and the time required for device actuation.

PROBABILISTIC FIRE MODELS

Because it plays such a big part in daily life, most people have some idea of what probability is about. They know it involves weighing the chances, or likelihood, that something will take place. They often hear, or make statements, such as, "It is likely a fire will start there"; "We have a better chance of controlling the fire if we can ventilate"; "Sprinklers have a very good probability of success." Such statements refer to situations in which the outcome is not certain but in which one has some degree of confidence that the statement will be correct. The theory of probability provides a mathematical framework for such statements.

Occurrence of fires, aspects of fighting fires, and sprinkler performance are repetitive operations, repeated often under similar circumstances. The percentage of times a certain outcome occurs, under the same conditions, will always remain approximately unchanged, only rarely deviating significantly from some average figure. It can, therefore, be said that this average figure is a characteristic measure of the given repetitive operation under prescribed conditions. Knowledge of such measures is very important as it enables us not only to describe the outcome of repetitive operations that have already occurred but also to predict the outcome in the future. There are more sophisticated definitions of probability that vary according to application. Detailed treatment can be found in the *SFPE Handbook of Fire Protection Engineering*[38] and in basic texts on probability.[39,40]

Applying probability to fire problems, the assignment of measures and the analysis of logical possibilities may, at times, depend on masses of data that are best obtained, analyzed, and interpreted by professional statisticians. At other times, the task depends more on qualitative knowledge and judgment of facts with which the fire protection professional is most familiar and is, therefore, the person best qualified to assign measures and analyze logical possibilities. Often a combination of objective fact and subjective judgment is the best source of information in assigning probabilities.[41]

Dealing with Uncertainty

Fire protection has significant uncertainty associated with most decisions. The concept of safety itself is one of uncertainty. There is no such thing as absolute safety; therefore, human activities will always and unavoidably involve risks. The concept of fire is also uncertain. Unwanted combustion is the least predictable common physical phenomenon. Reliability of manufactured, or fabricated, systems for suppression and confinement is another source of uncertainty. Reliability analysis is itself a concentrated area of study that uses probabilistic models such as fault trees to quantify the time-dependent failure of a system.[42]

Having a measure for probability is important to be able to deal with situations involving chance or uncertainty. There are many cases, when knowing the probabilities of certain events, it is useful to find the probabilities of more complicated ones. It would be inconvenient to search for a particular method of solution for each new problem of this sort that is encountered. Science tries to form general rules, the knowledge of which would readily permit one to solve mechanically, or almost mechanically, individual problems that are similar to one another. In the area of repetitive phenomena, the science that formulates such general rules is called probability. Probability theory is a branch of mathematics and, therefore, involves precise reasoning and uses formulas, tables, diagrams, and so on as its tools.

Types of Probabilistic Fire Models

Probabilistic models recognize variables as having a degree of randomness, which is more realistic than simple deterministic models and is especially useful when evaluating fire risk, since risk, by definition, includes the uncertainty of loss. There are many forms of probabilistic models. Complex models may involve both deterministic and probabilistic components. When a probabilistic model is a function of time, it is commonly referred to as a *stochastic model.* In this section we introduce three types of probabilistic models that can be used independently or as part of a more comprehensive fire risk analysis. They are networks, statistical models, and simulation.

Network Models

A network model is a graphic representation of paths, or routes, by which objects, energy, information, or logic may flow, or move, from one point to another. Network models are useful for minimizing the time or distance of travel from point to point and have many applications in solving complex problems. The connected points in a network are called nodes. The connections themselves are called links, arcs, or branches. The simplest network is two nodes connected by a single link (Figure 3.5.6).

A path is a sequence of links connecting two nodes and usually passing through other nodes. In driving from Los Angeles to New York, for instance, one might go through Denver and St. Louis. The cities could be considered nodes and the roads

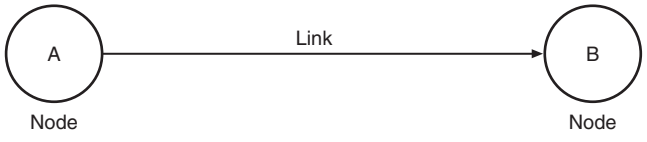

FIGURE 3.5.6 Network Components

between them links. Then one path from Los Angeles to New York would consist of the links connecting the intermediate cities. A significant advantage of a graphic model like a network is the qualitative representation of the structure of the problem or system. Such a diagram functions as a visual aid to help convey an intuitive understanding of the process for obtaining and using probabilities.

The term *tree* is used to describe a special type of network in which there is only one path connecting any two nodes. The simplest probability model, and one of the most powerful, is the event tree. Event trees model the sequence of possible states of a system and of corresponding events that lead to those states. Nodes represent events, and the links between them show how one event leads to another. Figure 3.5.7 shows a simple event tree. The tree proceeds chronologically, left to right, showing events as they occur in time.

By assigning probabilities to the outcome of each event, the tree can be used to calculate the probability of the consequences. For example, given that a fire occurs, consider the example likelihood of events as shown in Table 3.5.1.

Assuming the events are independent, the probabilities along each path are multiplied. Thus, looking at the outcome represented by the uppermost path, "Very large consequence," the probability of this path is

$$(1 - 0.7)(1 - 0.9)(1 - 0.8) = (0.3)(0.1)(0.2) = 0.006$$

Subsequently, the example probabilities for each consequence can be estimated as shown in Table 3.5.2.

Using this model, one can examine conditions such as the effect of a smoke detector to assist occupants in the discovery of a fire, the impact of automatic suppression, and the need to alert the fire department.

Other types of network models applicable to fire protection problems include fault trees,[42,43] evacuation diagrams, and system dynamics. Network models have been used in a wide variety of fire safety applications.[44,45] These model forms and others are explained more fully in textbooks on the subject.[46,47]

Statistical Models

The fields of probability and statistics are closely linked. Most statistical concepts, such as sampling protocol and hypothesis testing, have their basis in probability theory. Statistical modeling involves the description of random phenomena by an appropriate probability distribution.

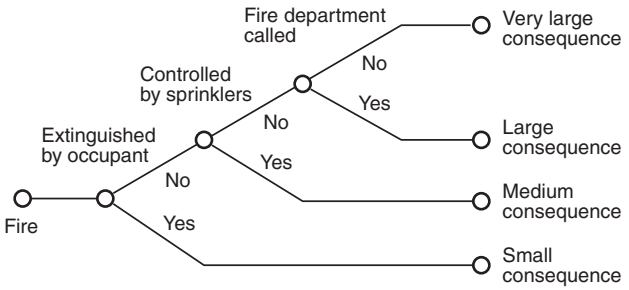

FIGURE 3.5.7 Event Tree

TABLE 3.5.1 Example Likelihood of Events

Event	*Probability of Success*
Extinguished by occupant	0.7
Controlled by sprinklers	0.9
Fire department called	0.8

TABLE 3.5.2 Example Probability of Consequences

Consequence	*Probability*
Very large	0.006
Large	0.024
Medium	0.270
Small	0.700

A probability distribution may be thought of as a mathematical function that defines the probability of an event. For example, the probability distribution that describes the roll of a die is

$$P(x) = 1/6$$

where $x = 1, 2, 3, 4, 5,$ or 6. All the possible outcomes, 1 through 6, have an equal probability of 1/6, which is called a uniform distribution. Another example of a uniform distribution is the outcome of a spin of a roulette wheel, which can be modeled mathematically as $P(n) = 0.0263158$. This equation indicates that the probability of any possible outcome, n (the numbers 1 through 36 plus 0 and 00), is 1/38 or 0.0263158. All models have underlying assumptions. In the roulette model, a perfectly fair wheel is assumed. If one chooses not to accept this assumption, then it becomes necessary to collect a lot of statistical information about the roulette wheel to calculate the individual probability of each outcome.

In addition to the uniform distribution where each outcome has the same probability, there are many other probability distributions used to describe many different types of random events. An example using historical data on fire calls is shown in Table 3.5.3. The first column shows the number of calls that might be received in any one day, and the second column shows the number of days with that many calls. The data are from a 4-month period consisting of a total of 443 calls in 123 days.[48]

Charting the data, as shown in Figure 3.5.8, reveals a trend. The frequency starts out low, increases rapidly, decreases rapidly, and then tails off toward higher numbers of calls. If more data were collected, this trend would be "smoother." A Poisson distribution can mathematically describe the shape of this trend.

The Poisson distribution is widely used to describe random events having a large opportunity to occur but a small likelihood that any one of these opportunities will actually result in an occurrence. This accurately fits the description of fire incidents.

TABLE 3.5.3 Number of Days Having a Specified Number of Calls for Service[48]

Number of Calls for Service per Day (n)	*Number of Days Having* (n) *Public Service Calls*
0	6
1	8

5	14
6	7
7	8
8	0
9	0
10	1
11	0

Mathematically, the probability of k fire alarms occurring over the period s is given by

$$P(k) = \frac{(\lambda s)^k}{k!} e^{-\lambda s}$$

where λ is the mean frequency of fire alarms. This statistical model describes the probability of a given number of alarms, k, occurring during a specified period of time, s.

Other probability distributions used to model aspects of fire protection include the familiar normal distribution and the less familiar lognormal distribution. The normal distribution (Figure 3.5.9) finds wide application in describing biological phenomena, such as human height and IQ. It also applies to characteristics such as shoulder width and walking speed to exits.

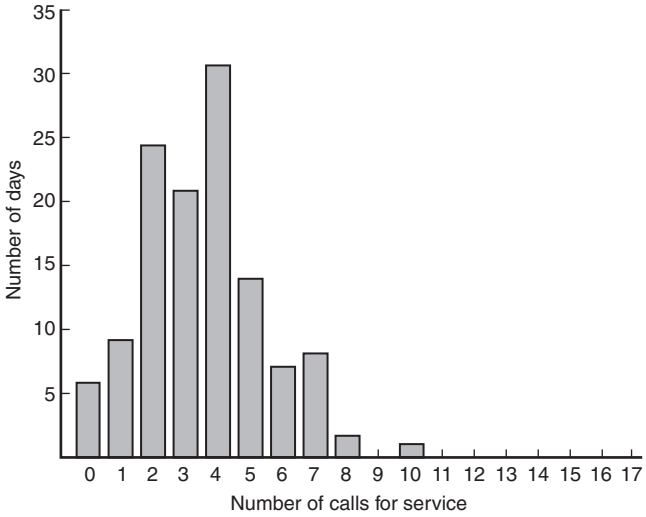

FIGURE 3.5.8 Distribution of Public Service Calls (Source: National Institute of Standards and Technology)

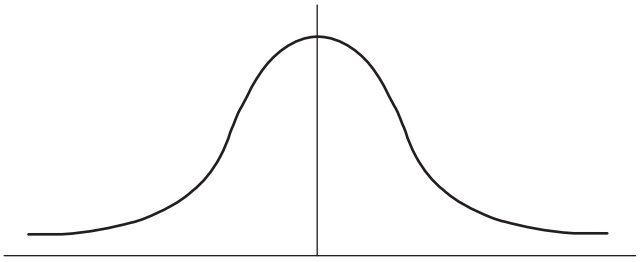

FIGURE 3.5.9 Normal Distribution

The lognormal distribution (Figure 3.5.10) is skewed like the Poisson distribution. It has been shown to describe fire load in offices.[49]

The exponential distribution is often used as a model of fire growth,[50] and the extreme value distribution is used to characterize fire loss.[51] More sophisticated statistical models use principles of the probability theory to combine probability distributions of two or more random variables.[52,53]

The event tree model in Figure 3.5.7 assumed that the probability of each event is the output of a simple binomial distribution similar to tossing a coin [$P(x) = ½$] but, in this case, the outcomes are not equiprobable. Data might show that the likelihood of a fire being extinguished by the occupant is a function of the time of day, for example, when the occupant is home and alert. A statistical model of this probability could be incorporated into the calculation of the consequences in the network.

More details of statistical modeling can be found in basic texts[39,40] and in the *SFPE Handbook of Fire Protection Engineering*.[54]

Simulation Models

Often the relevant variables in a decision problem are too numerous or the interactions too complex to be handled mathematically. One way to deal with such problems is by computer simulation. Simulation models try out different sets of conditions to see how they affect the outcome. In a flight simulator, an airplane pilot tries various maneuvers to see which work and which do not without risking life or the loss of an airplane. The

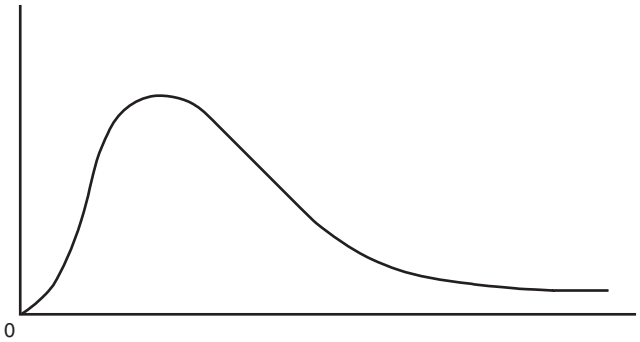

FIGURE 3.5.10 Lognormal Distribution

operation of an airplane is "simulated" by the electromechanical training device. Although there are many types of simulation, the most common form of computer simulation of systems and events is Monte Carlo.

Monte Carlo simulation uses mathematical models to predict the range of outcomes from probabilistic situations by condensing time (or some other variable). For example, a year of activity can be simulated in a few seconds of computer time. Considering the roulette wheel, letting the computer select a random number from 1 to 38 would simulate a spin of the wheel. Using the computer, the wheel can be "spun" thousands of times in a fraction of a second.

The roulette wheel analogy can be used to describe a computer simulation of fire scenarios. First, the wheel is divided like a pie chart so that a likely ignition source, such as smoking materials, has a big slice covering several numbers and a less likely ignition source, such as spontaneous combustion, has fewer or only one number. Then spinning the wheel simulates the first part of an ignition sequence, the heat source. Next, a second wheel is divided according to the most common materials first ignited. Spinning the second wheel will complete the ignition simulation. A refinement would be to provide a different second wheel for each heat source, thereby modeling the observed situation that some materials are more likely to be ignited by some heat sources than by others.

Subsequent stages of fire growth can also be included in the simulation. Fire development could be represented by a state transition model, a type of model that describes a progression from one defined state to another. In a fire, these "transitions" are determined by parameters, or variables of the fire area, such as flame spread, fire load, ventilation, and so on. Now, more roulette wheels should be added to represent these varying state transitions and to allow the computer to "spin" all these wheels hundreds of times. To calculate the resulting probabilities analytically would be intractable. This is a typical application of Monte Carlo simulation and there are several computer simulation packages that facilitate such modeling of probabilistic events.

Consider again the event tree in Figure 3.5.7. If each of the events in the tree has a complex statistical model of probability, then the calculation of consequence probabilities can become thorny. However, the nodes can be modeled individually and input to a computer simulation to estimate results. Many probabilistic models use a network to describe the framework, statistical models of events, and Monte Carlo simulation to provide resulting values.

Because of the flexibility of simulation modeling and the complex nature of fire problems, there is a wide range of applications. One area where simulation is used extensively is in the modeling of building evacuation.[55] Computer simulations of emergency egress range from simple travel time models to detailed representations of human decision making. Other applications include fire growth and development,[56,57] emergency response,[58,59] and those described in the *SFPE Handbook of Fire Protection Engineering*.[60]

Probabilistic models have many forms. The three categories discussed previously range from graphical network models with visual impact, through abstract mathematical representation of statistical models, to computer simulations that repeat possibilities enough times that they turn into probabilities. The important message is that the uncertain, probabilistic nature of fire can be modeled.

FIRE MODELING TRENDS

Having briefly discussed the current and near-term capabilities of models to predict fire effects, we will now focus on observable trends and the possibilities for the future of modeling.

Hardware

The past decade has witnessed a revolution in computing capacity available to individual users. Such prior technological advancement has made it relatively safe to forecast that more powerful, easy-to-use computer hardware will continue to evolve, which has eliminated most computational speed problems with respect to zone models. Although the computational requirements of CFD models have been reduced, computational speed will continue to be a challenge as more complex submodels are introduced into these codes to more accurately model the complex nature of fire phenomenon.

Developments in hardware should also appreciably extend the range and utility of these calculation methods, perhaps into the real-time world of the fire incident commander. The use of these models in conjunction with interactive video training and simulation will likely result in "fire simulators" becoming widely available to fire departments.[61]

Longer-term hardware developments in the area of intelligent sensors integrated with software derived from fire modeling may revolutionize fire detection. The "smart" building will include fire protection.

Application and Use

Although current applications are somewhat limited in terms of routine use, the trend has been for a relatively rapid increase in the application of models across all aspects of fire protection. Application and use of fire modeling include performance-based fire safety design, postfire reconstruction, fire risk assessment, and extrapolation of small-scale testing.

Performance-Based Fire Safety Design. There is currently widespread use of modeling in the design and evaluation of the fire safety of buildings and facilities. Computer models and other analytical tools have not, however, been formally integrated into fire protection engineering design practice. Application of fire modeling often arises in the context of "code equivalency" or the "performance-based" approach to fire safety. There are relatively few fire safety problems for which direct comparison or equivalency based on the prediction of fire growth or smoke spread alone is possible. There are almost always probabilistic, risk, economic, and political factors involved. Computer models are still helpful, however, given the almost nascent state of development, in that they provide the ability to approximately compare expected fire conditions across a range of scenarios. The potential impact of various intervention strategies can also

be evaluated in a relatively crude fashion. A major question exists on the application of these models in fire safety design relative to building codes and fire safety standards. The primary determinants in this area will likely be the degree to which relatively prescriptive codes and standards can be harmonized with more performance-based design and engineering methods. This process is, of course, more complicated than it sounds, given the legal, social, and political realities under which buildings are approved.

Postfire Reconstruction. The problem of postfire reconstruction lends itself readily to modeling tools. Several case studies of "reconstructed" fire incidents using computer models have been published.[62–68] Such case studies generally demonstrate how a computer model used as part of a more general engineering analysis is a powerful tool. One lesson of these case studies is that the state of the art is not such that one sets up a reasonable input file and the computer describes how the fire evolved. Rather, the models are more appropriately used to evaluate in approximate terms the time sequence of the event or to establish in more detail the reasonableness of one or another ignition growth and spread scenario. These programs are also used to pose "what if" questions related to the contribution of a particular material, furnishing item, or other factor versus one of greater or lesser combustibility, energy release rate, and so on. Most modeling applications occur today and have occurred in the recent past in fire litigation circumstances. Most of these applications are never published.

Fire Risk Assessment. Applications outside of litigation are often associated with the evaluation of the fire hazard posed by a product or material.[69–73] Modeling received a major boost in the context of predicting the "toxic hazard" posed by materials. The combination of deterministic models with risk assessment methods into integrated hazard assessment schemes has begun.[74,75] The method enables one to integrate ignition, flammability, and toxicity properties with the end use of the material under varying scenarios to estimate the outcome. As always, the quality of these applications is driven by the methods, data, approximations, and assumptions that are used. Additional applications that reflect the increasing use of models for a range of applications can be found in work by Peacock and Bukowski,[73] Bengston and Hagglund,[76] and Hagglund and Wickstrom.[77] An additional prerequisite for the general use of modeling in building design is the need to deal with the inherently probabilistic nature of fire events and the reliability of various construction features and fire safety systems. Several generic approaches have been suggested to integrate deterministic modeling with probabilistic problems.[78–83] This challenge also poses the greatest opportunity. The tremendous potential of this significant technological advance for improved fire safety will be recognized and exploited.

Extrapolation of Small-Scale Tests. The development of small-scale fire test methods, which in principle enables the extrapolation of the results to real fires, was essential to the development of modeling. Some of these test methods have been standardized by ASTM and NFPA. The input data required by models, which describe the burning behavior, energy release rate, smoke properties, and combustion gas yields of materials, come largely from these small-scale test methods. It is expected that the availability of these data for a wider range of products and materials will increase. The availability will accelerate dramatically if these relevant test methods are referenced in buildings codes and fire standards in lieu of or in conjunction with more traditional methods. Since models form the basis for extrapolating this flammability data to full-scale performance, increased use of models in this context is expected. In many ways, this particular class of applications may be ideal for the direct integration of modeling into building design standards.

Clearly, the use of models in postfire reconstruction will continue, and their application to special facilities and problems not directly dealt with in codes and standards will also increase. Although zone models have been the tool of choice due to the inherent simplicity and practicality, the application of CFD to fire problems has been and will continue to dramatically increase. This expanded use of CFD in the fire protection community has followed the release and further development of Fire Dynamics Simulator (FDS)[31,32] by the National Institute for Standards and Technology. To date, the most extensive use of CFD in fire is in the prediction of smoke movement, especially in large, complex open spaces like atria.

Although there are significant limitations in the treatment of important physics in widely used models, the primary difficulties arise in the overall context of the model's use. Appropriate selection of expected or worst-case input parameters, consensus on the safety factors or margins of safety to be applied, and, more fundamentally, the lack of clear design objectives remain important areas of concern. Significant differences in the results of modeling analyses of fire safety appear to arise more from these external factors than from the limitations of any particular model.

Validation

Although progress has been made, the predictive capability of computer models is limited since models rely on approximations for naturally occurring phenomena. That is, there is some level of uncertainty in the predicted results. Validation is the process of measuring the level of uncertainty of the model's predictions. It is clear that ongoing research and development efforts aimed at resolving some of these uncertainties will result in improved predictive capability. The use of heuristics to aid in simplifying particularly difficult problems will continue. Confidence in the capabilities of models will increase with improved validation and careful use.

The use of approximations also yields limitations with respect to the application to a specific scenario. It is not known with confidence to what limits these models can be applied. These issues involved in the evaluation of fire models have begun to receive attention in the technical fire community.

ASTM has developed guides to documenting and evaluating fire models,[84,85] and SFPE has begun to take on the task of providing guidance documents on the use of fire models.[86] ISO TC 92/SC 4 is also developing guidance on validation and verification of models. The U.S. Nuclear Regulatory Commission has

begun the process of evaluating and validating models within the room of fire origin.[87] Although these efforts are first steps, they reflect recognition of the need within the fire community to understand the applicability, limitations, and accuracy of fire models that are being used in hazard analysis and design.

Numerous validation studies of computer fire models have been undertaken. Surveys of fire models have been conducted that include reference to validation studies.[5,6] Most validation studies have been undertaken for relatively small (approximately 100 ft^2 [9.3 m^2]) compartments with well-defined fire sources (cribs, pool fires, or gas burners).

It is arguable that complete validation of any fire model is an impractical objective. It is unlikely given funding and prioritization realities that any significant systematic and complete validation will ever be performed on any model. Thus, models will be evaluated and the results accepted in a relatively slowly evolving time frame. The obligation that this lack of independent validation places on users and approving authorities is obvious. Particular attention must be paid to using these programs within their stated limits and, perhaps more importantly, to searching out experimental data for cases similar to the problem being evaluated. The dearth of complete validation studies should not be taken as rationale for rejecting the use or results of a model in any particular case. The validation picture could improve dramatically if it became clear that the lack thereof was a significant barrier to more widespread use.

Although validation of more complex models is an arduous task, papers have begun to appear in the literature in which experimental data and CFD model predictions are computed. Evaluation of CFD results for a particular application poses particular challenges. The sheer quantity of output data, the importance of the computational grid size, and subtleties in the internal model treatment of important physics require substantial effort to critically evaluate and ensure reliability of the results.

Acceptance

A decade of continued progress in modeling, with the increase in the number of published application studies in the *NFPA Journal* and other widely read fire literature, has led to greater acceptance of performance-based designs (which may include the use of fire models) by authorities having jurisdiction (AHJ). The trend in greater acceptance of predicted results in resolving fire safety issues is highlighted by the development of guidelines for peer review of performance-based design[88] when the engineering rigor is beyond the technical capabilities of the AHJ. This trend will continue and likely accelerate. Progress related to integration of these methods into the design of facilities is more problematic.

SUMMARY

Computer models are simply computer programs that implement a mathematical model simulating a process or phenomenon. Computer models have been used for some time in the design and analysis of fire protection systems. Models can be classified into two broad classes: (1) physical models and (2) mathematical models. Physical models attempt to reproduce fire phenomena in a simplified physical situation. Mathematical models are sets of equations that describe the behavior of a physical system. Mathematical models can be further classified into two classes: (1) deterministic models and (2) probabilistic models.

Deterministic models are sets of equations that describe the behavior of a physical system. The resulting mathematical model can then be used to predict the behavior of real physical systems. Probabilistic models attempt to deal with the random nature of fire behavior, whereas deterministic models presume that, given a well-defined physical situation, fire growth and behavior are entirely determined. This chapter presents information on deterministic and probabilistic models of fire behavior and relevant aspects of fire protection. This chapter discusses the most widely used types of models and provides a brief introduction to probability theory, including information on evaluating and assigning probability.

The development of fire models is a very active area. The preceding review is intended to offer the reader a perspective on what is currently available. The reader should also recognize that the information in this chapter is not exhaustive. Papers listed in the reference section provide additional information on the topic. Before using any fire model, the user should be aware of the underlying fire science and fire protection engineering principles assumptions and limitations for that model. The brief descriptions provided in this chapter should not be used as the basis for the selection of a model for a particular application. Further, the range of validity for an individual computer fire model is difficult to determine and is the topic of a significant amount of continuing research. Before using any model, the user should study the comparisons of model predictions with experimental data to aid in determining if the use of the model is appropriate.

Fire modeling is an old and well-developed field, though much remains to be done. Physical and mathematical models have made important contributions to fire safety and it is no longer a question of whether modeling will be used in the solution of fire safety problems but rather to what extent. The degree to which scientifically based engineering models can impact fire safety will be driven largely by their application to design practice and requires some integration with building codes and fire safety standards. Without such integration, incremental progress in predictive capability and applications can be expected. If fire safety engineering methods and codes are successfully integrated, the forecast will be one of rapid revolutionary change in all aspects of modeling as well as building design.

Chapter 6

Applying Models to Fire Protection Engineering Problems and Fire Investigations

Revised by
Richard L. P. Custer ❏ David T. Sheppard ❏ Christopher B. Wood

Chapter Contents

Definition of Fire Models
Types of Models
Model Applications
Computer Modeling in Fire Investigation
Considerations for Selecting and Using Fire Models

Key Terms

computational fluid dynamics (CFD) model, computer fire model, failure analysis, field model, *Fire Dynamics Simulator,* fire model, fire reconstruction, *FPETool,* hazard, heat release rate, performance-based design, sensitivity analysis, t^2 fire, zone model

Starting in the 1980s, computerized fire models were developed and applied to fire safety problems. In general, these models estimate changes (such as open or closed doors) to a building or space within a building and its environment (such as temperature or visibility), based on user input data for an assumed fire in that structure. For the most part, these models do not model the fire directly but use the input data selected by the user to predict the impact of the selected fire or the enclosure. A more extensive discussion of computer fire models and their elements is covered in other chapters in this section. The purpose of this chapter is briefly to advise the user on some of the types of applications where modeling can be of assistance and provide some guidance for users to establish criteria for selection of the model chosen and the input data used.

As an outgrowth of the major advances in understanding the dynamics of fire and its effects on the operation of fire protection devices, workers in the field have developed a number of predictive models. These models range from prediction of upper-layer gas temperature in a compartment fire[1,2] and the time of sprinkler head operation[3,4] to human response to the heat and toxic species produced.[5] Many of the models have, in turn, been assembled into larger consolidated models and hazard assessment tools[6–11] that provide a wide capability for the calculation and assessment of the predicted effects of fire using today's state-of-the-art personal computers.

See Section 3, Chapter 7, "Fire Hazard Analysis Techniques"; Section 3, Chapter 11, "Overview of Performance-Based Fire Protection Design."

DEFINITION OF FIRE MODELS

The term *model* can be applied to many physical and mathematical procedures designed to simulate reality. For the purpose of this chapter, *fire models* are defined as mathematical procedures developed to estimate the change in the environment of a space (such as a room or compartment) or building caused by a fire that varies in intensity and/or area of involvement with time. Many of these models predict the temperature of the smoke layer produced by that fire. Most fire growth models also predict the depth of the smoke layer. In addition, many models predict other variables such as the oxygen, carbon monoxide, carbon dioxide, and other gas species concentrations in

Richard L. P. Custer, M.Sc., FSPE, is associate principal and technical director at ARUP Fire in Westborough, Massachusetts. Mr. Custer is a fellow of the Society of Fire Protection Engineers.

David T. Sheppard, Ph.D., is senior fire research engineer at the Fire Research Laboratory (Bureau of Alcohol, Tobacco, and Firearms). Dr. Sheppard is a member of the Society of Fire Protection Engineers.

Christopher B. Wood, M.Sc., JD, P.E., is a member of FireLink LLC in Tewksbury, Massachusetts, and a member of the Society of Fire Protection Engineers.

the smoke; the rate of flow of smoke, gases, and unburned fuel from one space to another; and the temperatures of the walls, ceiling, floor, and air not yet drawn into the fire. Some models also predict the time of smoke and heat detector activation (including sprinkler heads) and the effects of opening or closing doors, breakage of windows, or other physical events that take place during a fire. Some models are limited to the room of fire involvement, others can track the flow of fire products through a series of rooms, and a few follow the spread of fire outside the room of origin.

Typically, the models involve the simultaneous solution of two or more differential equations. The more sophisticated models involve the simultaneous solution of such equations for many variables and use sophisticated techniques to obtain the results. The range of complexity and sophistication is wide, but all models follow the basic conservation principles of mass, energy, and momentum.

TYPES OF MODELS

As discussed more thoroughly in Section 3, Chapter 5, "Introduction to Fire Modeling," prediction models can generally be classed into the categories of zone models that solve the basic conservation equation for distinct regions (control volumes), and computational fluid dynamics (CFD) or field models that solve the fundamental equations of mass, momentum, and energy in a space that has been divided into a grid of small-volume cells.

Fire Dynamics Calculation Tools

The most commonly used class of models are fire dynamics calculation tools. This class of models typically calculate single values based on given input. Examples of these types of models calculate the flame height of a fire or calculate the heat release rate required to produce flashover in a compartment. Fire dynamics calculation tools are typically based on empirical correlations or on solutions of specific engineering scenarios. Fire dynamics calculation tools are popular because they provide simplified solutions of what are often complicated equations with many input variables. They also provide credible solutions because they have typically gone through a peer-review process through either publication or critical scientific review.

Fire dynamics calculation tools first became popular with the introduction of *FPETool,* published by the National Institute of Standards and Technology (NIST). The publication of *FPETool* by a governmental entity provided credibility to common fire dynamics calculations that had previously been considered unsubstantiated or poorly documented by some authorities having jurisdiction (AHJs). *FPETool* combined a variety of calculation tools and a zone model with an easy-to-use interface. The state-of-the-art fire dynamics calculation tools have been compiled by the U.S. Nuclear Regulatory Commission (NRC) and are based on spreadsheet solutions for the fire dynamics formulae.[12]

Zone Models

Most of the fire growth models in common use are *zone models.* These usually divide each room into two spaces or zones: (1) an upper zone that contains the hot gases produced by the fire and (2) a lower zone that contains a space beneath the upper zone that is the source of the air for combustion. Zone sizes change during the course of the fire. The upper zone can expand to occupy virtually all the space in the room. In zone models, any changes to the conditions in the upper layer occur instantly throughout the layer. Calculations from zone models are typically completed in minutes using desktop computers.

Computational Fluid Dynamics (CFD) Models

In the past, CFD models usually required large-capacity computer workstations or mainframe computers. Advances in memory space and operating speed now allow CFD models to run off high-end PCs. In addition, reductions in cost of high-speed networking equipment and more general operating system support of clustering approaches allows for parallel processing in typical engineering office environments. Small compartments and simple geometries can now be run in a few hours, whereas large complicated problems may take days or weeks. By dividing the space into many small cells (frequently hundreds of thousands or millions), CFD models can examine much greater detail than zone models. For example, CFD can represent the actual variation in thickness and temperature gradients in the upper layer and depict flows around obstructions and through openings. If such detail is needed, it is often necessary to use the sophistication of a CFD model. In general, however, CFD models are much more expensive to use, require more time to set up and run, and often require a high level of expertise to make the decisions required in setting up the problem and interpreting the output produced by the model. The use of CFD models in fire protection applications, however, is increasing. CFD models are particularly well suited for situations where the space or fuel configuration is irregular, turbulence is a critical element, or very fine detail is sought. CFD is particularly valuable in complex smoke management system evaluation and design.

Predictive Capability of Models

The reality of accidental fire is more varied and complex than can be exactly described by any existing collection of equations and data. Users should not expect that the model will produce an exact duplication of reality. Rather, the results of models should be considered as engineering estimates, valid to the degree that the physical relationships being calculated are those that actually dominate the situation and that the data entered into the model is accurate. Figures 3.6.1 through 3.6.6 demonstrate the type of approximation that should be expected. In Figure 3.6.1, four different models and one simple correlation were used in an attempt to reproduce the results from a well-documented test of a fire in a room.* In Figure 3.6.1, the curve using the letter x to indicate

*The fire test used for this comparison is test PRC17W4-¼. This was one of a series of compartment fire tests conducted under the sponsorship of the Product Research Committee. Test PRC17W4-¼ was conducted in a room 2.18 m^2 and 2.41 m high. The room had a single vent opening 0.19 m wide and 2 m high. The fuel for this test consisted of four wood cribs having a total weight of approximately 14 kg located near the center of the room[13] (1 ft = 0.305 m; 1 ft^2 = 0.0929 m^2; and 1 lb = 0.4536 kg).

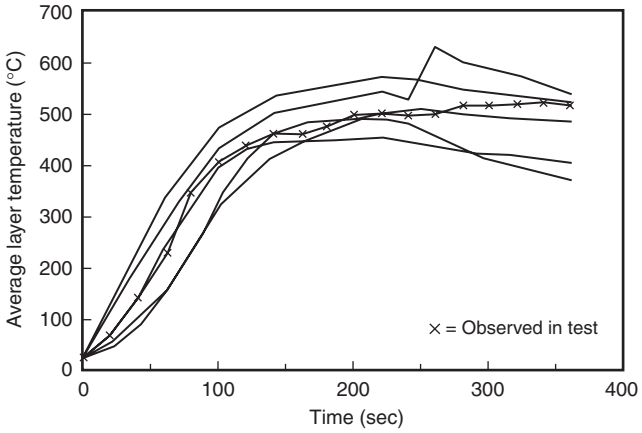

FIGURE 3.6.1 Predicted Layer Temperature by Zone Models versus Test Measurements (°F = 9/5°C + 32)

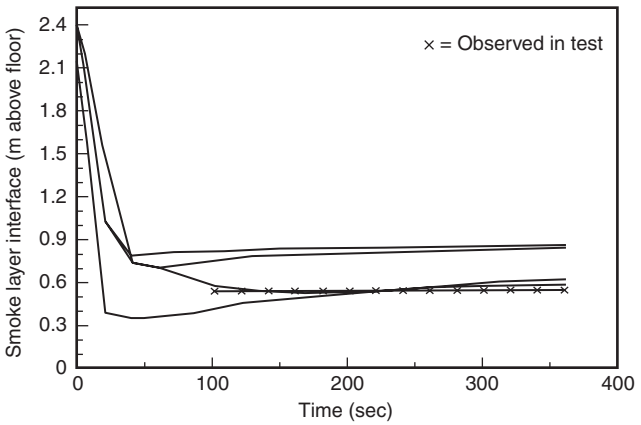

FIGURE 3.6.4 Prediction of Smoke Layer by Zone Models versus Test Measurements (1 m = 3.28 ft)

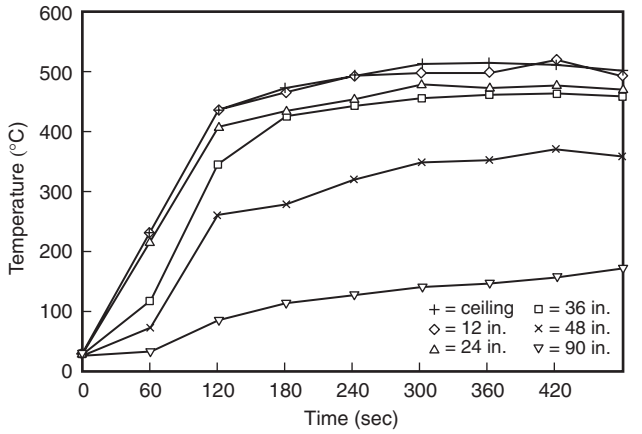

FIGURE 3.6.2 Actual Temperature Plots at Various Distances Below Ceiling (°F = 9/5°C + 32; 1 in. = 25.4 mm)

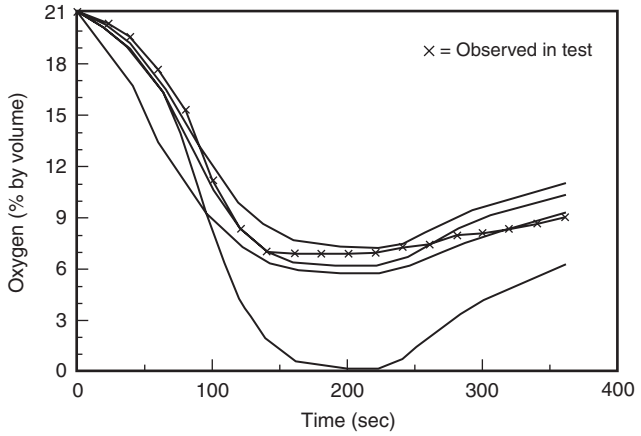

FIGURE 3.6.5 Prediction of Oxygen Concentration by Zone Models versus Test Measurements

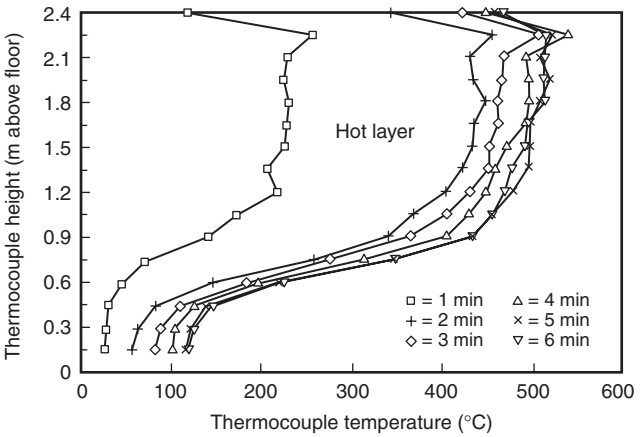

FIGURE 3.6.3 Actual Temperature Profile at 1-Min Intervals, Showing Hot Layer ("Zone") (°F = 9/5°C + 32; 1 m = 3.28 ft)

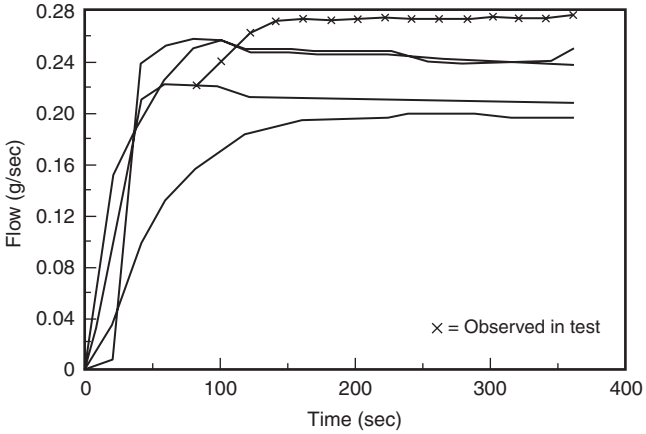

FIGURE 3.6.6 Prediction of Mass Flow Through Vents by Zone Models versus Test Measurements (1 g/sec = .0022 lb/sec)

data points plots the average upper layer temperature computed from thermocouple readings during the test. The other curves graph the predictions by the various models. The complexity of the models varied widely in this exercise. The simplest model was a single correlation equation, whereas the most complex involved the coordination of almost a hundred variables. In the case of this test, the most sophisticated model was the most accurate, but other much less sophisticated models grouped in the same range. Figure 3.6.2 is a reproduction of the actual data obtained in the burn test. Figure 3.6.2 reports the actual measured temperatures detected by a thermocouple tree near the center of the room but away from the fire plume. Every third thermocouple is plotted. Each of the lines depicts the temperature recorded by one of the thermocouples. The thermocouples were mounted with one near the ceiling and the others at 6 in. (0.15 m) intervals, with the bottom thermocouple located about 6 in. (0.15 m) above the floor. Figure 3.6.3 plots the same information as Figure 3.6.2, but rearranges the data to show the temperature profile from floor to ceiling at 1-minute intervals through the first 6 minutes of the test.

All of the models used to produce the results in Figure 3.6.1 are classed as zone models; that is, they predicted a single "upper layer" (smoke) temperature. As shown in Figures 3.6.2 and 3.6.3, an upper layer or "zone" of hot fire gases with an approximately equal temperature did exist. Although the type of approximation produced by these models is often more accurate than previous methods of estimation, the results must still be recognized as an engineering approximation. Figure 3.6.4 plots the smoke layer interface calculated by the models with that observed by the investigators. Figure 3.6.5 compares the oxygen concentration measured in the smoke in the test to concentrations calculated by the models. Figure 3.6.6 compares the measured mass flow through the vent opening with the same flow as calculated by the models. These four measures (i.e., temperature, smoke layer interface, oxygen concentration, and mass flow through the vent opening) were chosen to represent the full range of model outputs.

When using models for fire engineering or forensic investigation applications, it is important to be aware of the differences between actual and predicted fire effects as demonstrated above. The literature contains many model validation studies comparing full-scale fire test results with model predictions.[13–20] If, for example, a model overpredicts the temperature of the hot gas layer at the ceiling, the estimated time of a heat detector operation would be faster than the actual response. This would give the impression of earlier warning than would occur in reality. If the time to failure of a fire-rated ceiling was being evaluated, the failure would be predicted to occur earlier than would be expected to occur in the actual conditions.

MODEL APPLICATIONS

In the broadest sense, a fire model can be applied as a tool in the solution of any fire protection problem where the fire-produced conditions inside a building or space or the response of fire protection devices in that space are needed as input to the decision. The following are some typical examples of application classes.

Predicting a Hazard

In this case, *hazard* is defined as the expected fire-produced conditions. To start, a set of circumstances that represents a specific scenario, such as the maximum expected fire, is postulated. All of the conditions are fixed and the model is run to make a prediction of the rise in smoke (upper layer) temperature, the volume or depth of that smoke, the response of fire protection devices, the onset of serious conditions such as flashover, smoke gases or toxicity, or other items of concern. Often, this type of analysis searches for the most serious case and is used to answer questions such as, "How serious are the fire-produced conditions that can occur in this space?" Answering this question requires quantification of the conditions given a particular fire scenario, which is the role of a fire model. Frequently, a number of scenarios will have to be run to establish the most serious case. For example, consider an analysis of the hazard of a hotel room that contains a type of bed that fire tests indicate will grow, if ignited, at a moderate rate, eventually reaching a fire size of 2 megawatts (MW); a chair having a very fast fire-growth rate if ignited but a maximum rate of energy of less than 1 MW; and a number of pieces of furniture that would not be expected to be points of ignition but could join a fire at a later state. Discovery of the worst case might require a series of computer runs in which the ignition source was placed first on the bed and then on the chair, runs where the distance between the bed and the chair were varied, runs with the door open and the door closed, and other possible variations.

Sensitivity Analysis

In all of the above examples, it is frequently necessary to answer the question, "What if a change were made?" Models provide excellent tools for such parametric or sensitivity studies. Most frequently, the changes would involve the change of a material (construction, finish, furnishings), a change of an arrangement (door opened or closed, air conditioner on or off, spacing variations between fuel packages), or the presence or absence of a protection system such as smoke detectors or sprinklers. Variations in design parameters of fire protection systems can also be evaluated, such as detector or sprinkler spacing or sprinkler operating temperature and response time index (RTI). Using the example of the hotel room, typical questions might include the change in hazard or risk that would occur should the mattress be changed from a moderate-burning mattress to one that is fast burning or one that is treated to burn at a very slow rate. A similar question might relate to the use of a combustible wall material. In the case of a fire analysis, questions might relate to the difference in the situation had there been an ordinary versus a fast-response sprinkler in the space or had the door been equipped with a door closer. A first-order approximation of the contribution of an item of furnishing or a material can be made by exercising the model with and without that material present and noting the differences.

Reconstruction of a Fire

Fire models can be useful in reconstructing incidents that occur during a fire or testing suggested hypotheses or fire

cause scenarios. Ideally, there will be enough physical evidence, data available on conditions at the time of the fire, and reliable witness statements to produce all of the information necessary as input to run the selected model. In actual practice, only part of the necessary information is usually available, and running the model may in itself involve assumptions as to what the conditions were most likely to have been. Often, running the model will help demonstrate which assumptions are plausible and which are not. In the case of the example of the hotel room, the comparison of the known data to the various scenarios may demonstrate that giving the unknown data the values used in the calculation (assumptions) could not be correct as the model results do not agree with the consequences that actually occurred. In some cases, a single dominant fire scenario will emerge. The use of computer modeling in fire reconstruction and failure analysis is of particular interest to many fire protection practitioners, and papers have begun to appear in the literature.[14,15] This topic is discussed in more detail below.

Computer Modeling in Performance-Based Fire Protection Design

The application of computer fire models to performance-based design requires that the user understand the limitations and intended uses of the models selected. Several sources are available to provide guidance.[21,22] Valuable guidance can also be found in published case studies of performance-based designs found in the literature.

COMPUTER MODELING IN FIRE INVESTIGATION

Among the applications that have evolved for computer modeling has been the analysis of actual fire incidents after the fact to determine the most likely fire scenario or group of scenarios that could have produced the end result—a process called *fire reconstruction* or *failure analysis*. (See Section 3, Chapter 2, "Fire Loss Investigation.") Often, reconstruction includes an analysis of the role played by building fire protection features and how the fire might have progressed had additional fire protection measures been present, particularly when none existed at the time of the fire. *Failure analysis*[23] involves identification of the primary and contributing factors that caused the loss. Examples of factors that may result in failure include design, material or equipment selection, maintenance, and postconstruction modifications. Traditionally, these activities have been carried out by field investigators, based on physical evidence, witness statements, and the investigator's knowledge and experience, but with limited analytical tools.

Application to Reconstruction and Failure Analysis

One of the early attempts at application of the emerging analytical tools was carried out by Fleming,[24] who focused on the role that sprinklers might have played had they been present in the Haunted Castle of the Great Adventure Six Flags Amusement Park, Jackson Township, New Jersey. Fleming employed a combination of modeling and results of a variety of full-scale tests of manufactured home and compartment fires in reaching his conclusions. Since that time, a number of analyses have been carried out of major fires using progressively more sophisticated tools and approaches[25–32] in fire reconstruction and failure analysis modeling.

Because each fire incident will be different, there will be no "standard" set of models and techniques to apply. The purpose of this section is to outline the process of collecting the necessary data and setting up the modeling "experiments." The reader is encouraged to study the referenced reports as examples for specific fires.

Before a modeling effort can begin, a great deal of information needs to be obtained about the incident, beginning with an accurate layout of the building at the time of the fire. One also needs to know about the location and position of doors and windows, the type of heating, ventilating, and air-conditioning (HVAC) system, and the size and location of stairways and other vertical openings between floors. Although it may not be possible, a visit to the scene is valuable. Photos of the building during and after the fire should be studied if available. Often, news videos can be obtained.

Information needs to be gathered about the materials of construction, including the interior finishes and the furnishings and their distribution. Sources for this information include building occupants or their relatives, building owners or managers, contractors, interior decorators, or others who may have been involved in the construction, renovation, or operation of the building.

Figure 3.6.7 is a form that may prove helpful in gathering the type of data needed to use compartment models or similar analytical methods.

Where there are fire victims, important information, such as location and severity of burn injuries or blood chemistry, can be obtained from hospital or autopsy reports.

Because fire growth and the effect of fire on the building and its systems and occupants is largely time dependent, it is essential to obtain as much information as possible regarding the timing of events leading up to ignition (prefire events), during the fire (transfire events), and after the fire (postfire events).[23]

The best way to organize this information is through the use of timelines or event sequences. Benchmark events, those for which the time is known and not merely relative to a known event, are important to establish. If there are only a few events, a single timeline may suffice; otherwise, multiple timelines or event sequences[33] on the same scale may be useful. The timelines are then used for comparison with the results of the modeling experiments.

Once the data have been gathered and organized, a modeling plan should be developed based on the objectives of the study. The objective may be to assess the validity of a given hypothesis for the origin and cause of a fire or to develop new alternative hypotheses. In this case, the following questions are to be answered:

- Would the fuels, fire location, ventilation conditions, and building and occupant characteristics hypothesized result in the actual fire conditions?

Data for Compartment Fire Modeling

Room Number _____ Use _____

Size (use diagrams if possible) Wall/Floor/Ceiling Construction

Length _____ _____

Width _____ _____

Height _____ _____

Lining Materials (that represent over 10 percent of room lining)
(Include thickness, density, and other material characteristics, if known)

Wall Material	Percent of walls or area involved
_____	_____
_____	_____
_____	_____

Ceiling Material

_____	_____
_____	_____

Floor or Floor Covering Material

_____	_____
_____	_____

Doors, windows, and other openings [Enter all heights as distance above floor. If door sill is at floor enter zero (0).]

Opening	To	Top	Sill	Width	Changed During Fire (How?)*
_____	_____	_____	_____	_____	_____
_____	_____	_____	_____	_____	_____
_____	_____	_____	_____	_____	_____
_____	_____	_____	_____	_____	_____
_____	_____	_____	_____	_____	_____

Heating, ventilating, and air conditioning (HVAC). Include air flows from HVAC systems. Give rates and positions of supply and return or exhaust in this room. Also sizes and types of ducts/diffusers.

_____

_____

_____

Tightness of walls, closed windows, door fits, etc. (Unless fit is very loose, classify fit as tight, average, or loose. If fit is very loose try to get size, number, and location of cracks, etc.)

Doors _____

Windows _____

Inside walls _____

Exterior walls _____

*For example: "window broke at 10:33" or "door was closed until opened by escaping occupant, then left open—Exact time 10:30."

FIGURE 3.6.7 A Sample Compartment Fire Modeling Data Form

- Which scenarios, given the range of available fuels, possible ventilation conditions, and building characteristics, could result in the actual fire conditions?

Another objective might be to determine whether or not someone might have been injured had a detector been in use. In this case, the question to be answered could be posed as follows:

For the set of scenarios that could result in the actual fire conditions, what conditions would the potential victim be exposed to, given the range of initial locations of the victim relative to the fire, the conditions at the time of operation of the detector, and the actions and route taken during an escape attempt?

Using the questions as a guide, a list of scenarios to be modeled and the associated variable can be prepared and perhaps arrayed as a "test matrix." For the detector case above, the matrix could be multidimensional and very large. The matrix can be pruned by eliminating highly unlikely scenarios and by starting with the most conservative scenarios, that is, those that place the occupant at greatest risk. See the following scenarios, for example:

- Fire remote from the detector
- Fire between occupant and detector
- Occupant impaired
- Fuel has highest heat release rate

Once the matrix has been developed, it will probably be noted that there are not enough facts to provide all the needed model inputs. If the initial fuel package is furniture, and the construction materials and design characteristics are not known, a database for several items that bound the actual item might be used. If the characteristics are known, an exemplar might be tested. If nothing is known about door position, this becomes a variable, as would the starting position of victims.

Most models are driven by a heat release curve (Figure 3.6.8) input by the user. The user may apply one of several "standard" fires (slow, medium, fast, or ultrafast[34]) or develop a curve more specific to the fire under investigation. These "standard" fires assume the fire grows as a function of time squared (t^2) modified by a specific factor for slow, medium, fast, and ultrafast results. The closer the rate of the heat release curve is to the actual occurrence, the more accurate the results. If "standard" t^2 fires are used, it is incumbent on the user to justify their appropriateness. Developing a case-specific heat release curve is one of the more difficult tasks in a reconstruction. One begins with the first item ignited, if this is known. If the first item is not known, part of the reconstruction will be to experiment with several possible "first items." Next, the ignition of nearby items is determined and the heat release curve(s) added to that of the first item, making adjustments for the radiation effects from the burning first item, as necessary. It has been shown[35] that the developing hot layer in a compartment fire increases the burning rate of items before the onset of flashover. Adjustments must be made to reflect this phenomenon.[26] Considerable data and reference material on heat-release rates for a variety of items and materials are available to assist in the development of case-specific heat release curves.[36,37]

Once a fire curve has been developed, one way to prune the matrix is to plan a set of experiments to test the sensitivity of

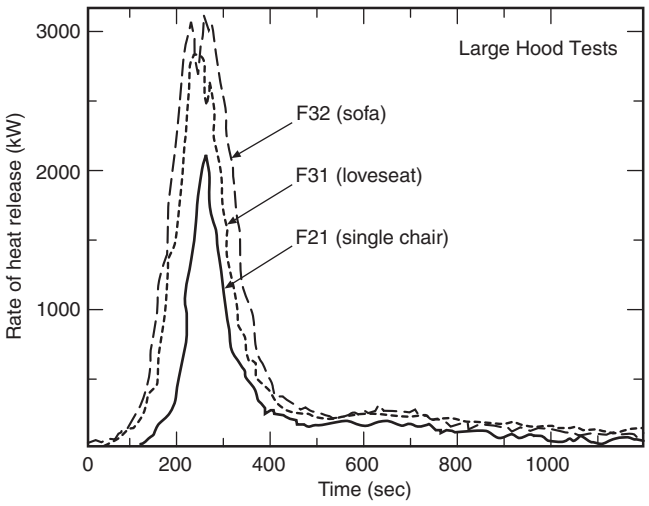

FIGURE 3.6.8 Typical Upholstered Chair Heat Release Rates (Source: Philip J. DiNenno et al. (Eds.), *SFPE Handbook of Fire Protection Engineering,* 2nd ed., National Fire Protection Association, Quincy, MA, 1995. Fig. 3-1.6)

the results to the unknowns. If, for example, the HVAC has little or no effect on the time to flashover, it may be ignored, but it may have a major effect on tenability in an area remote from the fire, in which case HVAC would need to be included. Keeping detailed records of the modeling experiments is important. It is very easy to "check a few things out" at the keyboard and not remember what the results were. Keep a "lab" notebook, which is increasingly done with a computer spreadsheet that relates the fire scenarios examined with results and run file names. It is suggested that a file-naming convention be used that tracks the scenario number as well as the key variables.

It is clear that many, many runs will be necessary for even the most straightforward analysis. It is not the intent of this chapter to thoroughly examine all aspects of modeling for fire construction and failure analysis. However, the following guidelines should be observed:

1. *Know the limitations of the models used.* ASET,[2] for example, assumes a vent flush with the floor to relieve pressure, but this is only a mathematical provision for consistency with the solved equations and the data is questionable after flashover. ASET also requires that the user assign a heat loss factor within a specified range to the space being evaluated. Most models do not consider the effect of radiation from the upper layer on the heat release of the burning items.[18] Heat detector models may not include the transit time for heated gas to reach the sensor. This can be a consideration for low-heat output fires (weak plumes) or high ceilings. The importance of transport time may be evaluated using a technique proposed by Mowrer.[38]
2. *Use more than one model.* For example, different models use different correlations for plumes[39] and for preflashover layer temperature.[40]
3. Where possible, check the model against actual experiments[41] or test data collected under similar conditions.

4. Use ranges of values for variables to which the model is sensitive, unless the value is known to be correct. For example, the heat of combustion of materials with generic names such as "polyurethane" can vary from product to product. Modeling with both upper and lower bounds will give a range of results that brackets the problem.
5. *Consider the ambient conditions.* For example, the hot layer formed under a metal deck roof on a blistering hot day will delay the transport of smoke to a detector. If the model being used for detector operation relies on temperature rise above ambient, the "ambient" used should be that of the hot layer, not the temperature lower in the compartment or outside the building. When there are open windows, the effects of wind should be considered in modeling the effects of low-energy fires (i.e., smoldering or small flaming fires).

Consistent with the development of fire models at NIST, the most recent addition to the models is the CFD model, *Fire Dynamics Simulator*[42] (FDS). It has found extensive use both in fire protection design and reconstruction. The model's increased detail in fluid dynamics has allowed its use in complex situations for which fire dynamics calculations or zone models would provide little, if any, additional insight into the scenario that occurred. NIST has used FDS to address conditions and fire development in reconstructions such as the Cherry Hill fire,[43] involving multiple fire fighter deaths, and the World Trade Center attack.[44]

Cautions on the Use of Computer Models in Fire Reconstruction and Failure Analysis

One should always keep in mind that there are some situations where a real-world fire is so complicated that the use of models at the present level of sophistication to analyze the entire event may not be valid. However, parts of the event, particularly the early stage of growth within the compartment or on the floor of origin, may be studied.

The use of fire models for forensic applications is expanding. For fire models to gain credibility in the forensic arena, they must be applied with care, keeping in mind their limitations.

CONSIDERATIONS FOR SELECTING AND USING FIRE MODELS

Models and Engineering Tools

Fire models are engineering tools. Like engineering handbooks, they arc available to all persons, regardless of competence. Unlike engineering handbooks, however, many models have been made user-friendly and can be executed by persons who may not understand their capabilities, limitations, or the impact of the choices made in setting up the problems. When decisions produced by a model impact on the safety of life and property, one of the two following cases must hold:

1. Users must understand what the model is doing and how it is achieving the results, thereby treating it as an engineering tool. In such cases, the users are as responsible for the results as they would be had they gone to the engineering handbooks and extracted the equations themselves. Engineers are encouraged to use models, understand them, and become fluent with them. They will become an excellent tool under their control, or
2. Users must ascertain the limits to which the model has been demonstrated as rational and restrain their use within these bounds. If the occasion necessitates exceeding these bounds, the user should obtain the advice and/or service of individuals competent to examine the model and determine its appropriateness for the use desired.

User Inputs

Many models require that the user provide inputs beyond a simple description of the space and its contents. Some of these inputs can greatly affect the result. The user may or may not have the data available or an understanding of the impact of his or her decision. Some models provide information to assist users; others do not. It is important that users exercise the model, find the variables required, and ensure that they can properly assign these before using the model. An important thing to remember is that many models include default values for the variables. A default value is one that has been included in the model and will be used by the model unless changed by the user. Usually, the values are ones felt to be reasonable by the model developer. However, they may or may not be appropriate for the case involved. The user must examine and responsibly accept or alter the default values as is appropriate for the case at hand.

Level of Sophistication Needed

The sophistication or detail of a model may or may not be related to its accuracy for the case involved. A general principle is to use the simplest model that meets the user's needs for the type and quality of information desired and the information required to run the model. Many of the more sophisticated models provide masses of detail that are not available in the simpler version. Conversely, some of the very simple models omit important fire phenomena. The balance between ensuring that the necessary phenomena are modeled and maintaining the sophistication of the model is best achieved by frequent use and examination of the models of interest.

Review and Adjustment

Finally, many computer fire models undergo regular review and possible adjustments. Users should try to stay abreast of updates, revisions, or other changes to models they use. They should be wary of models that are not being maintained and adjusted as needed by a competent organization.

SUMMARY

Fire growth models are tools used to solve fire protection problems. This chapter provides general guidance on the types of applications in which computerized fire growth models might

be useful. For example, fire models may be used to predict a hazard, to reconstruct a fire, or to analyze how changing the parameters of a fire might affect its outcome.

This chapter also provides specific information on the predictive capability of models and on types of models, including fire dynamics calculation tools, zone models, and CFD models.

Chapter 7

Fire Hazard Analysis Techniques

Morgan J. Hurley ■ Richard W. Bukowski

Chapter Contents

Performing a Fire Hazard Analysis
Developing Fire Scenarios and Design Fire Scenarios
Quantification of Design Fire Scenarios
Prediction of Hazards

Key Terms

bounding condition, design fire curve, design fire scenario, fire hazard analysis, fire model, fire scenario, performance-based design, *t*-squared fire

Available methods to estimate the potential impact of fire can be divided into two categories: risk-based and hazard-based. Both types of methods estimate the potential consequences of possible events. Risk-based methods also analyze the likelihood of scenarios occurring, whereas hazard-based methods do not. Fire risk analysis is described more fully in Section 3, Chapter 8, "Fire Risk Analysis." Section 3, Chapter 9, "Closed Form Enclosure Fire Calculations," provides simple fire growth calculation methods.

The goal of a fire hazards analysis (FHA) is to determine the expected outcome of a specific set of conditions called a fire *scenario.* The scenario includes details of the room dimensions, contents, and materials of construction; arrangement of rooms in the building; sources of combustion air; position of doors; numbers, locations, and characteristics of occupants; and any other details that have an effect on the outcome of interest. This outcome determination can be made by expert judgment, by probabilistic methods using data from past incidents, or by deterministic means such as fire models. "Fire models" include empirical correlations, computer programs, full-scale and reduced-scale models, and other physical models. The trend today is to use models whenever possible, supplemented if necessary by expert judgment. Although probabilistic methods are widely used in risk analysis, they find little direct application in modern hazard analyses. Probabilistic models are discussed in Section 3, Chapter 5, "Introduction to Fire Modeling." Typically, when the potential impact of fire is estimated, a hazard basis is used. When probabilities or frequencies are considered, it is usually in the context of determining whether or not a scenario is sufficiently likely to warrant further analysis.

Hazard analysis can be used for one of two purposes. One is to determine the hazards that are present in an existing or planned facility. The other use is for design, where trial design strategies are evaluated to determine whether they achieve a set of fire safety goals. Hazard analysis can be thought of as a component of risk analysis. That is, a risk analysis is a set of hazard analyses that have been weighted by their likelihood of occurrence. The total risk is then the sum of all of the weighted hazard values. In the insurance and industrial sectors, risk assessments generally target monetary losses, since these dictate insurance rates or provide the incentive for expenditures on protection. In the nuclear power industry, probabilistic risk assessment has been the basis for safety regulation. Here the risk of a release of radioactive material to the environment is commonly examined, ranging from a leak of contaminated water to a core meltdown.

Available fire hazard calculation methods range from relatively simple equations that can be performed with a hand calculator to complex methods that require powerful computers, and many methods that fall between.

Morgan J. Hurley, P.E., is the technical director of the Society of Fire Protection Engineers, where he is responsible for advancing the science and practice of fire protection engineering internationally. He is also adjunct faculty in the University of Maryland's Department of Fire Protection Engineering.

Richard W. Bukowski, P.E., is a senior research engineer and coordinator of codes and standards activities for the Building and Fire Research Laboratories at NIST.

Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety"; and Section 3, Chapter 11, "Overview of Performance-Based Fire Protection Design."

PERFORMING A FIRE HAZARD ANALYSIS

Steps of a Fire Hazard Analysis

Performing an FHA is a fairly straightforward engineering analysis. The steps include the following:

1. Selecting a target outcome
2. Determining the scenario(s) of concern that could result in that outcome
3. Selecting an appropriate method(s) for prediction of growth rate of fire effects
4. Calculating the time needed for occupants to move to a safe place
5. Analyzing the impact of exposure of occupants or property to the effects of the fire
6. Examining the uncertainty in the hazard analysis
7. Documentation of the fire hazard analysis process, including the basis for selection of models and input data

Fire hazard analysis can also be used as part of the performance-based design process. For more information on performance-based design, see Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety," and Section 3, Chapter 11, "Overview of Performance-Based Fire Protection Design."

Selecting a Target Outcome

The target outcome most often specified is avoidance of occupant fatalities in a building. Another might be to ensure that fire fighters are provided with protected areas from which to fight fires in high-rise buildings. The U.S. Department of Energy (DOE) requires that FHAs be performed for all DOE facilities.[1] Their objectives for such FHAs, as stated in DOE 5480.7A, include the following:

- Minimizing the potential for the occurrence of fire
- No release of radiological or other hazardous material to threaten health, safety, or the environment
- An acceptable degree of life safety to be provided for DOE and contractor personnel and no undue hazards to the public from fire
- Critical process control or safety systems are not damaged by fire
- Vital programs are not delayed by fire (mission continuity)
- Property damage does not exceed acceptable levels (e.g., $150 million per incident)

An insurance company might want to limit the maximum probable loss to that on which the insurance rate paid by the customer is based; a manufacturer might want to avoid failures to meet orders to avoid erosion of its customer base; and some businesses might want to guard their public image of providing safe and comfortable accommodations. Any combination of these outcomes could be selected as appropriate for an FHA.

DEVELOPING FIRE SCENARIOS AND DESIGN FIRE SCENARIOS

Fire Scenario and Design Fire Scenario Defined

Determining the fire source is one of the most important parts of performing a fire hazard analysis. To determine the fire source, a design fire scenario must be developed. A *fire scenario* is a set of conditions that defines the development of fire and the spread of combustion products. Fire scenarios comprise three sets of features: building characteristics, occupant characteristics, and fire characteristics. Building characteristics describe the building features that could affect fire development and the spread of combustion products. Occupant characteristics describe the state(s) of occupants at the time of the fire. Fire characteristics describe the ignition and growth of the fire. A *design fire scenario* is a set of conditions that defines the critical factors for determining the outcomes for trial fire protection designs of new buildings or modifications to existing buildings.[2] Design fire scenarios are the fire scenarios that are selected to analyze a trial design. They are generally a subset of the fire scenarios.

The design fire scenario is based on a fire that has a reasonable likelihood of developing from a series of events. Fire scenarios need to be based on reality and should be developed accordingly. For example, the occupancy, the purpose for which the design is being developed, the fuel load, potential changes in the property, the presence of sprinklers and fire detection, the presence of alarm and notification systems, and smoke management should be considered. Design fire scenarios differ by occupancy and should be based on reasonably expected fires and worst-case fires. Although this chapter deals with hazard-based approaches, some risk must be included in the analysis when developing design fire scenarios. For instance, if a fire may be technically plausible but is extremely unlikely, that scenario may not be necessary to include in the design fire scenarios.

Determining the Scenario(s) of Concern

Records of past fires, either for the specific building or for similar buildings or class of occupancy, can be of substantial help in identifying conditions to be avoided. Statistical data from NFPA or from the National Fire Incident Reporting System (NFIRS) on ignition sources, first items ignited, rooms of origin, and the like can provide valuable insight into the important factors contributing to fires in the occupancy of interest. (See also Section 3, Chapter 4, "Use of Fire Incident Data and Statistics.") Anecdotal accounts of individual incidents are interesting but might not represent the major part of the problem to be analyzed.

Murphy's Law ("if anything can go wrong, it will") applies to major fire disasters; that is, significant fires seem to involve a series of failures that set the stage for the event. Therefore, it is important to examine the consequences of things not going according to plan. In DOE-required FHAs, one part of the analysis is to assume both that automatic systems fail and that the fire department does not respond. This is used to determine a worst-case loss and to establish the real value of these systems. The 2006 edition of NFPA *101*®, *Life Safety Code*®, includes a performance-based design option containing a basic set of design fire scenarios. Scenario 8 is a common fire that starts while

either the fire alarm system or the sprinkler system (in turn) is rendered ineffective. Given the normal high reliability of these systems, it is not required for the performance objectives to be met fully under these conditions, but stakeholders should feel that the resulting losses are not catastrophic or otherwise unacceptably severe. In a risk assessment, the consequences of such failures would be weighted by the probability of failure and added into the total risk. In a hazard analysis, the objective is hazard avoidance, so the contribution of low probability events is more subjective. Scenarios must be translated into design fires for fire growth analysis and occupant evacuation calculation. See the discussion in the Quantification of Design Fire Scenarios section later in this chapter.

NFPA *101* Design Fire Scenarios

NFPA *101* provides eight design fire scenarios that should be considered in the development of a performance-based design. Briefly, these design fire scenarios are as follows:

1. An occupancy-specific design fire scenario that is representative of a typical fire for the occupancy
2. An ultrafast-developing fire in the primary means of egress, with interior doors open at the start of the fire (for a discussion of fire development, see Section 2, Chapter 4, "Dynamics of Compartment Fire Growth")
3. A fire that starts in a normally unoccupied room that may endanger large numbers of occupants
4. A fire that originates in a concealed wall or ceiling space adjacent to a large occupied room
5. A slowly developing fire, shielded from fire protection systems, in close proximity to a high-occupancy area
6. The most severe fire resulting from the largest possible fuel load characteristic of the normal operation of the building
7. An outside exposure fire
8. A fire originating in ordinary combustibles with each passive or active fire protection system individually rendered ineffective; this scenario is not required where it can be shown that the level of reliability and the design performance in the absence of the system are acceptable to the authority having jurisdiction (AHJ)

Although only eight scenarios are listed in the performance option of NFPA *101,* more than eight scenarios will be developed and analyzed. For most building designs, for example, there will usually be far more than a single scenario that is representative of a typical fire in a given occupancy.

Applying NFPA *101* Design Fire Scenarios

For a typical building, what happens when each of these eight general scenarios is applied to what might occur as a reasonable design fire in that building? For the purposes of this illustration, a multistory hotel building with some meeting rooms on lower floors is considered. The following fires might be used as design fires in meeting the eight-scenario criteria of NFPA *101:*

1. A typical fire based on the occupancy might include a patron smoking in bed, or a sterno-initiated fire in a meeting room or restaurant area.
2. An ultrafast fire in a primary means of egress would likely mean a flammable liquid fire in the corridor near one of the exit doors.
3. Fire in a normally unoccupied room would likely include a fire in a janitor's closet, started by oily rags or ignition of some cleaning fluid.
4. Fire in a concealed space, particularly if the hotel were of combustible construction, might occur in the drop ceiling above the bathroom. This would likely be an electrical fire.
5. A shielded fire near occupied space might be in a maid's cart or under a display table in a meeting room.
6. The most severe fire from the largest fuel load typical to the building might occur during remodeling or might occur due to storage of furniture in one room or storage of chairs in a meeting room.
7. The outside exposure fire could include other buildings, skylights in the roof of a low-rise building nearby, or a wildland fire. This fire would be specific to the occupancy and building being considered.
8. Failure of a system would need to include looking at rated walls, rated floors, as well as sprinkler and fire alarm systems. When looking at these systems, one should consider what might fail rather than failure of the entire system. For instance, failure of a sprinkler system might mean failure of the entire water supply or it might mean failure of a single sprinkler to react when expected. By providing redundancy into water supply and fire pumps, and monitoring main valves, failures could be limited as a part of this evaluation.

Bounding Conditions

During development of the fire scenarios and design fire scenarios, the allowable future changes in the facility must also be considered. The extent of the changes that are considered by the design become bounding conditions for the analysis and subsequent use of the building. One can expect that a design fire scenario is not exactly what will happen and that the building as originally designed and anticipated will not remain exactly as analyzed. Therefore, as one develops design fire scenarios and one calculates the expected fire response, some amount of change in those scenarios must also be considered.

When conducting a hazard analysis, it is important to consider the types of changes that may occur. If the hazard analysis only considered a specific set of initial conditions, then it would be necessary to revise the fire hazard analysis any time changes were made in the future. The range of changes that will be considered by the hazard analysis is a judgment call between the designers and the owner.

For example, a hotel room floor might become a meeting room floor; a meeting room area might become an exposition center; occupant loads could be greater than expected or calculated; movable walls could create simultaneous use when nonsimultaneous use was expected; or the space between a ballroom ceiling and the floor above might be used for storage. All of these events are reasonably foreseeable, but some may fall outside of the bounding conditions. Bounding conditions must be clearly identified because changes in the building may occur.

Other situations that might occur on a more general basis, for any occupancy, include the response of a fire department and cutbacks in fire department funding or unwanted alarms causing deactivation of a system. Some of these bounding assumptions can be addressed specifically—for instance, maximum fuel load or occupant characteristics.

Implied Risk

Although this chapter addresses fire hazard analysis, there is some implied risk in any such analysis. The primary risk factors involved are included in the design fire development. The design fires described for the hotel building did not include such accidents as gasoline tanker trucks crashing into the side of the building or bombs ignited at the base of the building. There is always the risk that these events could happen, but the engineer must evaluate the likelihood of these events. For example, buildings are typically not designed to survive the impact and ensuing fire of a missile strike. If this were to occur, achievement of the design goals and objectives might not be expected. Similarly, it is conceivable that simultaneous fires could occur, although prescriptive building codes such as NFPA *101* explicitly exclude such an event. These might be limitations described in the fire strategy report to clarify what is covered and what is not.

When proposing to exclude a scenario from further consideration, it is important to ensure that stakeholders understand the implications of excluding the scenario. For example, if the fire scenario associated with a gasoline tanker truck crashing into the side of the building is dismissed, and the building is located on a highway leading to a major oil refinery, stakeholders would need to understand and accept that if a gasoline tanker truck did crash into the side of the building, goals and objectives might not be met.

Data Sources

In developing design fire scenarios, it is useful to have data on which to base future quantification. Members of the NFPA *Life Safety Code* Technical Committees developed the design fire scenarios based on statistical analyses prepared by the NFPA Fire Analysis and Research Division and also on past fires that have occurred in different occupancy types.

The NFPA One Stop Data Shop provides much information regarding fire statistics and results. Other sources addressing typical fires in occupancies include Factory Mutual data, state or local jurisdiction data for various occupancies, the National Fire Incident Reporting System, or past fire history published in the *NFPA Journal.* Other possibilities include fire test results (many of which can be found on the National Institute of Standards and Technology Fire Internet site), manufacturers' data regarding specific fire performance of materials, or listings of materials by recognized test labs. It can be reasonably expected that the amount of data to develop a design fire will not be sufficient to exactly predict what will happen in all cases.

Overall Example

The following example develops scenarios for a large exhibit hall at a convention center and describes some of the work that might be done using the scenarios that have been developed.

The first step is to investigate potential fires that might occur so that the design fire scenarios can be chosen. Based on the scenarios from NFPA *101,* the scenarios examined for a typical convention center might be as follows:

1. The occupancy-specific design fire scenario might include a fire in an exhibit booth or a fire in auditorium seating.
2. The ultrafast fire might involve a fire in a plastic boat display located near the main exit.
3. A fire in a normally unoccupied room could occur in the storage of stacked chairs in an exhibit hall next to the exhibit hall being considered. There could be a show in one exhibit hall with large numbers of people, and the adjacent hall might be used as temporary storage during that event.
4. A fire in a concealed space is unlikely in Type 1 construction but could occur in electrical or insulation areas.
5. A shielded fire could occur in the plastic boat previously mentioned or in a covered exhibit space. More and more jurisdictions are requiring automatic sprinklers in covered exhibit spaces, but that is not yet universal.
6. The most severe fire to be considered would likely be the boat fire previously mentioned.
7. An outside exposure fire would typically not be considered for this occupancy because convention centers are generally surrounded by parking lots and other open areas. However, if the loading dock is considered outside, the scenario might involve fire in a truck waiting to unload at the convention center.
8. A typical fire with failure might include failure of the sprinkler or fire alarm system or perhaps failure of the smoke control system.

If the purpose of the example is to perform an egress analysis, the worst-case fire may be all that is necessary for evaluation. The worst-case fire would likely be the shielded boat fire at peak rate of heat release. To quantify the fire, users might look at the fuel load and estimate the rate of burning, they might look at plastic fires and extrapolate, they might look at fast or ultrafast fires and assume the fire peaks at the estimated sprinkler response time, they might assume the fire is shielded on the inside of the boat and so not have the fire peak at the estimated sprinkler response time, or they might specify sprinklers inside the boat and limit the fire size. The user would likely try a combination of these factors to see the effects.

Once the fire scenario is developed, smoke-filling calculations can be performed to determine the clear height of a smoke layer over time. Those calculations would be compared to the timed evacuation analysis. Both calculations would likely start without suppression or smoke control to see whether the evacuation can occur without those two systems. If so, the analysis is simplified.

Finally, the user would identify bounding conditions via a sensitivity analysis. For instance, is the size of the boat important? How about the materials of the boat? Has the fuel been removed from the boat? If smoke control is necessary to make the design work, that smoke control needs to be identified as a critical system. Similarly, the occupant load, the exit sizes, the number of disabled persons, and the availability of an alarm system as well as its audibility must all be considered in the sensitivity analyses.

Once all of these factors have been considered and dealt with, the hazard-based analysis is complete. The documentation of the analysis is the next important part and cannot be omitted from any fire hazard analysis. The assumptions, bounding conditions, scenarios considered, and limitations should be identified to the AHJs, the owner, and other interested parties. See Section 3, Chapter 11, "Overview of Performance-Based Fire Protection Design," for more details on documentation requirements.

QUANTIFICATION OF DESIGN FIRE SCENARIOS

Quantification of design fire scenarios involves two steps. The first step is to develop the design fire curve for the design fire scenario or portion of the design fire scenario of interest. The design fire curve represents the heat release rate over time for the fire in question. Once the design fire curve is estimated, the second step, predicting the fire effects, is then possible.

The purpose of the design fire is similar to the assumed loading in a structural analysis—that is, to answer the question of whether the design will perform as intended under the assumed challenge. Keeping in mind that the greatest challenge is not necessarily the largest fire (especially in a sprinklered building), it is helpful to think of design fires in terms of their growth phase, steady-burning phase, and decay phase (Figure 3.7.1).

Design Fire Curves

The design fire curve is a description of the intensity (heat release rate) of a fire as a function of time. The design fire curve can be divided into four phases: ignition, growth, steady-burning, and decay. Because there is not a single framework for developing the entire design fire curve, each step is typically developed separately and then brought together as a single curve.

It is not always necessary to quantify each phase of a design fire curve, depending on the goals of the analysis. For example, to predict when a fire detection or suppression system would activate, it might only be necessary to quantify the growth phase. For sizing a smoke control system, only the maximum heat release rate might be needed. A structural analysis might need the peak burning rate and the duration of peak burning. Performing an evacuation analysis might require quantification of the growth and fully developed stages.

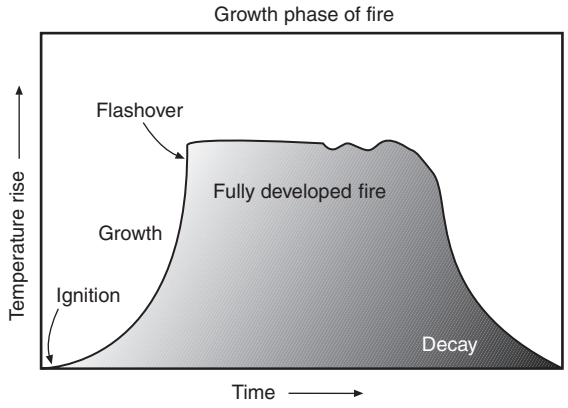

FIGURE 3.7.1 Design Fire Structure

Ignition. The design fire curve starts at ignition. A simple approach to developing a design fire curve is to assume that an ignition source of sufficient intensity is available to instantaneously ignite the initial fuel package to establish burning. However, if the heat transfer to a combustible object or the temperature of the object is known, calculations can be performed to predict whether the object will ignite. Calculations to determine whether ignition occurs depend on the state of the fuel: solid, liquid, or gas.

Ignition can be divided into two categories: piloted and nonpiloted. In the case of piloted ignition, a "pilot" such as a spark or flame initiates flaming. For nonpiloted ignition, flaming occurs spontaneously as a result of heating in the absence of flame or spark.[3] Except for piloted ignition of gases and liquids that are at a temperature above their flashpoint, all materials must first be heated before ignition can take place.[3]

Solids. With the exception of smoldering combustion, for a solid to ignite it must first be heated sufficiently to release flammable vapors. Flammable vapors can be given off either by pyrolysis or by melting and subsequent vaporization. Pyrolysis occurs when a material is heated and decomposes, releasing vapors known as *pyrolyzates.* Unlike melting and vaporization, in which no molecular changes occur, the vapors given off are different from the material that was originally heated.[4] The process of pyrolysis can be viewed as "thermal cracking," in which larger molecules are broken into smaller molecules.

Piloted ignition occurs if the concentration of pyrolysis gases is above the lower flammable limit and a "pilot" is present. For nonpiloted ignition to occur, the pyrolysis gases must be at a concentration above the lower flammable limit and they must be above their autoignition temperature. Because of this, it requires less energy for piloted ignition to occur than for nonpiloted ignition.[4]

Methods of predicting ignition of solid materials exposed to thermal radiation differ depending on whether a solid is thermally thin or thermally thick. A thermally thick material is one in which a temperature rise will not be perceived on the unexposed surface when the material is heated. Wood is a typical example of a thermally thick material, whereas sheet metal is a good example of a thermally thin material.

An engineering guide[4] published by the Society of Fire Protection Engineers (SFPE) focusing on piloted ignition contains six methods for predicting the piloted ignition of solid materials under radiant exposure as follows.

For thermally thin materials, the method of Mikkola and Wichman can be used:

$$t_{ig} = \rho L_0 c \frac{(T_{ig} - T_0)}{(\dot{q}''_r - \dot{q}''_{crit})} \quad (1)$$

where

T_{ig} = Ignition temperature (°C)

T_0 = Initial temperature (°C)

t_{ig} = Time to ignition (sec)

ρ = Density of the material (kg/m^3)

c = Specific heat of the material (kJ/kg·C)

L_0 = Thickness of the material (m)

$\dot{q}''_r$ = External heat flux (kW/m^2)

$\dot{q}''_{crit}$ = Critical heat flux for ignition (kW/m^2)

For thermally thick materials, the following methods can be used:

- Mikkola and Wichman

$$t_{ig} = \frac{\pi}{4} k\rho c \frac{(T_{ig} - T_0)^2}{(\dot{q}''_r - \dot{q}''_{crit})^2} \quad (2)$$

where k is thermal conductivity (W/m·K).

- Tewarson

$$t_{ig} = \frac{\pi}{4} \frac{(TRP)^2}{(\dot{q}''_r - \dot{q}''_{min})^2} \quad (3)$$

where TRP is thermal response parameter (kW·sec$^{1/2}$/m^2) and $\dot{q}''_{min}$ is minimum heat flux for ignition (kW/m^2).

- Quintiere and Harkleroad

$$t_{ig} = \left(\frac{\dot{q}''_{min}}{b \cdot \dot{q}''_r}\right)^2 \qquad \text{for } t \le t_m \quad (4)$$

where b is a constant related to $k\rho c$ (sec$^{-1/2}$) and t_m is characteristic time to reach thermal equilibrium (sec).

- Janssens

$$t_{ig} = 0.563 \left(\frac{k\rho c}{h_{ig}^2}\right) \left(\frac{\dot{q}''_r}{\dot{q}''_{crit}} - 1\right)^{-1.83} \quad (5)$$

where h_{ig} is heat transfer coefficient at ignition, which incorporates both the radiative and convective components (W/m^2·C).

- Toal, Silcock, and Shields

$$t_{ig} = \frac{(FTP_n)}{(\dot{q}''_r - \dot{q}''_{crit})^n} \quad (6)$$

where FTP_n is flux time product and n is flux time product index is greater than or equal to 1.

See SFPE's engineering guide[4] for additional information on applying these methods as well as the appropriateness of these methods for different situations.

Liquids. For a liquid to ignite, it must be at a temperature that is equal to or greater than its flashpoint. NFPA 30, *Flammable and Combustible Liquids Code,* defines flashpoint as "the minimum temperature of a liquid at which sufficient vapor is given off to form an ignitable mixture with air, near the surface of the liquid or within the vessel used."

A number of test methods can be used to measure the flashpoint of a liquid. Flashpoint is not a physical property and is instead a model of physical phenomena associated with vaporization of a sufficient quantity of fuel to establish a gaseous mixture that is at the lower flammable limit at a distance above the fuel surface and therefore can change with the test method employed.[3]

Ignition of a liquid at its flashpoint is analogous to piloted ignition of a solid, in that for ignition to occur, a pilot must be present. The analogy for nonpiloted ignition of liquids would be ignition at the autoignition temperature. Values for flashpoints and autoignition temperatures for some common materials can be found in NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas.*

Gases. For ignition of a flammable gas to occur, it must be mixed with a sufficient quantity of oxygen for a reaction to take place. Concentrations where this occurs are represented by a flammability range, which corresponds to gas/air concentrations that are at or above the lower flammable limit and not exceeding the upper flammable limit. Flammability limits for a variety of gases can be found in NFPA 497.

For mixtures of flammable gases, Le Chatelier's principle can be used to determine the lower flammable limit.[3] Le Chatelier's law states that

$$L_m = \frac{100}{\sum_i \frac{P_i}{L_i}} \quad (7)$$

where

L_m = Lower flammability limit of the mixture

P_i = Volume fraction of gas i

L_i = Lower flammable limit of gas i

For more information, see Section 6, Chapter 10, "Gases."

Fire Growth. Following ignition, a fire might grow as it develops on the first item ignited or spreads to additional items. To determine whether spread would occur to adjacent items, the problem can be approached from the perspective of whether or not these items would ignite. For growth involving a single item, the fire could spread to unignited portions of the item. This could either lead to the entire item burning, or earlier ignited portions might burn out before the fire spreads to involve the entire item, such that the entire item is never fully involved.

Prediction of Fire Effects

The primary importance of the appropriate selection of the design fire's growth is in obtaining a realistic prediction of detector and sprinkler activation, time to start of evacuation, and time to initial exposure of occupants. In 1972, Heskestad first proposed that for the early fire growth period the assumption that fires grow according to a power law relation works well and is supported by experimental data.[5] He suggested fires of the form

$$Q = \alpha t^n \quad (8)$$

where

Q = Rate of heat release (kW)

α = Fire intensity coefficient (kW/sec^n)

t = Time (sec)

n = 1, 2, 3

Later, it was shown that for most flaming fires (except flammable liquids and some others) $n = 2$, the so-called *t*-squared growth rate.[6] A set of specific *t*-squared fires labeled slow, medium, and fast, with fire intensity coefficients such that the fires reached 1000 Btu/sec (1055 kW) in 600, 300, and 150 seconds, respectively, were proposed for design of fire detection systems.[7] Later, these specific growth curves and a fourth called "ultrafast,"[8] which reaches 1055 kW in 75 seconds, gained favor in general fire protection applications.

This set of *t*-squared growth curves is shown in Figure 3.7.2. The slow curve is appropriate for fires involving thick, solid objects (e.g., solid wood table, bedroom dresser, or cabinet). The medium growth curve is typical of solid fuels of lower density (e.g., upholstered furniture and mattresses). Fast fires are thin, combustible items (e.g., paper, cardboard boxes, draperies). Ultrafast fires are some flammable liquids, some older types of upholstered furniture and mattresses, or materials containing other highly volatile fuels.

These *t*-squared curves represent fire growth starting with a reasonably large, flaming ignition source. With small sources, there is an incubation period before established flaming, which can influence the response of smoke detectors. During this incubation period, the fire may not significantly grow in size, although smoke would still be produced in quantities potentially sufficient to activate smoke detectors.

This specific set of fire growth curves has been incorporated into several design methods, such as that for the design of fire detection systems in *NFPA 72®, National Fire Alarm Code®*. They are also referenced as appropriate design fires in several international methods for performing alternative design analyses in Australia and Japan and in a product fire risk analysis method published in this country.[9] Although in the Australian methodology the selection of growth curve is related to the fuel load (mass of combustible material per unit floor area), this is not justified, since the growth rate is related to the form, arrangement, and type of material and not simply its quantity. Consider

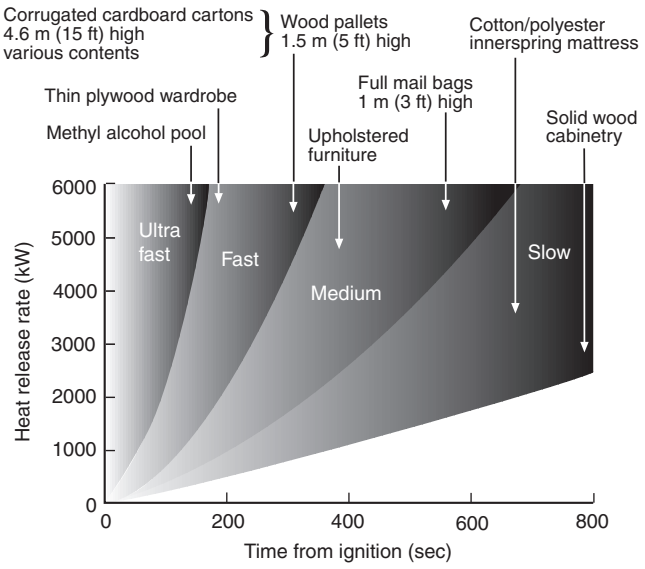

FIGURE 3.7.2 Set of *t*-Squared Growth Curves

22 lb (10 kg) of wood arranged in a solid cube, as sticks arranged in a crib, and as a layer of sawdust (Figure 3.7.3). These three arrangements would have significantly different growth rates although representing identical fuel loads.

Steady Burning. Where a fire scenario involves a fire in an enclosure, fire growth might continue until all the combustible items within the room are involved. Once this occurs, the rate of burning is influenced by one of two factors: (1) the available ventilation or (2) the available fuel. Calculation of fire temperatures within the room is easily accomplished by use of simple algebraic equations. Although computer models are frequently used in hazard analyses, they are generally no more accurate (and indeed may be less accurate) than simple hand calculations for prediction of temperature and burning rate during fully developed burning.[10] For example, for postflashover fires, hand calculation methods are generally used to estimate compartment temperatures.[11]

SFPE's engineering guide[11] on fire exposures of structural elements provides calculation methods for predicting fire temperatures and burning rates in fully developed compartment fires. Some of these methods are based on an assumption of ventilation-limited burning, and others model fuel-controlled conditions. For most cases, the method developed by Law was found to provide bounding predictions when the "Ψ" factor was not used and the predicted burning duration was increased by a factor of 1.4.

Law's method is as follows:

$$T = T_{gm}(1 - e^{-0.05\Psi})(^{\circ}C) \tag{9}$$

$$T_{gm} = 6000 \left(\frac{1 - e^{-0.1 \frac{A}{A_o\sqrt{H_o}}}}{\sqrt{\frac{A}{A_o\sqrt{H_o}}}} \right) (^{\circ}C)$$

$$\dot{m}_f = 0.18 A_o \sqrt{H_o} \left(\frac{W}{D}\right) \left(1 - e^{-0.036 \frac{A}{A_o\sqrt{H_o}}}\right) (kg/sec)$$

where

T_{gm} = Maximum compartment temperature (°C)

A = Surface area of interior of enclosure (m^2)

A_o = Area of ventilation opening (m^2)

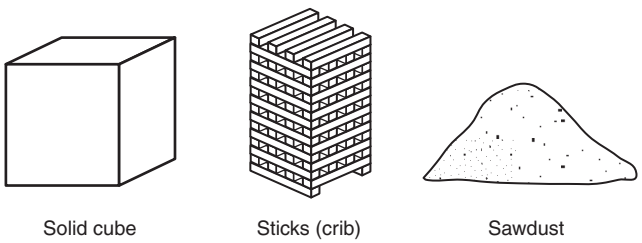

FIGURE 3.7.3 Dependence of Fire Growth on Fuel Form and Arrangements

H_o = Height of ventilation opening (m)

$$\Psi = \frac{m_f}{\sqrt{A \times A_o}}$$

m_f = Mass of fuel (kg)

$\dot{m}_f$ = Mass burning rate of fuel (kg/sec)

W = Width of wall containing ventilation opening (m)

D = Depth of compartment (m)

Law reports that the correlation for predicting burning rate is valid for

$$\frac{\dot{m}_f}{A_o\sqrt{H_o}}\left(\frac{D}{W}\right)^{1/2} < 60$$

In some cases, it may only be desired to predict whether flashover is possible for a given fire scenario involving a fire in an enclosure. In such cases, the approach described in the section Prediction of Flashover can be used.[12]

Decay. All fires eventually decrease in size. A fire can decay for one of three reasons: consumption of available fuel, oxygen depletion, or suppression. Because the hazards posed during the decay phase are typically insignificant in comparison to the hazards posed during the fully developed phase, decay is typically omitted from analysis. An exception is in calculations involving structural fire resistance of concrete or insulated steel. Where test data are available, they might include decay.

If decay occurs due to the exhaustion of fuel, Table 3.7.1 shows the expected temperature change as fuel is depleted.[11] For fires with a predicted duration of less than 60 minutes, a decay rate of 10°C/min can be used. In other case, a decay rate of 7°C/min can be used.

Decay could also occur in the event that a sprinkler system is present and activated. A simple assumption is that the fire immediately goes out, but this is not conservative. A National Institute of Standards and Technology (NIST) study documents a (conservative) exponential diminution in burning rate under the application of water from a sprinkler (Figure 3.7.4).[13] Since the combustion efficiency is affected by the application of water, the use of values for soot and gas yields appropriate for post-flashover burning would represent the conservative approach in the absence of experimental data.

Prediction of Flashover. Flashover occurs when a fire grows to such a size that it involves all combustible items within an enclosed room. Although occurrence of flashover is not a hazard in itself, flashover would affect the occurrence of other hazards as described in the next section. Several correlations are available to predict the minimum heat release rate necessary for flashover

TABLE 3.7.1 Rate of Decrease in Temperature

Temperature Decay (°C/min)	*Restrictions*
10	Duration < 60 minutes
7	Duration > 60 minutes

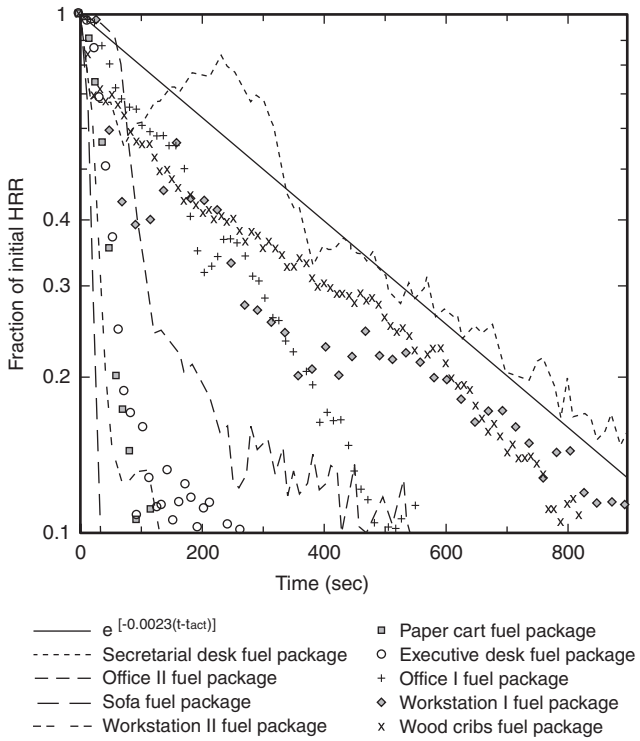

FIGURE 3.7.4 Decay Rates for Various Fuels

to occur in a room. The time at which flashover occurs can be estimated by determining when the fire is predicted to reach this minimum size. The following methods can be used to predict the minimum heat release rate necessary for flashover.[12]

- Method of Babrauskas

$$\dot{Q} = 750A_o\sqrt{H_o} \quad (9)$$

where

$\dot{Q}$ = Minimum heat release rate required for flashover (kW)

A_o = Area of opening into compartment (m^2)

H_o = Height of opening into compartment (m)

- Method of McCaffrey, Quintiere, and Harkleroad

$$\dot{Q} = 610(h_k A_T A_o \sqrt{H_o})^{1/2} \quad (10)$$

where

$$h_k = \frac{k}{\delta}$$

k = Thermal conductivity of compartment surface (kW/m·K)

δ = Thickness of compartment surface (m)

A_T = Total area of compartment surfaces (m^2)

- Method of Thomas

$$\dot{Q} = 7.8A_T + 378A_o\sqrt{H_o} \quad (11)$$

where the variables are as defined above.

PREDICTION OF HAZARDS

Fire is a dynamic process of interacting physics and chemistry, so predicting what is likely to happen under a given set of circumstances is daunting. The simplest predictive methods are algebraic equations. Computer models are used to automate fire hazard calculations and are particularly useful where many repeated calculations must be performed.

Simple Fire Hazard Calculations

Once the design fire curve has been developed, it is then possible to predict the hazards that would result. The types of hazards that might be of interest include the following:

- Radiant heat flux, which affects the potential for ignition of materials or thermal injury to people
- Smoke production, which dictates the volume of smoke produced
- Fire plume and ceiling jet temperatures and velocities, which could cause weakening of exposed structural elements
- Species production, which affects the rate at which an untenable environment could be created
- Depth of upper layer, which can be used as a surrogate for an untenable environment

As was the case with the stages of design fire curves, it is not always necessary to quantify all of the hazards that result from a design fire scenario. The hazards that are quantified are a function of the goals of the analysis. For example, if the purpose of the analysis is to determine whether a thermally activated detection or suppression system activates, only the plume and ceiling jet temperatures and velocities might be determined. For analysis of a smoke control system, only the smoke production rate might be determined. A structural analysis might only require calculation of the heat transfer to the structure. An evacuation analysis might require quantification of all of the hazards listed.

Radiant Heat Flux. Radiant heat flux is a measure of the rate of radiative heat transfer per unit area. An example of radiant heat transfer is the heating that can be felt from exposure to the sun on a hot day (although the intensity of thermal radiation in sunlight is too small to be of concern from a fire standpoint). The radiant heat flux from a single burning item can be predicted as a function of the distance from the item in accordance with Equation 18 of Section 3, Chapter 9, "Closed Form Enclosure Fire Calculations." For radiant heat fluxes resulting from fire gases, such as in a compartment fire, the radiant heat flux can be calculated if the gas temperature and the temperature of the target object are known by applying the following equation:

$$\dot{Q}_r = \varepsilon\sigma(T_1^4 - T_2^4) \tag{12}$$

where

$\dot{Q}_r$ = Rate of radiant heat transfer (kW)

ε = Emissivity of gas (0–1) (—)

σ = Stephan-Boltzmann constant (5.67×10^{-11} kW/m^2·K^4)

T_1 = Temperature of gas (K)

T_2 = Temperature of target (K)

The equation is only applicable for instantaneous calculations, as the temperature of the target will rise as a function of the thermal radiation that it receives.

Smoke Production. When calculating smoke production rates, *smoke* is usually defined as the products of combustion and the air entrained into the fire plume. Therefore, the amount of smoke produced is a function of the height above the fire. Section 3, Chapter 9, "Closed Form Enclosure Fire Calculations," provides a number of equations that can be used to predict smoke production.

Fire Plumes and Ceiling Jet Temperatures and Velocities. A fire will produce a plume of hot gas that will rise and contact the ceiling of a compartment, forming a ceiling jet. The temperature and velocity of a plume can be calculated as described in Section 3, Chapter 9, "Closed Form Enclosure Fire Calculations." Similarly, the temperature and velocity of a ceiling jet can be calculated in accordance with the following equations:[14]

$$\text{For } 0.18 \geq \frac{r}{H} \qquad \Delta T = \frac{16.9\dot{Q}^{2/3}}{H^{5/3}} \tag{13}$$

$$\text{For } \frac{r}{H} > 0.18 \qquad \Delta T = \frac{5.38(\dot{Q}/r)^{2/3}}{H} \tag{14}$$

$$\text{For } 0.15 \geq \frac{r}{H} \qquad U = 0.96\left(\frac{\dot{Q}}{H}\right)^{1/3} \tag{15}$$

$$\text{For } \frac{r}{H} > 0.15 \qquad U = \frac{0.195\dot{Q}^{1/3}H^{1/2}}{(r/H)^{5/6}} \tag{16}$$

where

ΔT = Temperature rise over ambient (°C)

U = Ceiling jet velocity (m/sec)

H = Height above fire (m)

r = Horizontal distance from fire centerline (m)

$\dot{Q}$ = Total heat release rate (kW)

When using these equations, it must be cautioned that they are only valid for horizontal, unobstructed ceilings where there is no smoke layer present. In cases where a layer forms, higher temperature rises can be expected.

Species Production. Fires can create a number of products of combustion that can be toxic or corrosive, including carbon dioxide (CO_2), water vapor (H_2O), carbon monoxide (CO), and many others that vary with the fuel and burning conditions. Species production rates can be calculated from the following equation:[15]

$$\dot{G}_j = y_j\frac{\dot{Q}}{\Delta H_c} \tag{17}$$

where

$\dot{G}_j$ = Smoke production rate of species j (kg/sec)

y_j = Yield fraction of species j (–)

$\dot{Q}$ = Heat release rate (kW)

ΔH_c = Heat of combustion of fuel (kJ/kg)

Yield fractions for several fuels are available in the *SFPE Handbook of Fire Protection Engineering*.[15]

Depth of Upper Layer. As smoke is produced in a compartment, it forms a layer that descends as a function of time. This is analogous to filling a bowl of water. Section 3, Chapter 9, "Closed Form Enclosure Fire Calculations," provides an equation that can be used to estimate the velocity of descent of the smoke layer. However, when applying this equation, it should be noted that the mass production rate of smoke is not constant, since as the layer descends, the smoke production rate decreases due to the reduced vertical distance available to entrain air into the plume. (See the equations for predicting smoke production rate in the same chapter.)

Toxicity. Toxic gases produced by a fire can incapacitate or kill people who are exposed to them. A commonly used approach to determine whether the fire-induced environment is potentially harmful to people exposed is the "fractional effective dose" (FED) model developed by Purser.[16] This can be expressed as follows:

$$F_{IN} = [(F_{I_{CO}} + F_{I_{CN}} + FLC_{irr}) \times V\mathrm{CO}_2 + FED_{I_O}] \quad \text{or } F_{I_{CO_2}} \tag{18}$$

where

F_{IN} = Fraction of an incapacitating dose of all asphyxiating gases

$F_{I_{CO}}$ = Fraction of an incapacitating dose of CO

$F_{I_{CN}}$ = Fraction of an incapacitating dose of HCN

FLC_{irr} = Fraction of irritant dose

$V\mathrm{CO}_2$ = Multiplication factor for CO_2-induced hyperventilation

FED_{I_O} = Fraction of an incapacitating dose of low-oxygen hypoxia

$F_{I_{CO_2}}$ = Fraction of an incapacitating dose of CO_2

Purser gives the following equations for calculation of the individual fractional effective doses:[16]

$$F_{I_{CO}} = \frac{8.2925 \times 10^{-4} \times [\mathrm{CO}]^{1.036}}{30} \tag{19}$$

where [CO] is the concentration of CO, expressed in parts per million.

$$F_{I_{CN}} = \frac{\exp(\mathrm{CN}/43)}{220} \tag{20}$$

where

CN = The concentration of HCN in parts per million added to the concentration of other nitriles minus the concentration of NO_2

FLC_{irr} = The fraction of the incapacitating dose from all incapacitating products (HCl, HBr, etc.)

$V\mathrm{CO}_2 = \exp\left(\frac{[\mathrm{CO}_2]}{5}\right)$, where $[CO_2]$ is the concentration of carbon dioxide in percent

$FED_{I_O} = \{\exp[8.13 - 0.54(20.9 - [O_2])]\}^{-1}$, where $[O_2]$ is the concentration of oxygen in percent

$F_{I_{CO_2}} = \{\exp[6.1623 - 0.5189[CO_2]]\}^{-1}$, where $[CO_2]$ is the concentration of CO_2 in percent

It should be noted that the equations for FED and the components of FED are based on a one minute exposure. For exposures to constant concentrations of fire products, the FED can be determined by multiplying the value determined using the previous equations by the exposure time in minutes. For exposures where the concentrations vary with time, the total FED can be calculated by discretizing the exposure (determining the average exposure at each one minute interval and summing the FED determined for each one minute interval).

It should be noted when applying the previous correlations that some populations are more susceptible than others to fire products (e.g., asthmatics, the old, and the young). Additionally, no single FED value for design has been widely agreed on even for "average" populations. A report by the National Institute of Standards and Technology investigates this subject in detail.[17]

Egress Calculations. Evacuation calculations are sometimes simple enough to be done by hand. The most thorough presentation on this subject (and the one that is most often used in alternative design analysis) is that of Nelson and Mowrer.[18] See also Section 4, Chapter 2, "Calculation Methods for Egress Prediction."

Simple Analytical Solution Techniques

Simple computer programs and spreadsheets can be used to perform simple fire hazard calculations. In the case of the equations listed previously or referenced in other chapters, this is a relatively straightforward task. However, many fires and fire effects are not steady state. An example is smoke filling within an enclosure. The smoke production rate is a function of the smoke layer height, so the rate of smoke layer descent is not constant. In such instances, spreadsheets can be used to develop solutions to differential equations for which developing an exact solution is nontrivial.

For a differential equation of the following form:

$$\frac{dy}{dt} = f(y, t) \tag{21}$$

where the initial value $y(t = 0)$ is y_0.

The Euler method is a numerical technique for solving differential equations of this form, and can be stated as

$$y_{n+1} = y_n + hf(y_n, t_n) \tag{22}$$

where

y_n = Value of equation y at time step n

y_{n+1} = Value of equation y at time step $n + 1$

h = Time step size

This process can be iterated over the desired length of time to obtain the desired solution. Since the Euler method determines the value of equation y at time step $n + 1$ based on the value at time step n and the slope of the tangent to y at time step n, errors can be introduced based on the nonlinearity of equation y. There are methods available to reduce this error, such as the improved Euler method.

However, another method of reducing the error is to reduce the size of the time step, recognizing that as the size of the time step approaches zero, the difference between the predicted value of y and the actual value of y also approaches zero. The computational power offered by modern computers allows very small time steps to be used and to still get a solution rapidly.

It should be noted that the default for many spreadsheets is to not permit iterative calculations. (The spreadsheet views the "circular reference" as an error.) Spreadsheets for which this is the case would need to be configured to allow iteration. The spreadsheet's user's manual or help function can be consulted for assistance.

EXAMPLE. *Thermal detector response can be used to illustrate application of the Euler method to a fire protection problem.* This example uses an algorithm similar to that used by the computer fire model DETACT-QS[19] to predict the time to activation of a thermal detector for a heat release rate that follows a power law curve. Two calculations will be performed. First, the instantaneous ceiling jet velocities are calculated in accordance with Equations 13 through 16. A quasi-steady assumption is made, which means that transport delays from the fire to the detector are ignored. Then, based on the temperature and velocity of the ceiling jet and the thermal response characteristics of the sensor (response time index), the temperature change at the detector will be calculated. See Section 16, "Water-Based Fire Suppression Equipment" for more information. The change in temperature of the detector can be expressed as[20]

$$\frac{dT_d}{dt} = \frac{\sqrt{U_g}(T_g - T_d)}{RTI} \tag{23}$$

where

T_d = Temperature of detector (°C)

U_g = Ceiling jet velocity at detector (m/sec)

T_g = Ceiling jet temperature at detector (°C)

t = Time (sec)

RTI = Detector response time index ($m^{1/2} \times sec^{1/2}$)

A Euler solution to this expression can be expressed as

$$T_{d_{n+1}} + T_{d_n} + \Delta t \frac{\sqrt{U_g}(T_g - T_{d_n})}{RTI} \tag{24}$$

where

$T_{d_{n+1}}$ = Temperature of detector at time step $n + 1$ (°C)

T_{d_n} = Temperature of detector at time step n (°C)

Δt = Size of time step (sec)

Equation 24 could easily be programmed into a spreadsheet or simple computer program, along with the ceiling jet temperature and velocity correlations expressed in Equations 13 through 16, to calculate U_g and T_g. It is also necessary to include a method of calculating the heat release rate at each time step.

The following example illustrates the use of this method in estimating thermal detector response. A heat detector is located on a 3 m high ceiling, 2 m away from a fire located on the floor with a constant heat release rate of 1000 kW. The room has an ambient temperature of 20°C and is sufficiently large that a smoke layer will not form quickly. The heat detector has a temperature rating of 75°C and an RTI of 50 $m^{½}sec^{½}$. When would the detector operate? Using Equation 24 and Equations 13 through 16, the solutions in Table 3.7.2 are obtained when different time steps are used.

Computer Models

Fire Models. A survey[21] documented available models and calculation methods that could be applied to FHA. The key to determining which are appropriate to a given situation and which are not is a thorough understanding of the assumptions and limitations of the individual model or calculation and how these relate to the situation being analyzed. Single-room models are appropriate where the conditions of interest are limited to a single, enclosed space. Where the area of interest involves more than one space, and especially where the area of interest extends beyond a single floor, multiple-compartment models should be used. This is because the interconnected spaces interact to influence fire development and flows.

Many single-compartment models assume that the lower layer remains at ambient conditions (e.g., ASET).[22] Since there is little mixing between layers in a room (unless there are mechanical systems), these models are appropriate. However, significant mixing can occur in doorways, so multiple-compartment models should allow the lower layer to be contaminated by energy and mass (Figure 3.7.5).

The model should include the limitation of burning by available oxygen. This is straightforward to implement (based on the oxygen consumption principle) and is crucial to obtaining an accurate prediction for ventilation-controlled burning. For multiple-compartment models, it is equally important for the model to track unburned fuel and allow it to burn when it encounters sufficient oxygen and temperature. Without these features, the model concentrates the combustion in the room of origin, overpredicting conditions there and underpredicting conditions in other spaces.

TABLE 3.7.2 Time Step(s) Predicted Activation Time(s)

Time Step(s)	*Predicted Activation Time(s)*
1	24.000
0.1	24.200
0.01	24.230
0.001	24.229

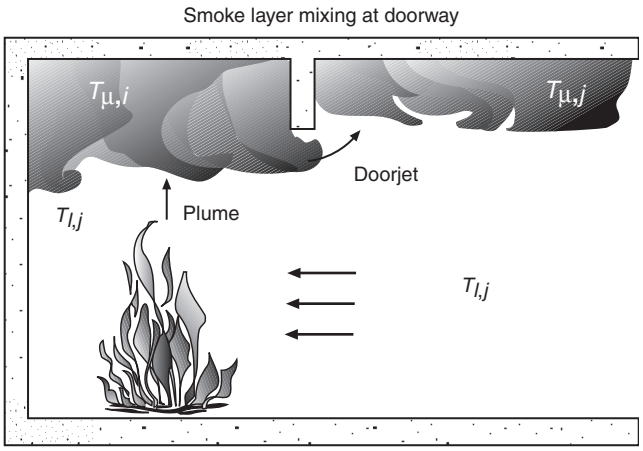

FIGURE 3.7.5 Assumption of Zone Models That Fire Gases Collect in Internally Uniform Layers

Heat transfer calculations take up a lot of computer time, so many models take a shortcut. The most common is the use of a constant "heat loss fraction," which is user-selectable (e.g., ASET or CCFM[23]). The problem is that heat loss can vary during the course of the fire.

Another problem can occur in tall spaces, for example, atria. The major source of gas expansion and energy and mass dilution is entrainment of ambient air into the fire plume. It can be argued that in a very tall plume, this entrainment is constrained. However, most models do not include this constraint, which can lead to an underestimate of the temperature and smoke density and an overestimate of the layer volume and filling rate—the combination of which may give predictions of available safe egress times that are either greater or less than the correct value. In the model CFAST,[24] this constraint is implemented by stopping entrainment when the plume temperature drops to within 1°C of the temperature just outside the plume, where buoyancy ceases.

Documentation. Only models that are rigorously documented should be allowed in any application involving public health, safety, or welfare, such as in code enforcement or litigation. This means that the model should be supplied with a technical reference guide that includes a detailed description of the included physics and chemistry, with proper literature references; a listing of all assumptions and limitations of the model; and estimates of the accuracy of the resulting predictions, based on comparisons to experimental data. Public exposure and review of the exact basis for a model's calculations, internal constants, and assumptions are necessary for it to have credibility in a regulatory application.

ASTM publishes a *Standard Guide for Documenting Computer Software for Fire Models,* ASTM E1472-05.[25] Documentation for any model used in a regulatory application should comply with this guide. Although it may not be necessary for the full source code to be available, the method of implementing key calculations in the code and details of the numerical solver used should be included. This documentation should be freely available to any user of the model, and a copy should be supplied with the analysis as an important supporting document.

Input Data. Even if the model is correct, the results can be seriously in error if the data that are input to the model do not represent the condition being analyzed. The FHA should include a listing of all data values used, their source (i.e., what apparatus or test method was employed and what organization ran the test and published the data), and some discussion of the uncertainty of the data and its result on the conclusions. The National Institute of Standards and Technology's (NIST) website contains a section of well-documented data for use in calculations, called *Fire on the Web* (http://fire.nist.gov). A much larger database, called FASTDATA, is available from NIST on a CD-ROM (see the URL above for information). (See also the subsection entitled "Accounting for Uncertainty" later in this chapter.)

Egress Models. The prediction of the time needed by the building occupants to evacuate to a safe area can be performed and compared to the predicted available safe egress time. Whether the evacuation calculation is done by model or hand calculation, it must account for several crucial factors. First, unless the occupants see the actual fire, time is required for detection and notification *before* the evacuation process can begin. Next, unless the information is compelling (such as seeing the actual fire), it takes time for people to decide to take action. The action they choose may or may not be evacuation. Finally, the movement begins. All of these factors require time, and that is the critical factor. No matter how the calculation is done, *all* of the factors must be included in the analysis to obtain a complete picture. An excellent discussion of this topic is found in SFPE's *Engineering Guide—Human Behavior in Fire.*[26]

The process of emergency evacuation of people follows the general concepts of traffic flow. A number of models perform such calculations and may be appropriate for use in certain occupancies. Most of these models do not account for behavior and the interaction of people (providing assistance) during the event. The literature reports incidents of providing assistance to disabled persons, again especially in office settings.[27] If such behavior is expected, it should be included, as it can result in significant delays in evacuating a building.

Crowded conditions, as well as smoke density, can result in reduced walking speeds.[28] A person's walking speed decreases in dense smoke until he or she moves as if blindfolded (Figure 3.7.6). Care should be exercised in using models relative to how they select the path (usually the *shortest* path) that the person travels. Some models are *optimization* calculations that give the best possible performance.

Analyzing the Impact of Exposure

In most cases, the exposure will be to people, and the methods used to assess the impacts of exposure of people to heat and combustion gases involve the application of combustion toxicology models. The HAZARD I software package contains the only toxicological computer model, called TENAB,[29] that is based on research at NIST on lethality to rats and by Purser on incapacitation of monkeys. TENAB accounts for the variation

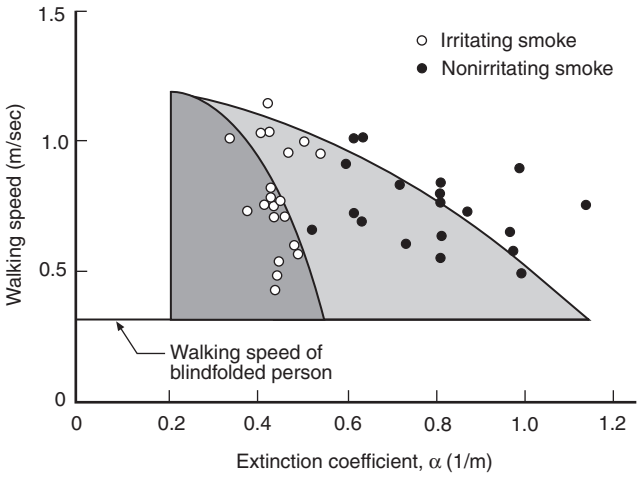

FIGURE 3.7.6 Reduced Walking Speeds Resulting from Crowded Conditions and Smoke Density

in exposure to combustion products as people move through a building, by reading the concentrations from the fire model in the occupied space during the time the person is in that space. If the person moves into a space with a lower concentration of carbon monoxide, the accumulated dose can decrease. Details such as these ensure that the results are reasonable.

Assessing the impact of exposure to sensitive equipment is more difficult, since little data exist in the literature on the effects of smoke exposure on such equipment. Of particular importance here is the existence of acid gases in smoke, which are corrosive and especially harmful to electronics. Fuels containing chlorine (e.g., polyvinyl chlorides) have been studied. However, unless the equipment is close to the fire, acid gases, especially HCl, deposit on the walls and lower the concentration to which the equipment may be exposed. CFAST in the HAZARD I package contains a routine that models this process and the associated diminution of HCl concentration.

Accounting for Uncertainty

Uncertainty analysis refers to dealing with the unknowns and variation inherent in any prediction. In the calculations, this uncertainty is derived from assumptions in the models and from the representativeness of the input data. In evacuation calculations, there is the added variability of any population of real people. In building designs and codes, the classic method of treating uncertainty is with safety factors. A sufficient safety factor is applied such that, if all of the uncertainty resulted in error in the same direction, the result would still provide an acceptable solution. In the prediction of fire development/filling time, the intent is to select design fires that provide a *worst likely* scenario. Thus a safety factor is not needed here, unless assumptions or data are used to which the predicted result is very sensitive.

The FHA report should include a discussion of uncertainty. This discussion should address the representativeness of the data used and the sensitivity of the results to data and assumptions made. If the sensitivity is not readily apparent, a sensitivity analysis (i.e., varying the data to the limits and seeing whether the conclusions change) should be performed. This is also a good time to justify the appropriateness of the model or calculation method. For more information, see Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety."

Final Review

If a model or calculation produces a result that seems counterintuitive, there is probably something wrong. Cases have been seen in which the model clearly produced a wrong answer (e.g., the temperature predicted approached the surface temperature of the sun), and there have been others in which it initially looked wrong but was not (e.g., a *dropping* temperature in a space adjacent to a room with a growing fire was caused by cold air from outdoors being drawn in an open door). Conversely, if the result is consistent with logic, sense, and experience, it is probably correct. This is also a good time to consider whether the analysis addressed all of the important scenarios and likely events. Were all the assumptions justified and were uncertainties addressed sufficiently to provide a comfort level similar to that obtained when the plan review shows that all code requirements have been met?

SUMMARY

Quantitative fire hazard analysis is becoming the fundamental tool of modern fire safety engineering practice and is the enabling technology for the transition to performance-based codes and standards. (For more information on performance-based codes, see Section 3, Chapter 10, "Performance-Based Codes and Standards for Fire Safety.") The tools and techniques described in this chapter provide an introduction to this topic and the motivation for fire protection engineers to learn more about the proper application of this technology.

Predicted fire hazards are a function of the design fire scenarios analyzed. Therefore, when performing a fire hazard analysis, it is important to select design fire scenarios that are challenging enough to represent a realistic "worst case," but not so challenging that the likelihood of occurrence is too remote.

There are many fire hazard calculations that can be performed with a hand calculator, a simple spreadsheet, or a computer program. In some cases, these simple methods would not be sufficient, for example, in cases where compartment geometry is complex, where it is desired to optimize cost/benefit, or where predicted hazard values are very close to acceptable limits. However, even in these types of cases, simple methods can be used for initial predictions or as a reality check of results from more complex models.

In any engineering analysis, it is incumbent on the user to understand the application and limitation of any methods used. This chapter has outlined a number of simple fire hazard calculation methods, but the applicability and limitations of the methods were not included. Users are referred to the documents referenced in the text for information regarding the applications and limitations of any of the methods included in this chapter.

ACKNOWLEDGMENT

James R. Quiter, P.E., wrote portions of the discussion of design fire scenarios, which originally appeared in the "Simple Fire Hazard Calculations" chapter in the 19th edition of this handbook.

Overview of Fire Analysis
General Approaches to Risk Evaluation
Analysis Frameworks

Key Terms

acceptable risk, consequence analysis, cost-benefit analysis, cost-effectiveness evaluation, event tree, fault tree, fire hazard, fire risk analysis, hazard analysis, probability analysis, risk estimation, risk evaluation, scenario cluster, scenario structure

Fire risk analysis is the most comprehensive form of analysis that can be applied to any fire safety choice. It looks at all the types of fires that may be affected by the choice, for example, of product, of building design, or of anything potentially affecting fire safety, not just one fire or a few selected fires. It provides a flexible framework for estimating the impact of any type of fire safety program or strategy in terms of actual reductions in losses—deaths, injuries, and property damage—and in terms that can be compared to the costs of those programs and strategies. There is no other method as well suited for the analysis of strategic options affecting large numbers of properties and their occupants. Product development, related research and marketing, and regulatory decisions can benefit from fire risk analysis, as can any program to manage and oversee fire safety from a financial point of view.

Also see Section 3, Chapter 4, "Use of Fire Incident Data and Statistics."

OVERVIEW OF FIRE ANALYSIS

Fire Risk Analysis Defined

Fire risk analysis supports risk reduction decisions by (1) identifying and grouping every type of unwanted fire that can lead to adverse consequences, (2) characterizing the severity of those consequences, and (3) characterizing the likelihood of those types or groups of fires. Fire types are called *scenarios*, and scenario characterization normally begins with hazard identification. *Fire hazard* is any condition with the potential to create (fire-related) harm. When that potential is quantified as to severity, this is *consequence analysis*, whereas the characterization of likelihood is called *probability analysis*.

The term *fire risk analysis* has sometimes been used to refer to an exercise of listing locations under the jurisdiction of the analyst that present the greatest potential for fire damage or for demand on fire suppression resources. Such an exercise lacks most or all of the key elements of a true fire risk analysis.

Other commonly used analysis approaches present subtler problems. Fire protection engineers often focus on alternative means for dealing with fires after fire has begun. It might seem natural to construct a fire risk analysis that takes established burning as given but measures the probability of performance for all building features and systems that operate after the fire. Assuming that it makes sense to write off fire prevention, there still will be a need to address explicitly different types of initial fires. A fast, accelerant-driven fire or an initial explosion will challenge the built-in fire protection in different ways than an ordinary flaming or smoldering fire. A concealed-space fire will present different problems than a fire in a room, and both will differ from fires that start in a means of egress. If each of these fires is analyzed separately, if the analysis leans on physics and chemistry, and if the focus is on preventing major fire extent as an either-or proposition, then the subject is more properly termed a *hazard analysis.* Although the terminology is not standardized, hazard analysis is best used to describe analyses that do not treat most probabilities explicitly, particularly probabilities of ignition and probabilities of occupant characteristics and behaviors. *Risk analysis* should be reserved for analyses that address all relevant probabilities.

John R. Hall, Jr., Ph.D., is assistant vice-president for fire analysis and research at NFPA.

John M. Watts, Jr., Ph.D., is director of the Fire Safety Institute in Middlebury, Vermont.

Fire Risk Assessment Process

A number of documents have recently emerged to support the application of fire risk analysis:

- *SFPE Engineering Guide to Application of Risk Assessment in Fire Protection Design*[1]
- NFPA 551, *Guide for the Evaluation of Fire Risk Assessments*[2]
- ISO/TS 16732, *Fire Safety Engineering—Guidance on Fire Risk Assessment*[3]
- ASTM E1776, *Standard Guide for Development of Fire-Risk-Assessment Standards*[4]

Figure 3.8.1 provides a simple overview of the risk estimation calculations at the heart of fire risk analysis. However, there are important steps not shown in this figure.

Figure 3.8.2 embeds this calculation sequence in the larger fire risk assessment process, with its critically important additional steps of (1) setting goals, objectives, and criteria; (2) developing scenarios from identified hazards and analyzing each one; and (3) comparing calculated risk to selected criteria to determine risk acceptability. A more detailed version of Figure 3.8.2 is used as the defining structure for the *SFPE Engineering Guide to Application of Risk Assessment in Fire Protection Design*, and a similar figure is given in ISO TS 16732.

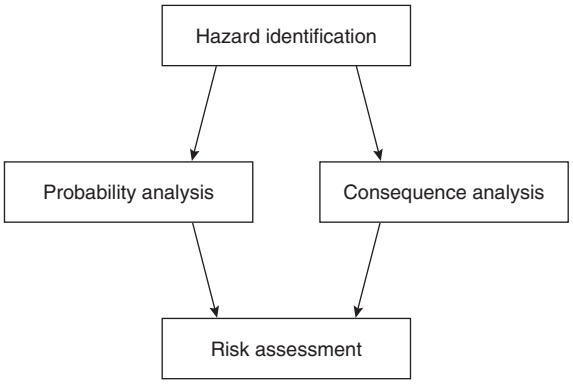

FIGURE 3.8.1 Risk Estimation Process

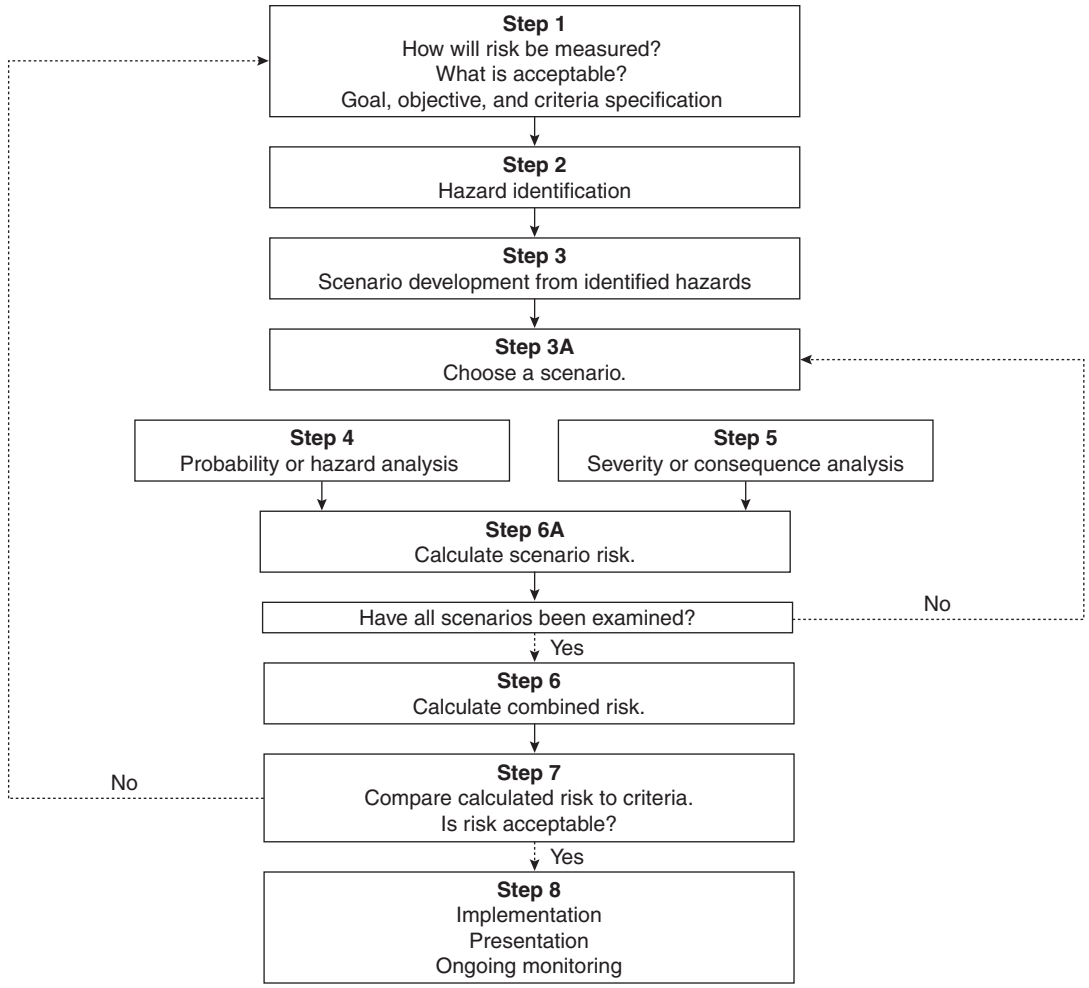

FIGURE 3.8.2 Risk Assessment Process

Figure 3.8.2 also shows the need to state, in terms suitable for analysis, the design or other decision that will be the subject of the fire risk analysis. The format and level of detail required for this specification of the decision are dictated by the models and their input data needs. Every input variable and parameter must correspond to (1) some specification of the design or other decision, (2) some defining element of the scenario, or (3) some additional assumption about the environment in which fire will occur and challenge the building, its occupants, or other setting.

If the proposed change involves the installation of new built-in smoke detection systems, for example, specifications for the systems would be needed. If the systems were available in two or more versions (e.g., ionization and photoelectric smoke detectors), the probability of each version being used should be estimated (e.g., from data on usage patterns or projected shares of market). Probabilities also would be needed for the variations in status of a system (e.g., fully operational, operational but blocked in one room, turned off, or removed). These specifications dictate precisely what fire protection and fire-related features would be in place to influence the course of fire if one occurs.

If the proposed change involves training staff or educating occupants, similar questions would be asked: What are the specifics of the program(s)? What is the likelihood that each version of the program would be used? If fire occurs, what would be the status of the program (e.g., everyone was trained and acted accordingly, some missed the training, some forgot, some panicked)?

It is sometimes useful to separate the parts of the decision model into those characteristics that were selected by a building owner or manager (e.g., a sprinkler was installed) and those that came into play after the selection (e.g., the sprinkler was installed incorrectly). The latter parts are those factors that are hardest to control, either because they require continued alertness (e.g., without scheduled testing and maintenance, a sprinkler system's reliability will decrease) or because they are not directly under the control of the building owner or manager (e.g., a manager can order a sprinkler system but has to work through others to make sure it is installed properly).

Neither the implementation model nor the larger decision model needs every bit of information on the proposed changes. The models need only those details that will affect the likelihood of having a fire, the development of that fire, or the reactions of people and property to the fire. For example, some factors will incapacitate the system so that the fire will develop as if no system were present, and that is all the information needed. Some factors will degrade system performance but still permit some impact on fire development; it may be possible to model such reduced impact as simple modifications to the impact expected if the system were fully functional.

Goals, Objectives, and Criteria

Goals, objectives, and criteria are the logical and mathematical representations by which value judgments are made about risk acceptability. As value judgments, they are not purely scientific constructs and are not governed solely, or even primarily, by engineering judgment, science, and empirical evidence. Instead, a process must be developed that will involve stakeholders and produce goals, objectives, and criteria that can be supported, or at least accepted, by all affected and interested parties. See the *SFPE Engineering Guide to Application of Risk Assessment in Fire Protection Design* for more details.

Specification of the criterion is not only a matter of deciding what kind of harm—such as deaths, injuries, property damage, or business interruption—is of concern. Sometimes, the most appropriate measure is not a simple count of how much harm is of concern.

For example, suppose harm to people is clearly of concern. Are all kinds of injuries of concern or only fatal injuries? Are injuries of concern if they are not discovered until hours or days after the fire? Are injuries of concern if they are never recognized as such, as can be the case for some symptoms of carbon monoxide poisoning? Are all injuries or deadly events of equal concern, regardless of how many people are injured or killed? Or is a count of the number of injuries and deaths more appropriate?

Are all injuries relevant, or are people disproportionately, or even exclusively, concerned about injuries in fire that can be attributed to the actions or deficiencies of strangers? Is there any level of user misuse—or of other contributions to ignition or to the degree of harm that followed—that would disqualify the resulting injuries from being counted, or being fully counted, in the severity measure of a risk analysis of a product or building?

Suppose the scale was dollars of damage. A severity measure of the number of dollars of damage would set the stage for a risk analysis on expected loss or average loss, the most common approach. Alternatively, one could set the severity measure equal to 1 if damage exceeded $100,000,000 and 0 otherwise. This would set the stage for a risk analysis focusing on large losses, which might be more useful for an insurance company that worries less about ordinary claims than about a single loss so large that the company cannot cover it.

Fire risk analysis can sometimes be separated into (1) *risk estimation,* the estimation and analysis of the measures of severity and probability and their associated uncertainties, and (2) *risk evaluation,* the additional steps required to decide on the importance of a particular value of risk or a change in risk. A fire risk analysis that includes risk evaluation may be called a *fire risk assessment* to underline the fact that the analysis will support value judgments. Risk evaluation involves comparison of the estimated risk to criteria derived from the safety goals and objectives.

GENERAL APPROACHES TO RISK EVALUATION

Cost-Benefit and Cost-Effectiveness Analyses

Risk evaluation should be familiar to anyone who has had to make business decisions because it essentially involves using analysis to determine whether you will get what you pay for. The most common approach to risk evaluation is *cost-benefit analysis,* a technique in which all benefits of risk reduction are

translated into monetary equivalents. This technique permits a proposed new product or fire suppression system to be assessed in terms of its net profit or loss, total cost plus loss, or ratio of profit to loss. In such a context, "profit" means saved lives, avoided injuries, and reduced property damage, all combined in one monetary scale, and "loss" means the cost—both initial and ongoing—of the new product or system. A variation is *cost-effectiveness analysis,* in which the benefits of risk reduction are translated into a single nonmonetary scale. For example, it is possible to derive the cost per life saved for a new system or product.

Cost-benefit and cost-effectiveness analyses require the explicit estimation or derivation of some controversial parameters. Examples include the value of reduced risk of death or injury and the discount rate by which future consequences are compared to present consequences (both discussed in more detail later in this chapter). Because these parameters are controversial, risk evaluation sometimes uses methods that downplay the role of these parameters.

Acceptable Risk

Acceptable risk is a term that is used when the method of risk evaluation involves treating risk as a constraint. This method may seem attractive because it refuses to consider costs until or unless a sufficient degree of fire safety has been provided. In an acceptable risk approach, a certain level of risk is defined as acceptable; then all alternatives meeting that level are evaluated strictly on the basis of cost.

This approach can produce unsatisfactory results. If risk is greater than the acceptable level by even a small fraction, no cost is too great to reach acceptable risk. If risk is already acceptably low, not a nickel more should be spent, no matter how much more fire safety could be purchased for very little money. This means that the selected level of acceptable risk is often set with an eye toward affordability and may be reset if technology changes. In effect, this makes the acceptable risk approach a kind of backdoor cost-benefit analysis and runs counter to most approaches to decision making in business.

When acceptable risk is not defined in terms of affordable risk, it is often defined in terms of (1) historically acceptable risk (i.e., anything in use for a long time is all right), which may be overturned if public understanding of the magnitude of the risk changes dramatically, or (2) unavoidable risk, such as the use of background radiation levels as a guide for acceptable exposure to medical X-rays. In fire protection, acceptable risk has sometimes been inferred from provisions of NFPA codes and standards. The most extreme version of an acceptable risk approach is a minimum risk approach, in which cost is not considered unless all feasible safety improvements have been made.

A logical complement to the acceptable risk approach would be an acceptable cost approach, in which the greatest risk reduction available within the fixed cost budget (but no more) would be sought. Although this approach is rarely mentioned in the literature, it almost certainly describes the way some decisions are made.

Note that the acceptable risk and acceptable cost approaches both can be very sensitive to the initial selection of a single key parameter. If these approaches are used, it is necessary to conduct a sensitivity analysis to see how conclusions would be changed if the reference level of acceptable risk or acceptable cost were different. Sensitivity analysis of key parameters is essential to all other forms of risk analysis as well and is one way in which the uncertainty surrounding estimates can be addressed systematically.

Assumptions in Fire Risk Analysis

In any fire risk analysis, there will be a certain set of assumptions about key conditions in the environment of interest: some or all of the buildings have sprinklers or detectors, some or all of the mattresses were built to a certain ignition-resistance standard, some or all of the occupants have been regularly trained in fire-safe behavior, and so forth.

Fire risk analysis refers to a systematic examination of how measures of fire risk change as the assumptions change. It may be done in conjunction with a parallel examination of changes in costs. On the one hand, if no smoke alarm is present, a household can expect to experience fires with a certain probability, and these fires will have a certain expected severity in terms of deaths, injuries, and property damage. On the other hand, if a smoke alarm is present, the household will pay purchase and maintenance costs that are not paid by the household without smoke alarms, but the smoke alarm household can expect on average to achieve lower severities of losses—and in particular, fewer deaths per fire. Risk analysis is used to quantify the expected size of the reductions in deaths, injuries, and damage. One can then determine whether these risk reductions are great enough to justify the cost. This is an analysis of cost versus risk reduction benefits in which the risk portion is measured explicitly.

Hazard Identification

The topmost box in Figure 3.8.1 and step 2 in Figure 3.8.2 refer to hazard identification. Typical buildings and processes have many fire hazards. Since each hazard represents a potential loss, it is important to identify them. In most cases fire hazards are identified on the basis of intuition and experience. At best, the experience of several persons would be combined to assess a given situation in order to fully identify all the potential hazards.

Fire Safety Checklist. The most common approach to hazard identification is some form of checklist. A traditional fire safety checklist is a list of specific items used to identify known types of hazards, design deficiencies, and potential fires associated with specific buildings, equipment, and operations. Usually, the identified items are compared to appropriate NFPA standards. Using checklists requires three simple steps: (1) identify or develop an appropriate checklist, (2) conduct a survey of the premises, and (3) document the results.

There are many forms of fire safety checklists in the literature, procedural standards, consensus codes, and industry guidelines. For example, *Uniform Fire Code™ Handbook* has checklists appropriate to different occupancies.[5] If no specific, relevant checklist is available, then information available from

authoritative references can be used to generate an appropriate checklist.

A dilemma in developing a checklist is determining the number of items to be checked. Checklists can become very large as various components are included. It can be very time-consuming for the user if large lists must be examined, especially if individual items on the checklist are so specific as to require the inspection of a large number of details. Determinations need to be made regarding which requirements should be included and which requirements should be excluded from the lists.

The checklist is completed based on observations from site visits, system documentation, interviews with operating personnel, and personal perceptions. The person using the checklist will need to determine whether or not the criteria in the list are met. If they are not met, the hazard should be identified and recommendations made.

Documentation usually consists of a summary of noted deficiencies and specific recommendations for fire safety improvement with appropriate explanations. The report should contain a copy of the checklist. The thoroughness of the analysis will depend on the level of detail of the checklist developed.

Extent of Fire Hazard Identification. The extent of fire hazard identification for any given situation will depend on several factors:

- Prior knowledge or experience with an activity
- The size and complexity of the facility, operation, process, or equipment
- The overall potential for loss
- The resources available to make the hazard identification and review

However desirable it may be to identify all fire hazards before a loss occurs, it may not be practicable to make highly sophisticated and expensive studies to locate every possible hazard. The process must be cost-effective within the context of the overall operation. Although the need to identify, evaluate, and control hazards is continuous, the costs involved must be balanced against the other demands on financial resources.

Scenarios

In general, the fire risk analyst will specify a *scenario structure,* which is a set of classification rules for dividing the range of possible fires into a manageable number of relatively homogenous groups, called *scenario clusters*. Then probabilities can be calculated or estimated for each scenario cluster, and a severity measure can be calculated or estimated for the average fire in each scenario, possibly by detailed examination of a typical or representative fire from each scenario.

Concern over computational burden is one reason why analysts sometimes conduct fire risk analyses using a very small number of scenarios (e.g., only three alternatives for where and how fire begins). There may also be concern over the shakiness of the available data and a desire to minimize the number of different terms supported by expert judgments.

In a situation like that, it is essential to understand what is being implicitly assumed by the use of a stripped-down scenario structure. One way or another, the scenarios that are modeled explicitly are being treated as representative of the far larger number of scenarios that are not modeled explicitly. If only a few scenarios are modeled explicitly, then each one is implicitly required to be representative of a much larger and more varied collection of other scenarios. There may be no good evidence to support this assumption. Is it better, for example, to examine the different types of flaming fires individually or to assume that they all behave like a burning wood crib ignited by a lighter? The variability and uncertainty are there either way; the only choice is how much to examine explicitly and how much to handle by assumption.

ANALYSIS FRAMEWORKS

Table 3.8.1, taken from NFPA 551, provides an overview of different analysis frameworks in which both probability and consequence may be treated qualitatively or quantitatively. Also in Table 3.8.1 is reference to the embedding of fire risk analysis in a larger cost-benefit context. Figure 3.8.3 is an expanded generic flow chart for such a cost-benefit framework.

Of the several approaches listed in Table 3.8.1, the simplest approach is the fully qualitative approach, which is illustrated in Figure 3.8.4 and Tables 3.8.2 and 3.8.3, all taken from the annex of NFPA 551.

For quantitative approaches, the three principal analytical approaches are (1) fault or success trees, (2) event trees, and (3) probability weights applied to consequence estimates derived from conventional fire protection engineering models or data.

Fault Tree

The most familiar fault or success tree, though unquantified as published, is the Fire Safety Concepts Tree, as shown in NFPA 550, *Guide to the Fire Safety Concepts Tree*. Fault or success trees are organized to deliver a probability of failure or success, respectively, as the outcome measure. For this reason, such trees are most useful in estimating probabilities—such as the probability of ignition—for use in a larger model with a different format.

The advantages of fault tree analysis (FTA) include, but are not limited to, the following:

- Fault trees provide the logic of how fires start and develop in a graphic format that is easy to understand.
- Fault trees show how different features, systems, and elements interact or act independently to affect fire ignition and development.
- It is easy to compute probabilities from a fault tree.

The disadvantages of FTA include, but are not limited to, the following:

- A fault tree explores only those faults and conditions that lead to a single specified event.
- It may be difficult to identify all contributing factors.
- The fault tree can become very large.

The Probability Analysis oval in Figure 3.8.3 would be a good place for use of fault or success trees.

TABLE 3.8.1 Categories of FRA Methods

Category	*Definition*	*Type of Output**	*Examples*
Qualitative method	Treats both likelihood and consequences qualitatively	Tabulations of outcome and relative likelihood of various fire scenarios and how they are affected by various protection options	What-if analyses Risk matrices Risk indices Fire safety concepts tree
Semiquantitative likelihood method	Treats likelihood quantitatively and consequences qualitatively	Determination of frequency of occurrence of different types of fires and/or fires with different types of protection	Actuarial/loss statistical analyses Stand-alone event tree analyses
Semiquantitative consequence method	Treats consequences quantitatively and likelihood qualitatively	Deterministic fire model outputs with qualitative representation of likelihood	Enclosure fire models for worst credible fire scenarios
Quantitative method	Combines quantitative estimates of likelihood and consequences	1. Determination of loss expectancy OR 2. Determination of probability of flashover OR 3. Determination of probability of fatalities in other rooms or floors of building OR 4. Plot of frequency versus number of fatalities OR 5. Plot of frequency versus size of loss OR 6. Determination of likelihood of injuries, fatalities, property damage, and business interruption OR 7. Determination of individual risk (to building occupants) and of societal risk (to entire population)	FRAs to determine probability of reactor core melt due to fire at a nuclear power plant Event tree analysis combined with fire models
Cost-benefit risk methods	Include determination of costs of alternative approaches to limit consequences and/or likelihoods	1. Determination of costs required to achieve various levels of risk reduction OR 2. Determination of "optimum" level of fire protection based on minimizing "overall risk" or some other risk criterion	Computational models that incorporate probability, consequences, and cost data in an integrated manner

*Types of output listed are representative rather than all-inclusive.

TABLE 3.8.2 Probability Levels

Probability	*Description*
Frequent	Likely to occur frequently, experienced ($p > 0.1$)
Probable	Will occur several times during system life ($p > 0.001$)
Occasional	Unlikely to occur in a given system operation ($p > 10^{-6}$)
Remote	So improbable, may be assumed this hazard will not be experienced ($p < 10^{-6}$)
Improbable	Probability of occurrence not distinguishable from zero ($p \sim 0.0$)

Source: Table A.5.2.5(a), NFPA 551.

Event Trees

Event trees, as the name suggests, represent fires as a sequence of events. An event may correspond to a change in the size or character of the fire, a change in the status or performance of various active systems or passive features, or a change in the status or behavior of occupants or first responders.

An event tree is a visual representation of all the events that can occur in a system. As the number of events increases, the picture fans out like the branches of a tree. The goal of an event tree is to determine the probability of an event based on the outcomes of each event in the chronological sequence of events leading up to it. The event tree displays the sequences of events involving success and/or failure of the system components. By analyzing all possible outcomes, one can determine the percentage of outcomes that lead to the desired result. To

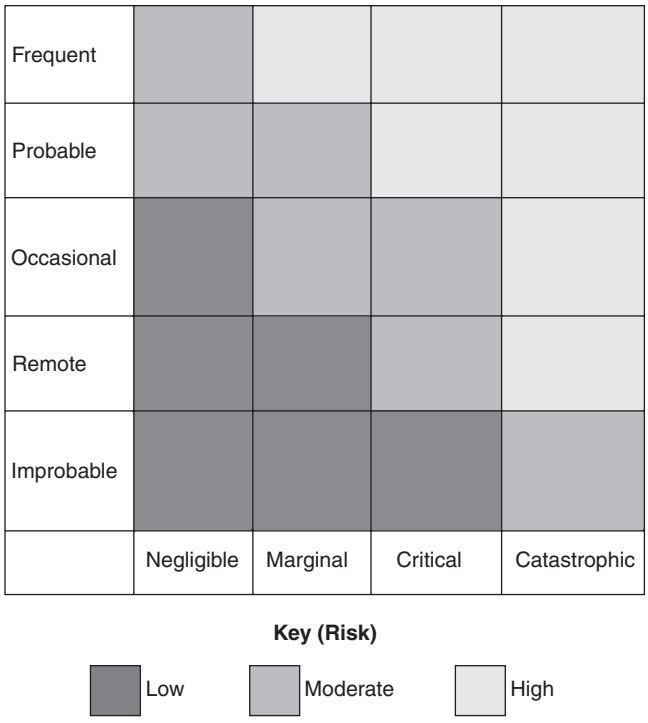

FIGURE 3.8.4 Risk Matrix (Source: Figure A.5.2.5, NFPA 551)

TABLE 3.8.3 Severity Categories

Severity	*Impact*
Negligible	The impact of loss will be so minor that it would have no discernible effect on the facility or its operations.
Marginal	The loss will have impact on the facility, which may have to suspend some operations briefly. Some monetary investments may be necessary to restore the facility to full operations. Minor personal injury may be involved.
Critical	The loss will have a high impact on the facility, which may have to suspend operations. Significant monetary investments may be necessary to restore to full operations. Personal injury and possible deaths may be involved.
Catastrophic	The fire will produce death or multiple deaths or injuries, or the impact on operations will be disastrous, resulting in long-term or permanent closing. The facility would cease to operate immediately after the fire occurred.

Source: Table A.5.2.5(b), NFPA 551.

make a model as complete as possible, the tree must represent all possible events as accurately as possible.

The initiating event, which is generally a fire, is what starts the sequence of events detailed in the event tree. All subsequent events stem from the initiating event.

As a simplistic example, an event tree can be constructed to analyze the possible outcomes of a fire. The system has two strategic components designed to handle this event: manual intervention by staff and an automatic suppression system. If the fire is too large to be controlled by staff, it will be mostly contained by the suppression system. If the suppression system fails as well, the loss is unacceptable. The event tree shown in Figure 3.8.5 can be constructed to model these events.
