Of equal importance is the prohibition in hazardous classified areas of equipment and processes that are not essential to dipping and coating operations but that are potential ignition sources. Included in this category are cutting and welding operations, portable heaters, spark-producing (ferrous) tools, and smoking. Nonferrous tools are available as are nonferrous rotating parts for exhaust fans. If hazardous maintenance operations, such as cutting or welding, must be performed in the vicinity of dipping or coating processes, it is imperative that these hot work operations are in accordance with recognized good practices and performed by competent personnel under strict supervision. "No Smoking" signs in process areas must be properly posted and the restrictions enforced. (See NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work*.)

Special Design Considerations

Hazards of dipping and coating operations can be reduced if special design features are implemented for the process equipment. Many flammable and combustible coatings are less dense than and immiscible with water. In the event of fire, water from hose streams or sprinkler systems could cause an overflow of liquid from the tank unless certain design precautions have been implemented. Examples of special design considerations for dipping and coating equipment and systems are discussed in the following paragraphs.

The top of the dipping or coating tank should be at least 6 in. (150 mm) above the floor, and the liquid surface should be at least 6 in. (150 mm) below the top of the tank. Tanks that exceed 150 gal (570 L) capacity or 10 ft^2 (1 m^2) of liquid surface area should be equipped with a trapped overflow pipe leading to a safe location. This overflow pipe should be capable of handling either the maximum rate of delivery of process liquid or the maximum rate of automatic sprinkler discharge, whichever is greater. In any case, overflow pipes should never be less than 3 in. (75 mm) in diameter.

Dipping and coating equipment should be constructed of noncombustible materials. For tanks that exceed 500 gal (1900 L) capacity or 10 ft^2 (1 m^2) of liquid surface area, the supports should have a fire resistance rating of at least 1 hour.

Larger tanks, having a capacity of 500 gal (1900 L) or more, should be equipped with a bottom drain of sufficient size to empty the tank in 5 minutes. If gravity flow is not practical, pumps may be used to empty the tank. The drain should be operable manually and automatically. However, if a manual drain release is used, it should be located at a safe and accessible area. Drains should be trapped and flammable liquid should discharge to a closed, vented salvage tank or to a safe location outside and away from all buildings. If, due to increased hazard or by nature of the operation, bottom drains cannot be provided, the process should be cut-off or fully diked. Fire protection for this area should be both an automatic special extinguishing system and sprinklers.

Where a salvage tank is utilized, a pumping arrangement should be provided for removal of the contents. The capacity of the salvage tank should be greater than the capacity of the dipping or coating tank. Further requirements are included in NFPA 30.

Conveyor systems used in dipping and coating processes should be arranged to stop automatically in the event of a fire, excess temperature indication, or failure of the ventilation system. Heating systems should be arranged to stop automatically in the event of excess temperature indication or if the level of liquid in the tank exceeds or falls below a safe level.

Heating and cooling units for flammable or combustible liquids should be of an approved type for the specific process design and maintained per manufacturer's instructions. Heating systems should be automatically shut down if the coating material liquid level is higher or lower than specified operating levels. In processes where there is a possibility of flammable liquids being heated above their boiling points or to within 100°F (55°C) of their autoignition temperatures, suitable excess temperature limit controls are needed to prevent rapid vapor buildup and possible autoignition. Controls should limit the surface temperatures of heated workpieces to at least 100°F (55°C) below the autoignition temperature of the coating material used.

Solvent distillation units having distillation chambers or still pots that do not exceed 60 gal (227 L) capacity and are used to recycle Class I, Class II, or Class IIIA liquids should be approved for the purpose and used only in locations per their listing or approval. These units should only be used to distill liquids for which they have been approved.

Limit controls, such as liquid level devices, meters, and timers, should be used to prevent overfilling of tanks where automatic filling is designed into the process. If pumps are used, they should be interlocked to shut down in the event of fire.

Where the dipping or coating equipment is enclosed for the purpose of confining vapors and mists, all panels for light fixtures or for observation should be heat-treated glass, laminated glass, wired glass, or hammered-wired glass, and the panels should be sealed to confine vapors or mists to the enclosure. This does not apply for secondary enclosures such as those installed for environmental purposes to capture low-level fugitive emissions or for observation purposes as vision panels.

Maintenance, Training, and Inspection

Location, ventilation, equipment design, and the elimination of ignition sources are key to the reduction of the hazards in dipping and coating processes using flammable and combustible liquids. Similarly, preventative maintenance, training, and regular inspection of equipment are essential to safe operations. Unfortunately, due to production schedules, changes in processes, and turnover of personnel, these essentials are sometimes neglected, resulting in unsafe operating conditions.

Areas in the vicinity of dipping and coating processes should be kept free of accumulations of combustible residues and unnecessary combustible materials. Spontaneous ignition, due to oxidation or exothermic reaction between various coating components, can readily occur if excess residue accumulates in work areas, ducts, duct discharge points, or other areas. When excess residues accumulate in such locations, operations should be discontinued until conditions are corrected.

Cleaning operations should be conducted with ventilation systems in operation. Cleaning solvents for dipping and coating equipment should have flashpoints above 100°F (38°C) or not less than that of materials normally used in the process.

Combustible coverings (e.g., thin paper or plastic) and strippable coatings are often used to facilitate cleanup of drippings and residues. Use of these coverings increase the amount of combustibles in the process, which could be offset by improved housekeeping and ease of cleaning. Suitable containers should be provided for the disposal of waste and rags used for cleaning. Waste containers should be emptied at least once per day or at the end of each shift.

The size and complexity of dipping and coating operations can vary widely, but, in all operations, the personnel involved should be instructed in the potential safety hazards inherent in the particular process. The nature of the process and operational criteria, maintenance, protection, and emergency procedures

should be included in the employee-training program. Also, there should be thorough instruction regarding proper flammable liquids handling procedures and safeguards. It is desirable to record such training and provide refresher instruction from time to time to ensure continuity and proper action in the event of an emergency.

Depending on the size and nature of the process, periodic (usually at least monthly) inspection should be made of dipping and coating processes. Inspections should include noting the condition of equipment covers, overflow pipe inlets and outlets, bottom drains and valves, electrical wiring and equipment, grounding and bonding connections, ventilation equipment, and fire extinguishing equipment. Inspections and protection equipment tests should be documented and conducted using an appropriate inspection form. Defective equipment and unsafe conditions should be corrected promptly.

FIRE PROTECTION

In spite of the considerable care taken in the operation of dipping and coating processes that use flammable and combustible liquids, fires and explosions do occur. Thus, fire protection and suppression equipment are necessary.

Damage on small processes can be as severe as in large operations. Less consideration is usually given to the location of small processes, and they might be in areas that expose high values or combustible construction. Some form of protection is usually required for all dipping and coating processes.

The simplest device for extinguishing a fire in a process tank is a self-closing cover, which cuts off the fire's air supply. Normally the cover is held open by a cable and fusible link. When exposed to the heat of a fire, the solder in the fusible link melts, releasing the cover and allowing it to drop tightly in place over the tank (Figures 9.3.16 and 9.3.17). Covers should be kept closed when the process is not in operation. Automatic sprinklers are often provided at ceiling level and can provide adequate protection for small processes and where combustible coatings are used with a limited liquid surface area exposure. Sprinklers are intended to help control the fire, prevent damage to the building, and allow effective manual fire fighting. Automatic sprinklers are often required as backup to special fire extinguishing systems. Sprinklers are essential protection for the building and to help control the fire at equipment, where larger dipping and coating processes are installed.

Automatic fire extinguishing systems are needed for dipping and coating processes, including enclosed processes, open processes with peripheral vapor containment and ventilation, and for process tanks exceeding 150 gal (570 L) or 10 ft^2 (1 m^2) in liquid surface area. The fire extinguishing system should be designed to simultaneously discharge to all protected areas of the process. In many cases, a connected reserve supply of extinguishant should be provided.

For dip tanks, the fire extinguishing system should protect the tank, drainboard, freshly coated objects or materials, pumping equipment, and exhaust ventilation ducts. Where processes involve considerable volumes, large liquid surface areas, or large wetted areas of low flashpoint materials, fire-extinguishing systems should be provided. Fire-extinguishing systems should be provided for tanks having capacities in excess of 150 gal (570 L) or surface areas greater than 10 ft^2 (1 m^2). Suitable protection systems use foam, carbon dioxide, or dry chemical as the extinguishing medium. For liquids having flashpoints above 140°F (60°C), water spray systems may be used. All systems should operate automatically and manually. The complexity and value

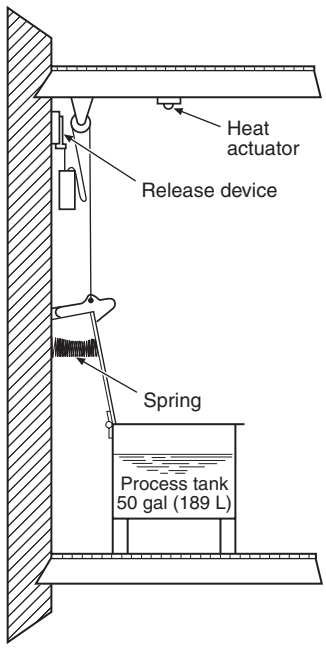

FIGURE 9.3.16 Small Process Tank with an Automatic Cover

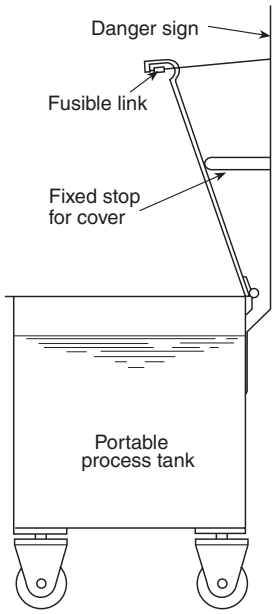

FIGURE 9.3.17 Portable Tank with an Automatic Cover

of some processes and/or the absence of sprinklers as backup often make it desirable to provide redundancy in protection systems.

For flow coaters, the system should protect open tanks, vapor drying tunnels, and exhaust ventilation ducts. Pumps that recirculate the coating material should be interlocked to stop in the event of fire. For curtain coaters and roll coaters, the system should protect the coated objects or material and open troughs and/or tanks containing coating material. Pumps that recirculate the coating material should be interlocked to stop in the event of fire.

For a small process with an open tank of less than 150 gal (570 L) capacity or less than 10 ft^2 (1 m^2) of liquid surface area, an automatic (and manually operable) closing tank cover or fire extinguishing system is needed. Covers should be of noncombustible construction and overlap the tank by at least 1 in. (25 mm). The operating and support mechanisms for the cover should be noncombustible. Drainboards should be designed so that they do not interfere with the automatic closing of the cover. Covers should be kept closed when the process is not in operation.

In the event of fire, preventing overflow of the tank due to sprinkler discharge is necessary. This can be accomplished by arranging drainboards to prevent sprinkler discharge from flowing into the tank, by automatic closing covers for the tank, or by providing an overflow pipe from the tank (Figures 9.3.18 and 9.3.19).

Ventilation and exhaust systems for dipping and coating processes should be interlocked with the fire alarm system and should remain in operation during any fire alarm conditions. However, shutdown of ventilation systems and closing of dampers in ducts might be necessary if the process is protected by a special fire extinguishing system.

Dipping and coating process areas should be equipped with portable fire extinguishers suitable for use on flammable and combustible liquids fires. Due to the flash fire conditions that can prevail in flammable liquids fires, emergency response personnel should be trained to act immediately to affect both automatic and manual protection methods to fight the fire to achieve rapid control and limit possible injury and damage. Fire-fighting efforts should be restricted to the level of personnel training and the company's selected level of emergency response. Also, these efforts should be coordinated with the local public fire authorities.

SUMMARY

Dipping and coating processes vary in the application of equipment and the hazard associated with the specific process. This chapter pertains to the processes, equipment, hazards, and fire protection of dipping and coating operations that use flammable and combustible liquids. Typical equipment is dip tanks, flow coaters, curtain coaters, and roll coaters. Properly designed ventilation systems for the process and classified electrical equipment for specific areas are critical to the safe operation of these processes. Also, there are special design considerations for these processes to reduce the hazard.

Because flammable or combustible liquids are normally involved in dipping and coating operations, elimination of the source of ignition and/or properly ventilating to reduce vapor-air mixture concentrations are the best method to avoid a fire or explosion event. Properly designed automatic fire extinguishing systems are necessary for most dipping and coating operations. An automatic sprinkler system is often provided to protect the building and to control fire spread in the vicinity of the dipping and coating process.

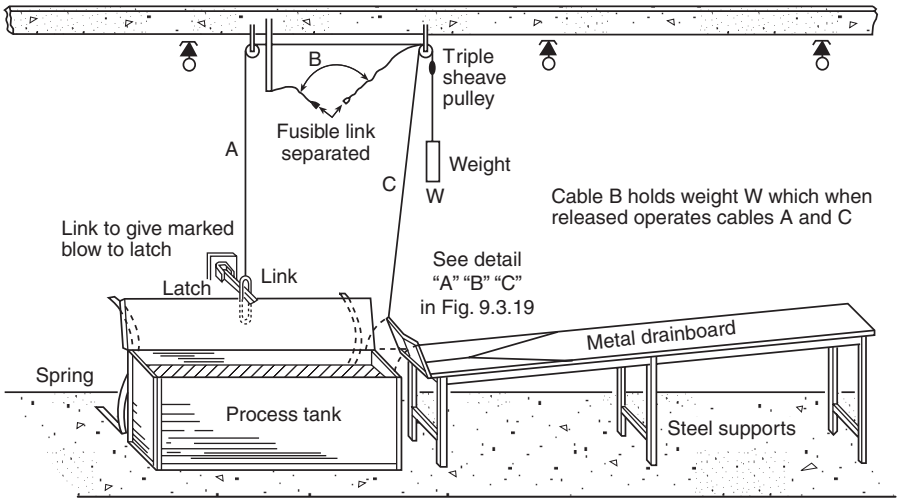

FIGURE 9.3.18 Process Tank, Automatic Cover, and Drainboard, with Drainboard Arranged to Prevent Interference with Latch Cover. The link in cord "B" has separated, weight "W" has lifted the hinged section of the drainboard, and the latch is about to release the cover.

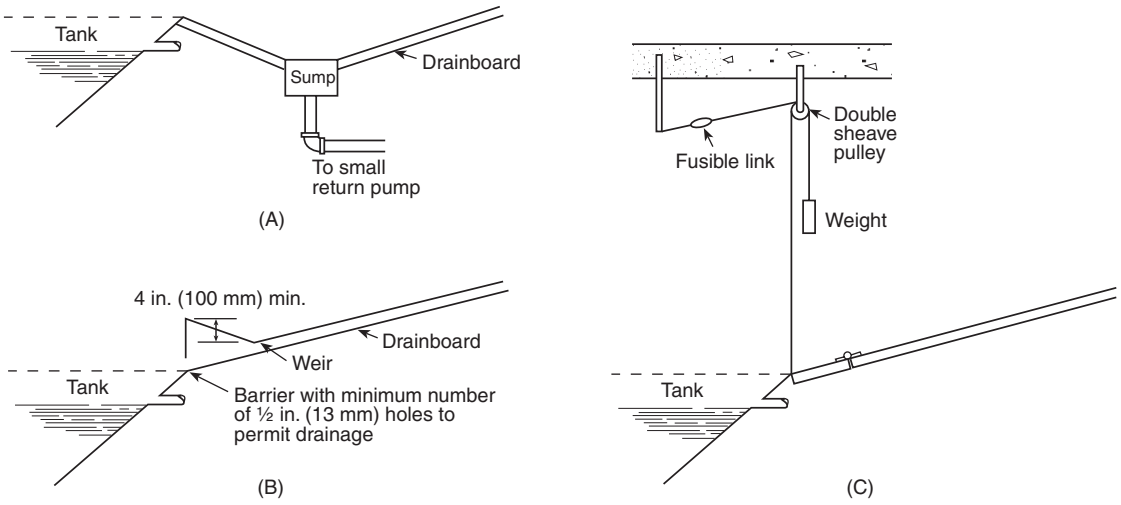

FIGURE 9.3.19 Suggested Arrangement to Prevent Sprinkler Discharge onto Drainboard from Entering Tank. A and B are most effective for other than paint process tanks. If used for aerosol process tanks, drain holes and piping should be cleaned frequently to prevent clogging.

Production Process
Fire Hazards
Safeguards

Key Terms

dusts, flammable solvent, foam plastic, plastic (class of), polymerization, static electricity, thermoplastics

The goal of this chapter is to provide an overview of the plastics industry, what constitutes a plastic, the terminology used in the industry, the types of processing techniques used to produce a product, the hazards that exist when producing that product, and the steps that industry and government have taken to provide a safe working environment for the personnel working within the facility and those people living nearby.

OVERVIEW OF THE PLASTICS INDUSTRY

Alexander Parkes unveiled the first human-made plastic in London in 1962. It showed great promise, except for the high cost of production. Since then the plastics industry has become a rapidly growing worldwide business. Today there are approximately 30 major classes of plastics or polymer groupings, with numerous variations within each individual plastic grouping.[1–4]

With many large plastic producers selling licenses to their technology, many small producers have joined the industry. They have built production plants worldwide to generate the products needed by the various regions of the world. Recent growth has been significant in China, Latin America, the Middle East, and Central and Eastern Europe. There has also been growth in the United States as companies have invested heavily to remain competitive. According to the American Plastics Council (APC), in 2004 production in the United States and Canada grew to 115.2 billion lb (52.4 billion kg) and this total continues to increase each passing year. But as there is growth in production of plastic in the United States, a massive influx of finished plastics from China has resulted in loss of jobs and the closure of a number of U.S. facilities.

Plastics are a basic material of use—on a par with metals, glass, wood, and paper. They have become increasingly important to advanced concepts in building and construction, aerospace, communications, electronics, packaging, fibers, and transportation, as well as medicine and the arts. As the number of applications for plastics grows, so has the possibility of the exposure of plastics to fire.

A plastic is any one of a large and varied number of materials consisting wholly or in part of combinations of carbon with oxygen, hydrogen, nitrogen, and other organic and inorganic elements. In most cases, the plastic is produced from a single "mer" unit, also known as monomer. These mer units are low molecular weight formations of organic elements. By chemical reaction or polymerization, these single mer units are connected to each other to form long polymer chains of high molecular weight. It is the high molecular weight polymer chains that provide the plastic with its unique properties and its ability to be processed and formed.

Although solid in the finished state, at some stage in its manufacture a plastic is liquid, molten, or softened and thus capable of being formed into various shapes, mostly through the application of either heat or pressure or a combination of both. Whatever their properties or form, however, plastics fall into one of two groups: (1) thermoplastics or (2) thermosets (Table 9.4.1).

Thermoplastic resins can be repeatedly softened and hardened by heating and cooling without a major chemical change taking place. There might be some breakdown of the long molecular

George Ouellette is a research technologist in quality assurance at Basell USA Inc. in Elkton, Maryland.

TABLE 9.4.1 Examples of Plastics Materials

Thermoplastic		Thermoset	
ABS (acrylonitrile-butadiene-styrene)	*Polyethylene*	*Epoxy*	*Silicones*
A combination of three different monomers—acrylonitrile, butadiene, and styrene gas—suitable for tough products; has good electrical insulating qualities; used to make automobile front grilles, household appliance components, and business machine and telephone components	Tough; excellent chemical resistance and electrical insulating quality; near zero moisture absorption; used for packaging, molded housewares, and toys	Excellent for chemical resistance, electrical properties, and dimensional stability; will bond metals, glass, hard rubber, etc.; used for aircraft components, tanks, and electrical and electronic assemblies	Long-term heat resistant, water repellent, electrical insulator, and mineral acid resistant; used in the electrical and electronics industry; insulation in meters and generators and induction heating apparatus

chains resulting in a decreased molecular weight and reduced viscosity of the product when reprocessed.

Thermoset resins, when heat treated, undergo a chemical reaction, sometimes going from a liquid to a solid. Once a solid is thermoset, it cannot be softened by further heating without causing a significant chemical change that will forever alter the material.

The diversity of major classes of plastics or polymer groups has made plastics applicable to an extremely broad range of end uses and products. Yet, paradoxically, this diversity has also made it difficult to grasp the concept of a single family of materials encompassing such a far-reaching span of physical and chemical properties and fire hazard characteristics.

Additional information on the formation of these various types of plastic and elastomeric materials can be found in Section 6, Chapter 13, "Polymeric Materials." For additional information on fire hazards, see Section 6, Chapter 8, "Dusts"; Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 8, Chapter 4, "Automated Equipment"; Section 8, Chapter 7, "Heat Transfer Fluids and Systems"; Section 8, Chapter 8, "Industrial and Commercial Heat Utilization Equipment"; Section 8, Chapter 13, "Electrical Systems and Appliances"; Section 10, Chapter 1, "Emergency and Standby Power Supplies"; Section 10, Chapter 2, "Heating Systems and Appliances"; Section 11, Chapter 1, "Waste Handling and Control"; Section 11, Chapter 2, "Housekeeping Practices"; and Section 18, Chapter 6, "Deflagration (Explosion) Venting." For additional information on the hazards of the polymerization or synthesis plant, see Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 3, "Storage of Gases"; and Section 7, Chapter 4, "Storage and Handling of Chemicals."

PLASTICS PROCESSING

The plastics industry as a whole has four broad areas of processing: (1) polymerization or synthesis, (2) manufacturing, (3) conversion, and (4) fabrication. Although each area of processing is basically distinct, each can be conducted at the same or different locations, and each area has its own types and levels of hazards.

The first step is the polymerization or synthesis of the product in which the feedstock or the monomer is reacted in a reactor to form the basic polymeric material. This step is where the mer units, along with catalysts, donors, and gases, set off a chemical reaction in the reaction chambers. The degree of polymerization or reaction determines the form of the basic plastic material. In this step, the basic material can be in the form of powder, granules, or viscous liquid.

An example of the polymerization of ethylene to polyethylene is shown in Figure 9.4.1, in which the *N* represents the number of mer units that are reacted. With the addition of each mer unit, the molecular weight of the product increases and the form of the product begins to change. In the case of polyethylene, the ethylene monomer is a gas with a molecular weight of 28. At 6 mer units the product is a liquid, at 35 mer units the material is a grease, at 140 mer units a wax, and at 430 mer units it has a molecular weight of 12,000 and is in the form of a hard resin. Further increases in the number of mer units result in higher

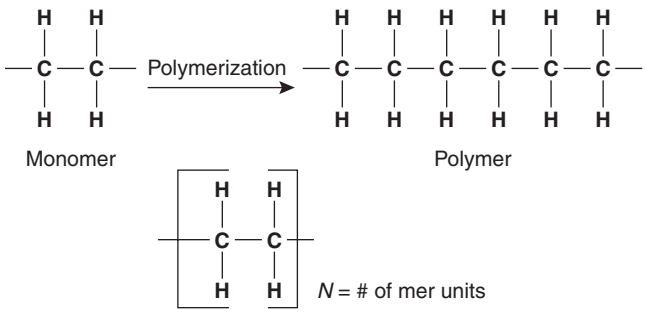

FIGURE 9.4.1 An Example of Conversion of Ethylene Mer Units to Polyethylene

molecular weights, which affect the processability, physical and mechanical properties, and the chemical resistance.[5]

The hazards of the polymerization or synthesis plant are basically those of a chemical plant. (See Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 3, "Storage of Gases"; and Section 7, Chapter 4, "Storage and Handling of Chemicals.") Additional information may be obtained from American Petroleum Institute Standard 500 and U.S. Department of Labor Occupational Safety and Health Administration Standard 29 CFR 1910.119 on Highly Hazardous Chemicals.

Because of the large amounts of gases and flammable liquids used in the polymerization step, it would be considered the most hazardous. Major disasters, including the 1984 incident in Bhopal, India, the 1989 explosion at Phillips Petroleum Company in Pasadena, Texas, the 1990 fire at BASF in Cincinnati, Ohio, and the 1991 incident at IMC, Sterlington, Louisiana, have shown that safety is a critical issue during this part of the process.

In the manufacturing step, the basic polymeric material is processed into a different form that can be easily handled in subsequent processing steps. The most common process used is compounding. In compounding, the basic polymeric material might be blended with colorants, rubber, other types of polymeric materials, fillers, reinforcements, flame retardants, or other additives to modify the physical, mechanical, optical, rheological, or chemical properties of the material or to protect it from harsh environments, such as heat or ultraviolet (UV) light. The subsequent properties of the compounded product will have a major influence on the type of conversion technique used to convert the material into the final application that is sold to the customer.

Conversion of the plastics materials into useful articles by molding, extrusion, foaming, or casting usually involves heating the plastic so it will flow into a shape that is retained when the plastic is cooled. In the case of thermoplastics there are normally no chemical reactions taking place. With thermosetting resins, the chemical reaction to cross-link the material to put it in its final unchangeable form is a significant part of these operations. The plastics industry refers to these operations as "processing" or "converting."

Fabricating encompasses the largely mechanical operations of bending, machining, cementing, welding, heat sealing, decorating, and polishing plastics.

These four areas (i.e., polymerization or synthesis, manufacturing, conversion, and fabrication) accurately categorize the fire hazards that can be encountered in the plastics industry. It is important to recognize, though, that the synthesis, or manufacturing, of a given plastic might be much more hazardous than its molding or extrusion. It is also crucial to recognize that some plants doing only nominal converting and/or fabricating may also be conducting chemical operations with flammable or reactive materials. One example is the overlapping of molding and synthesis operations in a plant that impregnates liquid polyester resins into reinforcing glass fibers for molding boat hulls or containers.

This chapter discusses the manufacturing and conversion phases of the plastics, recognizing, of course, that in some instances hazards associated with all four phases of the industry may be carried on in one location.

Basic Hazards

Most plastics are combustible organic compounds that can burn under certain conditions. Concern must be directed at the inherent combustibility of plastic formulations influenced by the basic polymers used, the nature of plastic additives, the form the final product takes, and the conversion of feedstock plastics into finished articles. Concern must also be shown for the hazards associated with combustible dusts, flammable solvents, electrical faults, hydraulic fluids, the storage and handling of large quantities of combustible raw materials and finished products, and housekeeping within the processing area. (See the chapters in this handbook that specifically discuss these hazards.)

Terminology

Before discussing the converting of plastic feedstocks into finished products and the associated hazards, certain process terms and definitions are provided:

Additive: Any material added in small amounts to basic resins or compounds to alter properties. Additives can be dyes, pigments, plasticizers for flexibility, fibers to reinforce, antioxidants to protect the polymer from degradation by heat, UV stabilizers to protect the polymer from ultraviolet light, lubricants to aid flow into or release from a mold, or fire retardants.

Binders: The resins in a plastic mixture that hold together all of the other ingredients

Blowing agent: Any substance that alone or in combination with other substances is capable of producing a gas by thermal or chemical action, resulting in expansion of the plastic, formation of a cellular structure, and reduction in density of the final part

Blown tubing: A thin film made by extruding a tube and simultaneously inflating it with air while hot; distention may be 20 times the diameter of the extruded tube

Casting: Flowing liquid material into a mold or against a substrate with little or no pressure, followed by solidification and removal of the formed object

Compound: An admixture of polymer with all the materials necessary for the finished product

Cure: To change the properties of the polymeric system into a more stable, usable condition by the use of heat, radiation, or reaction with chemical additives

Decomposition: The breakdown or change of a material into other chemical compounds

Depolymerize: To decompose macromolecules into simpler compounds

Elastomer: A macromolecular material that at room temperature returns rapidly to approximately its initial dimensions and shape after substantial deformation by a weak stress and release of the stress

Extrusion: The process of passing molten plastic under pressure through a die to form a continuous profile; the equipment is called an extruder

Fabrication: The making of articles by machining, cementing, heat sealing, or thermoforming of preformed sheets, rods, or tubes. The term is used in contrast to *processing.*

Fiber: The polymer is present in the form of essentially continuous cylindrical rods of very small diameter.

Fillers: Relatively inert materials added to plastic to modify physical properties and/or to reduce its cost. For example, fillers might be used to increase heat resistance and alter the dielectric strength. A wide variety of products are used, for example, wood flour, cotton, sisal, glass, talc, calcium carbonate, and clay.

Film: A general term for sheets of plastic not more than 0.01 in. (0.25 mm) thick, regardless of the process used to make them

Fines: Materials that are finely divided into small particles and are characterized by high surface area per unit volume or unit mass. These can also be called dust or powder.

Finishing: The removal of burrs, flash, gates, and defects from plastic articles, and also the development of a desired surface texture

Flash: Unwanted projections from molded articles resulting from flow of plastic into the gap between matching parts of a mold. (The term has no fire connotation.)

Flash ignition temperature: The minimum temperature at which sufficient flammable gases are emitted from the polymer and ignited when an external ignition source is applied[6]

Foam (cellular plastic): A plastic with numerous cells dispersed throughout its mass. Rigid foams have rapidly reached large-volume production as thermal insulation boards for construction, cups for hot and cold drinks, trays for prepackaged meats, and shock-resistant packaging; flexible foams are used for furniture padding and insulation of outer garments.

Foaming agent: See *blowing agent*

Forming: The process in which the shape of plastic pieces, such as sheets, rods, or tubes, is changed into a desired configuration

Laminate: A composition of several layers of material(s) firmly held together by heat and pressure, bonding, or impregnation

Layup: In reinforced plastics, an assembly of layers of resin-impregnated material ready for processing

Lubricant: Material added to improve feeding of powder or granules into molding or extrusion machines, to improve flow of molten plastic through machines and into molds, or to prevent adhesion of plastic to molds; the last of these uses is called "mold release." Typical lubricants are zinc stearate, carnauba wax, and silicone oil.

Molding: The process of forcing plastic into a cavity to achieve a desired shape

Molecular weight: The sum of the atomic weights of all the atoms in a molecule

Monomers: A simple compound usually containing carbon and of low molecular weight, which can react to form a polymer by combination with itself or with other similar molecules or compounds

Oligomer: A polymer consisting of only a few monomer units, such as dimer, trimer, tetramer, or their mixtures

Peroxide: A chemical with a single oxygen-to-oxygen bond with a specific half-life or rate of decomposition; added to the plastic during compounding to control the process rheology of the product

Plasticizers: Materials added to plastic to make the finished product more flexible or to facilitate compounding. Some plasticizers increase the combustibility of the plastic whereas others serve as flame retardants.

Plastics: Materials that contain as an essential ingredient an organic substance of large molecular weight, are solid in their finished state, and at some stage in their manufacture or processing into finished articles can be shaped by flow

Polymer: A substance consisting of molecules characterized by the repetition of one or more types of monomeric units

Polymerization: The process by which molecules of a monomer are made to respectively combine with other monomers. The result is a much longer chainlike molecule.

Processing: The converting of polymers into useful articles by molding or extrusion from granules, depositing film from solvent, or laminating resin and reinforcement. Most often the molding operation uses heat, but it is largely or entirely a physical rather than a chemical process.

Reinforced plastic: A plastic with a fibrous filler that significantly increases flexural, impact, or tensile strength. Additives are usually glass, cotton, or nylon fibers. Reinforced plastics can be thermoplastic granules for injection molding or materials using large areas of reinforcement as in layup molding or pulp molding.

Resin: A solid, semisolid, or pseudosolid organic material that often has high molecular weight and that exhibits a tendency to flow when subjected to stress and usually has a softening or melting range. However, common usage of the term in the plastics industry does not always conform to the definition. The term is often used for uncured fluid thermosetting materials, for some chemically modified material resins, and often synonymously with the terms *plastic* and *polymer.*

Rheology: The flow characteristics of a material, including viscosity

Self-ignition temperature: The minimum temperature at which self-heating properties of the material lead to ignition or ignition occurs of itself, in the absence of any additional ignition source[6]

Sheeting: A form of plastic in which the thickness is very small in proportion to length and width; similar to film except the thickness is greater than 0.01 in. (0.25 mm) in thickness

Thermoplastic: A plastic that can be repeatedly softened by heating and hardened by cooling through a temperature range characteristic of that plastic, and that in the softened state can be shaped by flow into articles by molding or extrusion

Thermoplastic elastomers: A diverse family of rubber-like materials that, unlike conventional vulcanized rubbers, can be processed and recycled like thermoplastic materials

Thermoset: A plastic that, after having been cured by heat or other means, is substantially infusible and insoluble

Viscosity: The property of resistance to flow of the material

RAW MATERIALS

Many plastic feedstocks are derivatives of petroleum or gas recovered during the refining process; for example, ethylene monomer (a widely used feedstock) is derived in gaseous form from petroleum refinery gas, liquefied petroleum gases, or liquid hydrocarbons (Figure 9.4.2).

The monomer is subjected to a chemical reaction, known as polymerization, that causes the small molecules to link together into increasingly longer molecules. Chemically, the polymerization reaction has turned the monomer into a polymer (the reason that names of so many plastics materials begin with the prefix *poly*). The polymer, or plastic resin, must next be prepared for use by the processor, which will turn it into a finished product. In some instances, it is possible to use the plastic resin or feedstock as it comes out of the polymerization reaction. More often, however, it is transformed into a form that can be more easily handled by the processor and more easily handled in processing equipment. The most common solid forms for the plastic resin are pellets, granules, flakes, and powder. Some feedstocks are also available as semisolids (e.g., pastes) or as liquids (for casting).

PRODUCTION PROCESS

The ways in which plastics can be processed into useful end products are as varied as the plastics themselves.

Common Elements

Though the processes differ, there are common elements. In the majority of cases, thermoplastic compounds in the forms of pellets, granules, flakes, and powder must be melted by heat so they can flow. Pressure is usually involved in forcing the molten plastic into a mold cavity or through a die, and cooling must be provided to allow the molten plastic to harden. With thermosets, heat and pressure are also most often used. In their case, however, heat serves to trigger a chemical reaction and causes the thermosetting resin to cure (set) in the mold under pressure. When thermoplastic or thermoset resins are in liquid form, heat, pressure, or both need not necessarily be used; however, in many casting techniques intended for high-speed production, they do play a role.

Basic Processes of Manufacturing Systems

The following descriptions of processes cover the basics of the major manufacturing systems. It should be recognized, however, that there are variations in virtually every process.

Blow Molding. This process is generally used only with thermoplastics. It is applicable to the production of hollow plastics products, such as bottles, automotive cooling reservoirs, and automobile fuel tanks. Blow molding involves melting the thermoplastics resin and then forming the molten, highly viscous polymer into a tube-like shape (known as a parison). The ends of the tube are then sealed, and air is injected into the tube. The tube, in a softened state, is inflated inside the mold and forced against the walls of the mold, where it cools, solidifies, and is ejected from the mold. Figure 9.4.3 is a diagram of continuous extrusion blow molding. The plastic parison (in cylindrical shape) is extruded from the die into a mold, which closes on the parison (knife cuts the parison off from the extrudate). The mold then rotates to the second station where air is injected into the parison (still hot and, therefore, formable) to blow it out to the shape of the inside mold cavity. At the third station, the

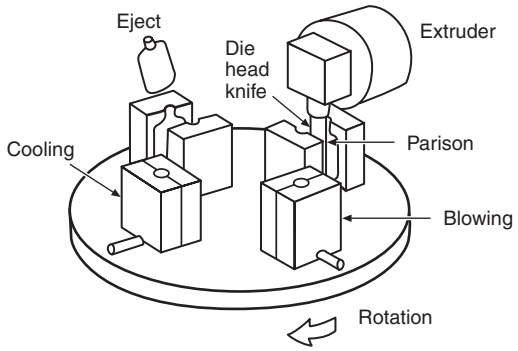

FIGURE 9.4.3 Continuous Extrusion Blow-Molding Setup, Using a Rotating Horizontal Table

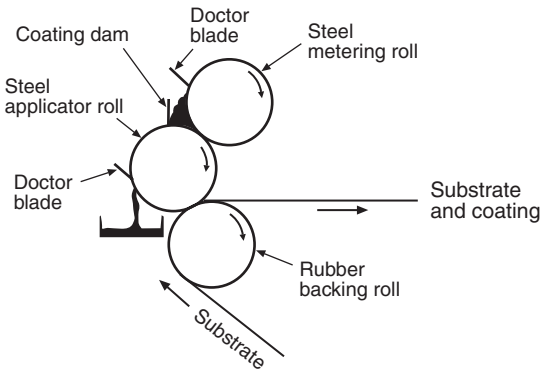

FIGURE 9.4.4 Typical Coating Setup, Known as a 3-Roll Nip-Fed Reverse Roll Coater

blown part is allowed to cool and set. The mold finally rotates to the last station where the finished part (in this case, a bottle) is ejected from the mold.

Calendering. Calendering can be used to convert thermoplastics into film and sheeting or to apply a plastic coating to textiles or other supporting materials. In calendering of film and sheeting, the material is initially processed in a kneading mixer or extruder to melt or soften it for further processing. The plastic compound is then passed between a series of three or four large, heated, revolving rollers running at different speeds to reduce the thickness of the material, forming it into a sheet or film.[7]

Casting. Casting can be used with both thermoplastics and thermosets to make products, shapes, rods, and tubes by pouring a liquid monomer-polymer solution into an open mold or a closed mold, where it finishes polymerizing into a solid. Pressure need not be used with the casting process, unlike the molding process. The starting material in the casting process is usually in liquid form rather than solid form.

Coating. Coating is accomplished by using either thermoplastic or thermosetting materials. The coating may be applied to metal, wood, paper, glass, fabric, leather, or ceramics. There are a number of techniques by which the coating may be applied. Figure 9.4.4 illustrates a 3-roll nip-fed reverse roll coater. In this setup, plastic feeds from the dam, through the nip, and between the steel metering and applicator rolls, rotating in the same direction. At the bottom of the applicator roll, plastic is laid on top of the substrate (e.g., fabric, paper, etc.) as it comes in contact with the substrate at the nip between the applicator roll and backing roll (which carries the substrate up from the bottom of the setup). A doctor blade is used to scrape off excess plastic from the applicator roll. Another technique is extrusion coating where the material is heated, melted, and extruded directly onto the substrate.

Compounding. Mixing additives into previously formed resin, using kneading mixers, screw extruders of varied design, masticating rolls, or calenders, is called compounding. Rolls and kneaders are heated by high-pressure steam or heat transfer fluids.

Screw extruders have largely displaced rolls and kneaders for compounding, because they provide better control, continuous output, and less exposure of hot plastic to air. The extrudate is cooled normally in a water bath and then chopped into pellets, which are easily used in other downstream processing operations.

Compounding for flexible polyvinyl chloride (PVC) packaging uses high-intensity mixers and ribbon blenders. The mixer spins the resin at high speed. This generates heat, which softens the resin and allows it to accept plasticizers, stabilizers, and so on. After absorption at 190 to 240°F (88 to 116°C), the batch drops to a blender to cool for storage or extrusion.

Compression Molding. Compression molding is the most common method of forming thermosetting materials. It can also be used for thermoplastics. Compression molding is simply the squeezing of material into a desired shape by applying heat and pressure to the material in a mold. In the case of thermoset resins, the material is heated until curing of the material takes place and the part is ejected from the mold hot. For thermoplastics, after the heat and pressure are applied to the part for a certain length of time to ensure complete flow within the mold, the mold is cooled, normally under pressure, to allow the material to solidify before ejection from the mold.

Figure 9.4.5 illustrates a simple two-piece compression mold. Plastic molding material is loaded into the lower half (cavity) of the heated mold (shown at top). The top half of the mold (mold force) is then lowered, and the two halves are brought together under pressure (shown below). The softened molding material is, thus, formed into the shape of the cavity and allowed to harden with further heating or cooling. The mold is then opened and the part is removed.

Extrusion. Extrusion is employed to form thermoplastic materials into continuous sheeting, film, tubes, rods, profile shapes, or filaments and to coat wire, cable, and cord. Figure 9.4.6 illustrates a basic single-screw extruder, in which plastics pellets (or powders) are fed into the hopper, through the feed throat, and into a screw that rotates in a heated barrel. The rotation of the screw (which is powered by the drive motor) conveys the plas-

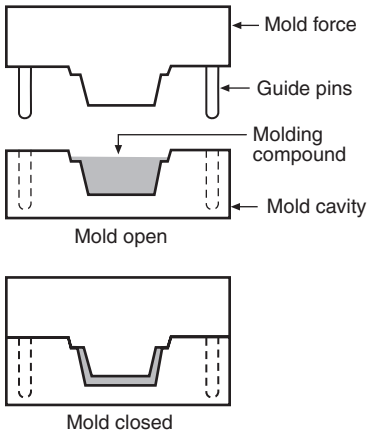

FIGURE 9.4.5 Basics of a Simple Two-Piece Compression Mold

tic forward for melting and delivery through the breaker plate (reduces the rotary motion of the melt), through the adapter, and into the die, which dictates the shape of the final extrudate. The final size of the extrudate is determined by the speed of the downstream take-off equipment.

Foam Plastics Molding. In foam plastics molding, foams can be used in casting, calendering, coating, rotational molding, flow molding, and even injection molding and extrusion. Figure 9.4.7 illustrates a setup for steam-chest molding. Among the many variations in molding foamed plastics is this setup for steam-chest molding expandable styrene beads into products such as foam cups, novelties, building products, and so on. In this operation, the expandable beads, containing a blowing agent, are preexpanded with steam, then screened to remove large clumps. The expanded beads are next blown into a storage hopper and allowed to dry and stabilize. From here, they feed into the final mold where steam is again used to complete expansion of the beads so that they fill the mold and fuse together. Water is used for cooling, prior to opening the mold and removing the finished foamed styrene part. The manufacture of foamed products is discussed in more detail later in this chapter in the section Flammable Solvents.

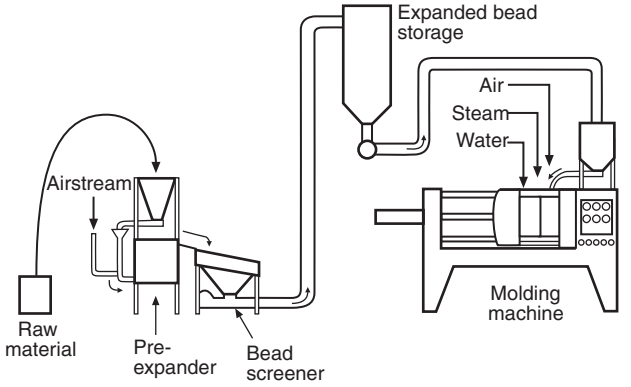

FIGURE 9.4.7 Setup for Steam-Chest Molding

High-Pressure Laminating. High-pressure laminating is a process that uses thermosetting plastics to hold together reinforcing materials, such as cloth, paper, wood, or glass fibers. Heat and pressures of at least 200 psi (1.4 kPa) are used to produce the laminated product.

Injection Molding. Injection molding is the method of forming objects from pelletized, granular, or powdered plastics, most often of the thermoplastic type, in which the material is fed from a hopper to a heated chamber in which it is softened, after which a ram or screw forces the material into a mold. Pressure is maintained until the mass is hardened sufficiently for removal from the mold. Figure 9.4.8 illustrates an injection molding machine with a reciprocating screw. Plastic pellets feed through the hopper into the screw (much like the screw in an extruder) where they are compacted, melted, and pumped by the rotation of the screw past the nonreturn flow valve to the front of the screw, where the molten material is allowed to accumulate. At the proper time in the molding cycle the rotation of the screw is stopped. The amount of molten plastic in front of the screw is injected into the mold, using the screw as a plunger activated by the hydraulic injection cylinder. In the mold, the molten plastic flows throughout the cavity, completely filling it. The plastic is then allowed to cool and harden, the mold is opened, and the finished part removed. The back end of the machine shown in

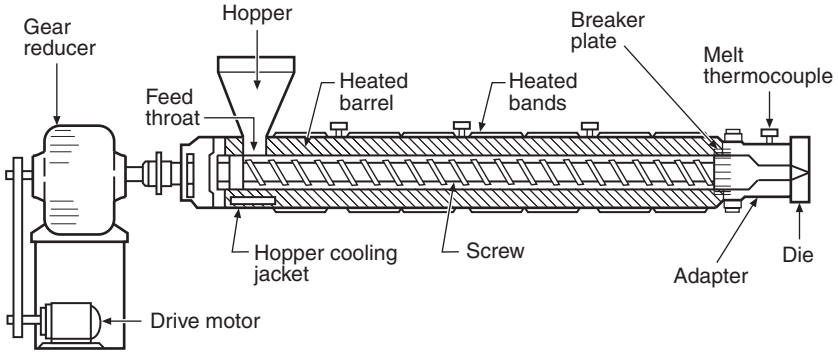

FIGURE 9.4.6 Basic Single-Screw Extruder

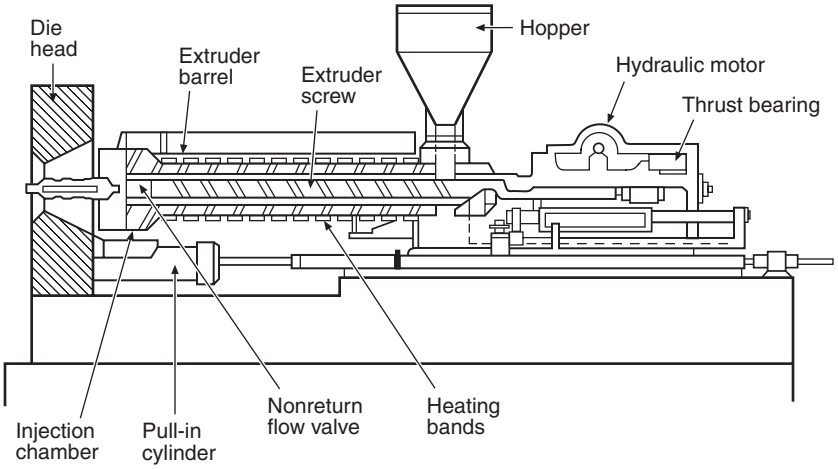

FIGURE 9.4.8 Injection Molding Machine (Reciprocating Screw)

this figure contains the motors and drives needed to power the machine.

Low-Pressure Laminating. Low-pressure laminating is a process that uses thermosetting plastics to hold together reinforcing materials, such as cloth, paper, wood, or glass fibers. Heat and pressures of less than 200 psi (1.4 kPa) are used to produce the laminated product.

Reaction Injection Molding (RIM). Reaction injection molding is a technique used primarily for molding polyurethane elastomers or foams into end products with solid integral skins and cellular cores. Basically, two or more pressurized reactive streams are impinged together under high pressure in a mixing chamber. The resulting mixture is then injected, under low pressure, into a mold. There the reaction begins and continues until the liquid mixture has set up into a solid or cellular finished product.

Reinforced Plastics Processing. In reinforced plastics processing, resins (acting as binder material) are combined with reinforcing materials (usually in fibrous form) to produce composite products having exceptional strength-to-weight ratios and outstanding physical properties. The resins may be either thermosets or thermoplastics.

Figure 9.4.9 illustrates the technique of matched-die molding. Basically, it is a compression molding process in which resin and glass fibers are shaped into the finished product under heat and pressure between the two halves of a mold (male and female halves). The glass-fiber reinforcements are laid over the male mold in the form of a "preform," a combination of glass and resin preformed before molding to the basic shape of the part to be molded. Additional liquid resin mix is added before the mold is closed.

Rotational Molding. Rotational molding is a process used to make hollow one-piece parts such as plastic barrels. Finely powdered plastic or molding granules are placed in a cavity that is rotated about two axes to distribute the plastic. While it is rotating, the mold is heated to melt the plastic and then cooled to solidify the part.

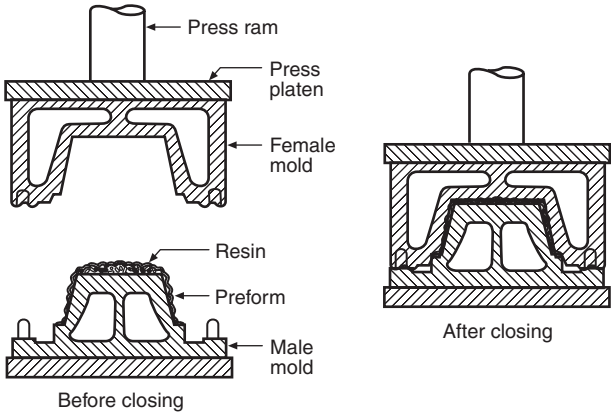

FIGURE 9.4.9 Matched-Die Molding Technique for Producing Reinforced Plastic Parts

Thermoforming. In thermoforming, thermoplastic sheeting is heated to its softening temperature and forced against the contours of a mold by mechanical means (e.g., tools, plugs, solid molds, etc.) or by pneumatic means (e.g., differentials in air pressure created by pulling a vacuum between the sheet and mold as in vacuum forming or by using the pressures of compressed air to force the sheet against the mold as in pressure forming). The part cools in the mold and is removed.

Figure 9.4.10 illustrates a variation on the thermoforming of plastic sheets known as plug-assist vacuum forming. In operation, the plastic sheet is clamped in place and heaters move in to heat the sheet top and bottom to soften it (A). Heaters are then withdrawn, and the frame holding the sheet is lowered down to contact the mold. At this point, the plug-assist is lowered into the softened sheet, stretching it down to the bottom of the mold cavity (B). After the plug-assist has reached its closed position,

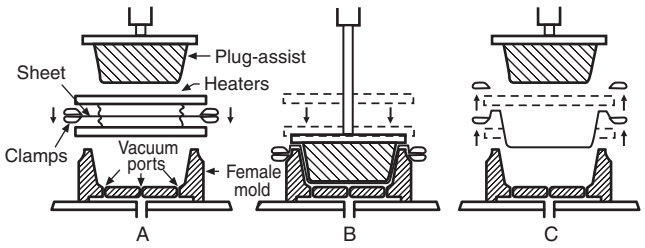

FIGURE 9.4.10 Variation on the Thermoforming of Plastic Sheets Known as Plug-Assist Vacuum Forming

a vacuum is drawn through the ports to pull the stretched sheet completely into the cavity and finish the forming. Next, the plug-assist is withdrawn, the formed sheet is cooled, and the clamps are opened to remove the formed part from the frame (C).

Transfer Molding. Transfer molding is most generally used for thermosetting plastics in a process similar to compression molding. The molding material is placed in a pot at the top of a closed mold and a plunger is used to force the material into the gates, runners, and cavities of the mold. Heat is used to cure the material, and the part is then removed.

FIRE HAZARDS

The sections that follow describe hazards that are specific to the plastics industries. The reader should understand that the hazards common to most industrial operations are also important. For additional information on fire hazards, see the chapters referenced at the beginning of this chapter.

Plants converting feedstocks into finished products are subject to a variety of hazards that can result in explosions and fire. The broad area of hazard involves the presence of combustible dusts (commonly called fines), flammable and combustible liquids, high-heat elements, static electricity, hydraulic and heat transfer fluids, and failure to observe good storage and housekeeping practices.

Dusts

Although when in solid massive form many plastics can be difficult to ignite and will not continue to burn on removal of an exposing flame, nearly all will burn rapidly in the form of dust and, if dispersed in air, can be explosively ignited by a spark, a flame, or a surface that is heated above the material's flash ignition temperature. The higher the ratio of surface area to unit volume or unit mass will significantly increase the possibility of ignition. Dust explosions should be considered possible when operations use pulverized plastic, convey larger granules through pneumatic conveying systems, or produce dust by machining or sanding in finishing work. Additives, such as wood flour or finely ground dyestuffs, also require safeguarding when being added to plastics.[6]

Plastic pellets for injection or extrusion molding are commonly known as molding powder. In reality they are not pulverized material but are cubes or cylindrical pellets. They are usually screened to remove finer particles to permit more uniform feeding to machines, and they are free from the hazard of dust explosion. However, dust (fines) can be generated by abrasion of these particles when conveyed in a long pneumatic conveying system.

Trimmings from injection molding, such as runners, sprues, and flash, are cut too small for reuse alone or for blending with fresh (virgin) molding pellets. This cutting is called "regrinding," although it is a shearing and impacting action deliberately intended to avoid making dust and fine particles. Regrinding usually generates some fine powder, and dust hazards should be considered when considerable regrinding is done.

Compounding of resins with such additives as dyes, pigments, fillers, mold-release or flow-improving lubricants, plasticizers for flexibility, ultraviolet or heat stabilizers, or modifying resins is also a source of dust hazards. For rapid mixing, most of these are charged to mixing equipment as fine powders, and dust explosions are possible with any of these ingredients. Some compounding, especially for reclaiming of once processed materials, is done at molding machines in plastics plants of all types.

Incorporation of wood flour, cotton flock, or other combustible fillers usually increases the explosibility of dust. Incorporation of low percentages of fire retardants has but little effect on explosibility of dusts. These fillers have a lower flash ignition temperature than the plastics in which they are used, making them more susceptible to spark or flame.

It is important that the escape and dispersion of dust into the atmosphere of a converting plant be kept to a minimum. Equally important is that provisions are made to reduce the possibility of ignition, relieve explosion pressure, and confine and control fire. Guidance in controlling dust explosion hazards in plastics plants is found in NFPA 654, *Standard for the Prevention of Fire and Dust Explosions from the Manufacturing, Processing, and Handling to Combustible Particulate Solids.* Other applicable standards are NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* and NFPA 69, *Standard on Explosion Prevention Systems.*

Flammable Solvents

Flammable organic solvents are found in nearly every plastics plant. They are used in very small quantities to apply adhesives, lacquers, or paints to molded or fabricated items or to clean tools or surfaces contaminated by resin; in large amounts to coat plastic on cloth, paper, leather, or metal; or on metal belts from which a dried film will be stripped. There might be increased hazard when solvents are applied to plastics, particularly when printing or coating on fast-moving films, because plastics usually have high electrical resistivity; they generate and retain static electric charges more readily than paper or cotton fabric.

Small plants are increasing their use of solvents for the preparation of both rigid and flexible foam plastic. The plastic is moistened with solvent and heated above the boiling point of the solvent in a closed mold or extruder. On release of pressure, the boiling solvent expands the resin and produces a bubbled structure. Another type of foaming process heats a resin containing

a chemical additive that evolves gas, usually nitrogen, carbon dioxide, or steam. Either the solvent or the chemical agent is called a blowing agent. The most common rigid foam is made from beads of polystyrene moistened with about 10 percent pentane or a similar hydrocarbon. The pentane does not soften and expand the resin at room temperature but does so at the low-pressure steam temperature used in molding to shape or in extruding as sheet. It is imperative that sources of electric spark or flame be avoided. Resin is usually shipped from the manufacturer with the hydrocarbon blowing agent already mixed with it. Containers will have free vapor of pentane and should be opened outdoors or with good exhaust ventilation. Expanded articles should be aged under forced hot air to remove nearly all the flammable blowing agent before shipping.

Flexible urethane foams for upholstery and garments or rigid foams for pour-in-place construction or refrigeration insulation are blown by steam and carbon dioxide generation, which are by-products of the formation of the urethane resin from basic ingredients. Urethane foams of lower density can be made with a low-boiling hydrocarbon in the resin mixture to increase the expansion.

Foams of polyvinyl chloride, used in garments and upholstery, are usually called "expanded vinyl," because the extent of foaming is limited to provide an essentially continuous outer surface. These are commonly made with the chemical blowing agent azodicarbonamide, also called azobisformamide. Above 300°F (149°C) it provides nitrogen gas at a controlled rate, is essentially nonhazardous in the proportions used, and does not give off flammable vapors. Drums of the reagent should be cooled with water when exposed to fire.

Improper handling of flammable liquids can cause serious fires in plastics plants. Failure to recognize the importance of preventing electrostatic spark, explosion-proof electrical equipment, and vapor removal systems has been the most frequent cause of flammable liquid fires. NFPA 30, *Flammable and Combustible Liquids Code,* NFPA 33, *Standard for Spray Application Using Flammable or Combustible Materials,* NFPA 35, *Standard for the Manufacture of Organic Coatings,* NFPA 70, *National Electrical Code®*, NFPA 77, *Recommended Practice on Static Electricity,* and NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids,* contain further information on safeguards to observe in the handling and use of flammable liquids as they might apply to the plastics industry.

Heating Elements

Molding and extrusion operations for both shaping and compounding have hazards associated with local overheating of electrical components. Operating temperatures normally range from 300 to 650°F (149 to 343°C), depending on the plastic being processed. The upper temperature range is beyond that practical for heat transfer fluids, so electric resistance heating is almost universally employed. Heater bands are required to melt or soften the resin in the feed section and at the upstream end of the extruder barrel. Heater bands along the barrel heat the material to higher temperatures to melt and make the material less viscous, so it can flow from the die. It is not uncommon for temperature controllers to stick, permitting resistance heaters to exceed the temperature set for the thermocouple controller. In most cases, the character of extrudate will markedly change—and, thus, warn the operator—well before heater bands get hot enough to be a source of ignition.

Some areas within equipment might not be regularly purged by flow of the plastic feedstock. Material remaining in such areas can be subject to excessively high temperature or be kept too long at a normally acceptable temperature. Decomposition can then take place, resulting in the release of gases that might be combustible. It is good practice to start heating such equipment first at the downstream end to ensure fluidity of material and, hence, relief of pressure. Never walk in front of an extruder when it is heating up to prevent burns from the material should it exit the die at high pressure.

Cleanliness in molding and extruding areas is vital to reduce the hazard of ignition from overheated bands where flammable vapors might be generated.

Electrical wiring in heat processing equipment on plastics machines should be installed in accordance with applicable provisions of *NEC®*.

Static Electricity

Many operations in plastics plants can generate static electricity through friction, heat, or pressure. Because plastics are such good electrical insulators, static electricity on them can rapidly build up to spark discharge—a hazardous condition if dust or flammable vapors are present. Operations that can generate static electricity include stripping of films from production or printing equipment, or rapid passage of films across rolls or guides. Belts for power transmission also are a significant source of static electricity discharge. Because of their low water absorption and high resistivity, plastics cannot have their electrostatic charge dissipated by high ambient humidity as practiced in cotton, wool, and paper mills.

There are three methods of neutralizing static electricity: induction, grounding, and ionization. The most common method of induction is the use of tinsel. Tinsel must be used properly if it is to work, and remember it can never reduce or neutralize static electricity to zero. Tinsel must have a conductive metal core, be properly grounded, be stretched tight, and be ¼ in. (6 mm) from the material to be neutralized.[8] Grounding is important for personnel who handle plastic. Without grounding, each time they touch a charged plastic part they increase the potential voltage on their bodies. Eventually, the potential becomes great enough to allow discharge to any convenient ground, causing a shock. The same is true of the equipment if it is not properly grounded. The third method is ionization, which generates positive and negative ions to neutralize the positive or negative ions that exist on the plastic's surface.

Care should also be given to separating vapor and dust hazards from machines where static electricity ignition sources could develop. NFPA 77 is a good source for the safeguards to use in protecting against static electricity hazards.

Hydraulic Pressure Systems

Hydraulic systems are used to clamp molds and to provide pressure to rams or screws that force molten plastic into molds by

compression, transfer, or injection molding. The molten plastic can be at pressures up to 30,000 psi (207 MPa), but the hydraulic systems are normally less than 2000 psi (13.8 MPa). Petroleum fluids have been used in plastics operations where heating elements are generally below 600°F (315°C). (The same fluids have a poor fire incident record in die casting of metal parts because the molten metal is generally at a much higher temperature than the ignition temperature of the fluid.)

Fire-resistant water-glycol or water-oil emulsions or "synthetic" fluids are available for hydraulic systems. Substituting fire-resistant fluids for petroleum fluids should follow the recommendations of the manufacturers of hydraulic system components.

Storage Arrangements

The fire hazards of plastics in storage, whether as feedstocks for the manufacturing, conversion process or as finished articles, are determined by their chemical composition, physical form, and storage arrangement. The physical form may be formed, foam, solid sheet, film, fiber, pellets, flakes, random-packed small objects, bags, or cartons. The storage of plastics generally should not exceed a maximum height of approximately 20 ft (6.1 m). The hazard of a particular plastic in any form of storage arrangement is the same whether it is encapsulated or nonencapsulated. If fire occurs, large quantities of smoke are usually generated, making manual fire fighting difficult and venting desirable in building construction consideration. In addition to smoke, many plastics give off gases that are volatile and toxic, including carbon monoxide, which is the leading cause of death in a fire.

Plastics, such as fluorocarbons, unplasticized polyvinyl chloride, and phenolics, can be protected the same way as any Class III commodity (wood, paper, and natural fiber cloth), regardless of their physical form or storage arrangement. Pellets and small objects can be protected the same as Class IV commodities.

Thermoplastics that present a fire hazard include polystyrene and acrylonitrile-butadiene-styrene (ABS), as well as polyurethane, polyethylene, polypropylene, plasticized polyvinyl chloride, and thermosets such as polyesters, although all of these to a lesser extent. These plastic materials will either continue to react or melt or break down (depolymerize or undergo decomposition) into their monomers or lower molecular weight compounds, acting and burning like flammable liquids. With some, after polymerization the unstabilized powder may be stored before it is later compounded. During this time in storage there may be some decomposition where heat is liberated by this reaction. If the heat is not lost to the environment, the bulk material increases in temperature, which leads to an increase in the rate of decomposition and increased heat until it reaches a self-accelerating decomposition temperature.[9] During storage of these powders, it is important that the temperature of the material containers be monitored to ensure that decomposition does not reach a point where it becomes a hazard.

When containers of these materials are subject to the heat of a fire, the decomposition or depolymerization becomes rapid, and the lower molecular weight oligomer fractions act like flammable liquids. With these materials, storage areas with high sprinkler discharge densities over relatively large areas are necessary to protect these types of plastics. In the form of foamed material, these plastics present the most severe fire hazard, because they can be ignited more easily and burn more rapidly.

One-story buildings without basements are preferable for storage of plastics materials because of greater efficiency for fire fighting, ventilation, and salvage operations. Plastics should be stored, handled, and piled according to their fire characteristics.

Housekeeping Practices

Housekeeping is basic to good fire safety. Good housekeeping practices reduce the danger of fire simply because they are time-proven methods of controlling the presence of unwanted fuels, obstructions, and sources of ignition. Approved containers should be provided and properly maintained for the disposal of refuse and rubbish. Spills of flammable liquids or combustible materials should be promptly cleaned up and properly disposed. Removal of combustible dust and lint accumulations from walls, ceilings, and exposed structural members is necessary. Smoking control, in addition to sensible regulations, also requires receptacles for spent smoking materials. Areas containing flammable liquids, vapors, or combustible plastics materials, as well as areas used for processing, manufacturing, or storage, must be clearly identified to prohibit smoking or the use of open-flame devices.

In some cases, trying to have a perfectly clean area can also result in a fire or injury to personnel. Personnel must understand that plastics are thermal insulators, which means it takes energy and time to heat a plastic and also requires a considerable amount of time to cool it down. Although the surface of the material might solidify and cool, the interior of the material remains very hot and might possibly still be molten. In both the extrusion and injection molding operation a quantity of material is always purged from the machine in order to get the equipment to the desired conditions necessary to make a good product. This large mass of purged material must be put in a safe area away from the personnel to prevent tripping hazards and the potential of serious burns. Purged material should never be placed in rubbish containers until it has completely cooled. Placing it in a container with other materials that have flash and self-ignition temperatures below that of the plastic could result in a fire.

SAFEGUARDS

Good fire protection starts with the fire-safe design of the plant or warehouse or inspection and modification of the existing facilities. Sprinkler-protected, noncombustible construction is appropriate for buildings occupied for storage, processing, and manufacturing of combustibles such as those involved in the plastics industry. Automatic sprinklers, standpipe and hose systems, and water-type portable extinguishers should be supplemented by fire extinguishers and special automatic systems suitable for flammable liquid fires and electrical fires, where these hazards exist.

Consideration should be given to the provision of roof vents, particularly in large one-story warehouses of manufacturing plants.

Besides design of the processing facility, the personnel working in the plant or warehouse must be trained to react in the proper manner should fire or explosion occur.

Building Construction

Long, narrow buildings provide greater ease in protection and fire fighting than large, square buildings. One-story buildings without basements are preferable to multistory buildings that could be subject to the spread of fire from lower to upper floors.

Large properties are best subdivided into separate fire areas to limit the spread of fire. Storage and manufacturing areas particularly need to be separated from each other by walls with sufficient fire rating to protect each area and occupancy from the other in case of fire. Preferably, fire walls should be without openings, but if openings are necessary, protection can be provided by self-closing or automatic fire doors suitable for openings in fire walls. Generally, a single fire area should not exceed 50,000 ft^2 (4645 m^2).

Fire Control Systems

An alarm system that alerts building occupants, notifies fire departments, and activates automatic suppression equipment is a necessary protection feature. Rapid extinguishment can be achieved by providing plastics processing equipment, conveyors, and manufacturing machinery subject to ignition or explosion with automatic fire-, smoke-, or explosion-detecting devices to initiate an alarm and to activate automatic suppressing systems (water spray, foam, dry chemical, carbon dioxide, or halogenated extinguishing agents).

Sprinklers are the most important single system for automatic control of fires in plastics plants. Among the advantages of automatic sprinklers is the fact that they operate directly over a fire and that smoke, toxic gases, and reduced visibility do not affect their operation. Automatic sprinklers, standpipes, and fire hose connections depend on an adequate water supply delivered with the necessary pressure to control fires.

Training of Personnel

Well-trained personnel minimize the possibility of a fire or explosion occurring and if a fire or explosion does occur their knowledge of what to do in that emergency situation can be lifesaving and possibly minimize the extent of damage.

In an emergency all persons at a plant should know their responsibilities. For some personnel, the main responsibility might be to evacuate the facility; for others, it might be to assist in containing a small fire until the fire department arrives or providing medical aid to those injured.

Before an emergency occurs, personnel should be thoroughly trained in the material safety data sheets (MSDSs) for each plastic, additive, and solvent that they use. The MSDS explains the potential hazards of each material should a fire occur.

Training should make each person aware of the location of fire alarm switches, fire extinguishers, and electrical panels containing switches for main power to the equipment. Something as simple as shutting off electrical power removes an energy source for the fire. Dumping water from an extruder cooling bath onto burning or smoldering plastic might be all that is needed to extinguish a potentially larger problem.

Properly trained personnel react—they do not panic. Proper training should be a top priority of all companies involved in the manufacture, conversion, or fabrication of plastics.

SUMMARY

Plastic is any one of a large and varied number of materials consisting wholly or in part of combinations of carbon with oxygen, hydrogen, nitrogen, and other organic and inorganic elements. Plastics fall into one of two groups: thermoplastics, which can be repeatedly softened and hardened without a major chemical change taking place, and thermosets, which undergo a chemical reaction when heat treated and cannot be softened again. The four broad areas of processing include (1) polymerization; (2) manufacturing; (3) conversion of the plastics materials into useful articles by molding, extrusion, foaming, or casting; and (4) fabricating, which encompasses the mechanical operations of bending, machining, cementing, decorating, and polishing.

Besides the hazards common to most industrial operations, hazards specific to the plastics industry include combustible dusts, flammable and combustible liquids, high-heat elements, static electricity, hydraulic and heat transfer fluids, and failure to observe good storage and housekeeping practices. Good fire protection for plastics facilities include fire-safe building design; automatic sprinkler systems, standpipes, and fire hose connections; an alarm system that alerts building occupants, notifies fire departments, and activates automatic suppression equipment; and well-trained personnel who know what their responsibilities are in an emergency.

The Metalworking Process
Alternative Means of Machining
Fire Hazards
Safeguards

Key Terms

cutting fluid, cutting tool, electric discharge machine (EDM), electrochemical machining (ECM), lubricating oil, machine tool, metal dust, metal powder, metalworking

This chapter describes the various methods used to shape, dimension, and finish metals. These include tool, electrical discharge, and electromechanical machining. The fire and explosion hazards of the various processes, metals, and fluids are indicated and the proper safeguards discussed.

For related topics, see Section 6, Chapter 8, "Dusts"; Section 6, Chapter 9, "Metals"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 8, Chapter 1, "Air-Moving Equipment"; and Section 8, Chapter 11, "Fluid Power Systems." For more information, the Bureau of Mines publishes a bulletin on the explosibility of metal dusts.[1]

THE METALWORKING PROCESS

The metalworking process includes shaping, dimensioning, or surface finishing of a wide variety of metals. The operations include turning, planing, shaping, slotting, milling, sawing, boring, drilling, grinding, abrasive cutting, filing, threading, reaming, broaching, deburring, lapping, chamfering, spinning, and so on. Some of these same operations and equipment are also used to work on other-than-metal materials, such as plastics or wood. These other materials likely would increase the hazard of the operation; however, the extent of that increase, or the additional protection that might be necessary, is not covered in this chapter.

On cursory observation of a machining operation, it would appear there are few, if any, fire hazards about which to be concerned. This is deceptive, for there are aspects of machining that require careful and constant attention. The fire record is full of experiences that point to the need for considerable pre-incident planning and preventive action. The principal hazards involve the coolants/lubricants used for the lubrication of the cutting tools and the possible combustion of the cuttings (chips) and fine particles (fines) that are produced as the workpiece is shaped and cut. The three principal sources of ignition directly associated with the operation are (1) the heat generated by the work being done, (2) the friction created by the cutting tool, and (3) the spontaneous oxidation of materials used. Other possible sources of ignition include smoking materials; hot surfaces such as furnaces and torches; electric sparks or arcing; and impact ignition of certain pyrophoric surface compounds that sometimes form during the earlier stages of fabrication. It is important to remember that nearly all metals will burn in air under certain conditions, depending on size, shape, and quantity.

The machining operation can be broken down into five components for the purpose of analyzing the hazards present: (1) machine tool; (2) cutting tool; (3) raw materials; (4) oils, including cutting oils, lubricating oils, and hydraulic oils; and (5) machine cuttings and their collection systems.

The Machine Tool

The modern industrial machine tool can be a single-motor machine, such as a drill press, or it can be a very large multimotored automatic machine with a highly complex electronic-control system. Stock can be brought as needed to an individual machine where a worker then mounts it to the machine and initiates the operation manually. More likely there is some degree of automation in these

Paul G. Dobbs is an account engineer for Global Risk Consultants Corporation, based in Plymouth, Michigan.

operations, and, in many cases, several machines can be located in close proximity to facilitate the easy movement of stock from one machining operation to the next. Almost all machines are electric-motor operated and likely contain some lubricating oils and grease. Electrical supply to this equipment is generally 480 V or less; however, some larger equipment will operate at higher voltages.

In almost all cases, the lubricating oil for the machine is self-contained (i.e., in the unit). Although the amount might be significant (50 to 100 gal [189 to 378 L]), it is generally not a significant hazard. The containment structures for these oils are usually substantial, and leaks are rare.

The electric motors and the lubricating oils systems on the machines usually do not alone constitute a hazard sufficient to warrant any automatic protection. However, portable Class BC extinguishers should be available in the area.

Traditionally, the machine tool is a stand-alone piece of equipment, usually operated manually by a trained operator, who sets up the stock, then controls the cutting operation. In the modern industrial setting, this arrangement has gradually given way to numerically and digitally controlled equipment, leading to more sophisticated electronic equipment in the vicinity of these operations. Today most machine tools rely on numeric control (NC), computer numerically controlled (CNC), programmable logic controller (PLC), or other microprocessors to function. Usually, this equipment does not itself present a significant fire hazard, but it does present an additional loss potential from fire exposure. Malfunction or failure of the automatic control equipment can also create hazardous situations in the operation of the machine tool, leading to fires. A significant number of fires in these occupancies have "automatic failure" cited as their cause, so reliability of this control equipment is also important. In addition, modern electronic equipment due to its value and fragile construction is more susceptible to damage from exposure fires. This potential for increased loss due to exposure fires should be included in the evaluation of automatic protection in occupancies that include such equipment.

Cutting Tool

The cutting tool can be either fixed in place while the stock is moved past it, such as on a lathe, or the tool itself can be moving, such as in a mill, surface grinder, or boring machine. The tools can be pointed or bladed and can be of hardened high-carbon steel, high-speed steel, hard ceramics, or steel tipped with hard metal carbides of tungsten, cobalt, tantalum, or other hard metallic elements. Grinding abrasives are usually alundum or silicon carbide grains bonded with resin or ceramics and pressed into the shape of wheels. These cutting tools shape the raw materials into the finished part. They can also represent a point of ignition, as they can develop significant heat from the friction of the work they are performing. Dull tools not only increase the requirement for power and influence the quality and tolerance of the work being done, but also can be the ignition source of fires in machines. Dull tools tend to produce finer particles that are more readily combustible or explosive than the larger chips generally produced by sharp tools. Cutting tools normally do not require any special protection. Of course, if they are transported on wood pallets or in cardboard cartons or other combustible containers, those materials might necessitate the provision of sprinkler protection where they are being stored.

Raw Materials

The raw materials arriving at a machining plant can be in the form of clean castings, forgings, rough-cut plate, rolled or drawn bar or merchant mill stock, fabrications, tubes, or rolled or extruded shapes. In general, these raw materials have significant mass and so can be considered as noncombustible unless exposed to massive fire. This applies even to the light metals that are known to be more readily combustible when they have a large surface-to-mass ratio. In most cases, though, the raw materials do not present any significant combustible loading. However, the packaging materials used in the transport of these materials must be considered, and, if sufficient combustibles are present, automatic sprinkler protection should be provided as necessary.

Other raw materials include cutting, lubricating, and hydraulic oils; cutting tools; and so on. Bulk shipments and storage of combustible oils should be handled in accordance with accepted standards. Further discussion of these hazards can be found in Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids."

Hazard potentials can change significantly once the raw materials are subjected to the metalworking processes. The type of operation the stock is subject to determines the size of pieces of that material that will be removed in the form of chips or fines. Chips and fines significantly increase the surface-to-mass ratio of the material, and, in some cases, they can become subject to spontaneous ignition or to ignition from outside sources. Table 9.5.1 shows the combustibility of fine powders of various metals and the amount of energy needed to initiate combustion. Almost all metals have some degree of combustibility, and, in the case of such materials as aluminum, magnesium, and titanium, they can represent a very significant hazard. As mentioned, some chips in cuttings are subject to spontaneous ignition. Zirconium and uranium powders can ignite spontaneously. Spontaneous ignition in such apparently noncombustible materials as iron and steel borings and turnings has been recorded in scrapyards and in the holds of ships carrying scrap. In these cases, fires have occurred where the heat of oxidation cannot be dissipated sufficiently to the surrounding atmosphere to prevent the development of ignition temperatures in these materials. In most normal situations, though, this should not be a problem.

Some metals, for example, magnesium and titanium, resist the normal extinguishing methods, such as automatic sprinklers, fire hoses, or regular portable extinguishers. When these materials are being used, special dry-powder extinguishers rated for Class D fires should be available nearby for use, if needed.

Cutting Fluids

Cutting fluids are often used in metalworking operations. Fluids can include various oils, soluble oils, semisynthetic fluids, and synthetic fluids. On the machines, lubricating oils and/or greases are often used to facilitate the operation of the equipment. Coolant/lubricants are often used to cool and lubricate the tool and stock at the point of operation, facilitating smoothness of the cut, life of the tool, and removal of chips and cutting fines. These

oils vary from alkaline aqueous solutions to light petroleum distillates and compounded oils. They are usually liberally applied to the point of operation for the mentioned purposes. Typical application methods include flood application, jet application, and mist application. After the fluid has performed its function at the work point, it is collected, separated from the chips, filtered, and reused. The cleaning and filtering equipment can be either self-contained to the machine itself or part of the larger central system that interconnects many machines. Essentially all of the oil-based and compounded cutting fluids are combustible to some degree. Of course, as with other combustible liquids, these oils must be heated above their flashpoint to be ignited.

Compounded oils that are acidic or contain organic additives that can oxidize and then become acidic with use should not be used for the machining of magnesium and certain other metals, because the acid can react with the metal to release hydrogen. In these cases, only uncompleted mineral oils should be used. Water-oil emulsions are also used as cutting fluids, especially where only light machining operations are taking place. In the emulsion state these oils are nearly noncombustible. Before being mixed with water or if they come out of emulsion, as might happen if the water evaporates from the emulsion, the hazard becomes that of the oil itself. Nevertheless, water-oil emulsions or other noncombustible oils should be used wherever possible to reduce hazards. Where regular cutting oils are used, the quantity and extent of use should be evaluated and automatic sprinkler protection considered.

In some cases where additional cooling is required, mineral oil, kerosene, or other materials having lower flashpoints are sometimes used. If these fluids are utilized within close proximity of their flashpoint (50°F [10°C]), special extinguishing systems, such as local applications of CO_2 or other gaseous extinguishents or dry chemical systems, should be considered.

With all the application methods, but especially the jet and mist application of cutting oils, an increased hazard is presented by the atomized material created by the application method and the machining operation itself. This can make ignition easier than under ordinary conditions. Additionally this atomized oil can drift from the equipment and condense on other machines, floors, and building structural members. Housekeeping in the surrounding areas is important in these instances, as severe fires can develop and spread over wide areas utilizing these oils. This is most significant where oil deposits have accumulated on vertical surfaces, such as the sides of equipment and building columns. Where such accumulations occur, periodic cleaning of these areas is important. Adequate enclosures and exhaust ventilation to remove this oil spray and mist should be provided.

Where central oil collection and cleaning systems are provided, the dirty oil is often collected in floor trenches that can interconnect numerous machines. If these systems are used, they should be tightly covered, or, preferably, fixed piping systems should be utilized. Where floor trenches are utilized, they create an avenue for spreading fire from one piece of equipment to the next; therefore, some form of automatic protection, such as sprinklers or carbon dioxide systems, should be considered. The central cleaning system will generally have quantities of oil present sufficient to warrant at least automatic sprinkler protection in the area. Provisions for overflow of the oil tanks in these areas caused by water from sprinklers or fire hose should be provided, channeling to a safe area.

As one of the purposes of the cutting fluid is to remove heat from the work area, the temperature of the return oil to the workstation should be checked regularly to ensure that it does not approach its flashpoint. Where oil from a central system is pumped back to individual workstations, provisions should be made for manual or, preferably, automatic shutoff of the oil supply. Automatic shutoff can be actuated by sprinkler waterflow detection, or other automatic fire detection systems.

Automatic ceiling sprinkler protection should be provided where combustible cutting oils are used on a general basis. This protection should be installed on an ordinary-hazard basis, with adequate water supplies provided.

Many machine tools employ hydraulic devices for various control actuators. Oil pressures used can vary from four hundred to several thousand psi (400 psi equals approximately 42 kPa). The reservoirs and pumps for the hydraulic oil can be either self-contained, that is, contained within the machine itself, or part of a larger central system.

Nearly all hydraulic oils are combustible to some extent, even though there are some less hazardous hydraulic fluids that significantly reduce the fire hazard. These less hazardous fluids will burn when released at high pressure and then brought into contact with a source of ignition. However, they do not sustain combustion when that ignition source is eliminated.

The fire resulting from a high-pressure hydraulic oil leak is usually a very intense torchlike flame that characteristically has a very high rate of heat release. Causes of hydraulic oil release can be deteriorated flexible hoses; failure of pipe joints, especially if threaded connections are utilized; or failure of valve packing or gaskets.

One of the easiest ways to dramatically reduce the intensity of a hydraulic oil leak fire is simply to shut off the oil supply. However, experience has shown that if there is a failure in a pressurized oil system, especially one that results in an intense fire, personnel in the area are likely to run for safety without shutting down the pump. For this reason, remotely located emergency shutoff switches should be provided, or, as a more positive step, automatic shutoff should be provided. Automatic shutdown can be provided by low-level switches in the main oil reservoir; an excess flow switch; a flame-actuated detector; a fixed-temperature release, such as a fusible link or thermostat provided in the vicinity of the equipment; or through interconnection to a sprinkler waterflow switch. In most cases where significant hydraulic oil systems are utilized, automatic sprinkler protection should be provided. If the building is not sprinklered completely, the system should extend for at least 20 ft (6 m) beyond all areas of hydraulic usage. Suitable Class BC portable extinguishers are also necessary throughout these areas.

Welded connections should be used wherever possible to eliminate the possibility of leaks from threaded joints. Tubing should be used in preference to pipe. Piping or tubing should be securely fastened in place, and flexible hoses should be kept clear of all objects and not allowed to bend in excessively tight turns. Routine maintenance checks of all hydraulic system components should be made and necessary repairs or corrective action taken on a timely basis. Leaks should not be allowed to continue, and good housekeeping should be maintained around all equipment.

Most petroleum-based hydraulic oils have a flashpoint between 350 and 600°F (177 and 315°C). Less hazardous hydraulic fluids also have flashpoints in a similar range; however, they do not sustain combustion when the ignition source is removed. These fluids are generally of the oil-water emulsion type, water and glycol type, or purely synthetic fluids. Each type has characteristics that cover nearly the entire range of operating temperatures and gasket and seal materials used in conjunction with petroleum-based oils. (See Section 8, Chapter 11, "Fluid Power Systems," for further information on the hazards and safeguards associated with hydraulic pressure systems.) It is important to ensure that the fluid being used is compatible with the seals, gaskets, and packing in the system. If a less hazardous fluid is being retrofilled to an existing system, this compatibility factor becomes especially important.

Machine Cuttings

All machining operations result in the creation of chips, which will vary widely in character, size, and configuration, depending on the operation being performed, the feed and speed of cutting, and the intrinsic characteristics of the metal being cut. Frequently, cuttings and chips appear to be quite large and heavy, and, for this reason, it is often an erroneous assumption that they do not constitute a fire hazard or an explosion hazard. However, a significant amount of fines can be obscured by the more obvious heavy chips.

Combustibility depends on the combustible character of the metal and on the ratio of the exposed surface of the cutting or chip to its mass. The thinner the cutting and the smaller the particles, the greater the likelihood of fire. Table 9.5.1 indicates that relatively small amounts of energy are needed to initiate combustion in some fine metal powders.

The accumulation of chips, cuttings, or fine particles should never be permitted at the machine. They should be removed and placed in a noncombustible container and suitably stored. In small, single-machine operations, the removal of chips is often done manually. In the larger integrated and automated operations, central collection systems are often used.

Where heavy chips and cuttings are generated, they are often mechanically separated from the cutting fluids and stored in some suitable container until disposed. Heavy chips represent the hazard attributable to the particular metal involved. In addition, there is the likelihood that cutting oil residue remains on these chips and that hazard must also be considered in determining protection for the storage and handling of these materials.

Where high-speed operations, harder metals, or grinding and more precise finishing operations are used, much smaller chips and finer particles of the metal are often generated. The removal and collection of these particles is often accomplished with a pneumatic transport system. These systems usually consist of hoods over the work area, connected by ductwork to a central material/air separator. These separators can be in the form of cyclone collectors, bag collectors, wet collectors, and electrostatic precipitators.

Because of the flow of a significant amount of fine particles in the system, it should be designed with explosion hazards in mind, especially when dealing with the more combustible metals. The system should be designed so that at no time will the fine dust concentration approach the minimal explosible concentration (MEC) of the dust. Ductwork should be designed and constructed so that it can contain the pressure buildup from an explosion without failing. Bag-type collectors are usually not utilized for collection of fine metal dust, because they inherently provide the optimum condition for rapid and complete combustion. Any combustible filter medium would tend to catch the particles of combustible or explosive metals and hold them in an envelope of oxygen; therefore, all that would be necessary to initiate a fire or explosion would be a very small amount of energy, such as an electrostatic discharge.

Wet collectors for fine metal dusts should be used only after careful consideration. Many light-metal dusts react with

water to produce highly explosive hydrogen gas. Wetted sludge of these metals is also highly explosive, unless it is kept submerged in the water. Figure 9.5.1 is a schematic diagram of a water-precipitation-type collector. It is intended to show only some of the features that should be incorporated in the collector design. The collector may be used for all combustible metal dusts. Further discussions of this aspect of metalworking operations can be found in Section 6, Chapter 8, "Dusts," and Section 8, Chapter 1, "Air-Moving Equipment."

ALTERNATIVE MEANS OF MACHINING

There are other processes used for the shaping and finishing of metals that require no cutting edge as such.

Electric Discharge Machining

The most important and widely used of the alternative processes is the electric discharge machine (EDM). Electric discharge machining is a process for metal removal by electric arc discharge. In this machine, an electrode is placed in close proximity of the workpiece and is bathed in a continuous flow of dielectric fluid. A direct current of up to 400 A at 400 V is pulsed from the control unit, and a current flows from the electrode through the dielectric fluid to the workpiece. Each pulse partially ionizes the dielectric fluid and causes a submerged spark that melts into and dislodges a small metal particle. Thus, the required shape is created by this eroding process. A continuous flow of the dielectric fluid is maintained to remove the metal particles. The fluid is filtered before being recirculated to the work area. The filtration system can either be proprietary to an individual machine or a part of a larger central system. The principal hazard associated with this operation is the dielectric fluid, which almost always is combustible. Flashpoints can be as low as 200°F (93°C). Under normal work conditions, there is a sufficient level of oil above the electrode to quench the spark and prevent the ignition of the oil. However, if the oil level is allowed to become too low, the electrode arc can become a ready source of ignition.

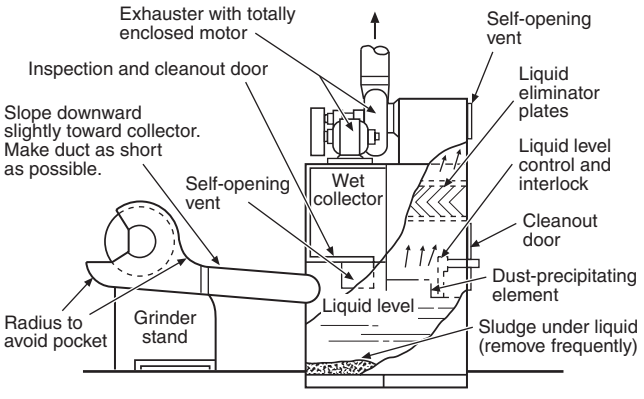

FIGURE 9.5.1 Water-Precipitation-Type Collector for Use in Collecting Dry Combustible Metal Dust Without Creating Explosive Dust Clouds or Dangerous Deposits in Ducts or Collection Chambers

Several large losses have occurred in recent years that have been associated with EDM operations. These losses highlight the importance of maintaining proper fluid levels in the machine and the need for proper precautions when central oil filtration systems are utilized. Because fires within the individual machine work areas are generally confined to a particular piece of equipment, it is important to keep some separation between these machines. At least 5 ft (1.5 m) is considered the minimum clearance to prevent fire spread from one machine to the next. Due to the quantities and combustible nature of the dielectric fluid, automatic sprinkler protection on an ordinary-hazard basis should be provided throughout areas of this occupancy. Suitable Class BC portable extinguishers are also necessary and should be provided within close proximity of these machines.

In order to prevent operation of the machine when there is insufficient fluid to cover the electrode, a low-level interlock should be provided within the work tank. If gravity flow of fluid to the work tank is provided, then automatic-closing fusible-link-operated shutoff valves should be provided to close off the flow of oil in the event of fire.

Significantly greater hazard is created in EDM operations where there is a central oil filtration system. Where these systems are used, at least a 1-hour fire-rated cutoff should be provided to separate these operations from the remaining occupancy. A manual emergency shutoff switch controlling the central oil system should also be provided and located in an area that would be easily accessible during a fire at either the central oil system or the EDM work station. Oil flow between the filtration system and EDM should only be within rigid or flexible metal piping. No plastic or rubber hoses should be utilized, unless specifically listed for such application.

Electrochemical (Electrolytic) Machining

Electrochemical or electrolytic machining (ECM) is a process in limited specialized use. It operates by anodic dissolution in an electric cell in which the workpiece is the anode and the tool is the cathode. The electrolyte (usually $NaNO_3$ aqueous solution) flows at a high rate through the gap (usually between 0.10 and 0.60 mm) between the cathode and the workpiece. A direct current of 50 to 2000 A at 4 to 30 V is imposed. At 1000 A, the rate of metal removal is approximately 1 $in.^3$ per min (16,387 mm^3/min). Current densities of 20 to 200 A/cm^2 are employed. The workpiece is dissolved (according to Faraday's Law) producing in the workpiece a negative mirror image of the cathode tool. This process is sometimes used in finishing dies and molds and in finishing turbine blades and vanes.

FIRE HAZARDS

The principal hazards encountered in a machining operation include the following:

- Chip fires at the machine, where ignition is caused by the heat of metalworking, friction of the chip against the tool, or both
- Spontaneous combustion of cuttings
- Combustion of coolant/lubricants
- Fine particles that are either combustible or explosible

- Reaction of certain metals with water or other agents
- Combustion of pressurized hydraulic fluids used for the actuation of machine tools and/or their accessories
- Combustion of oil vapors deposited on building structures
- Combustion of oil-saturated floors
- Combustion of dielectric fluid in EDM equipment

The principal sources of ignition are the following:

- Smoking materials
- Heat of cutting
- Spontaneous oxidation
- Hot particles from grinding, dressing of grinding wheels, and welding and cutting
- Hot surfaces, such as furnaces and torches
- Electrical sparking or arcing
- Impact ignition of certain pyrophoric surface compounds, which sometimes form during the earlier stages of fabrication (e.g., magnesium nitride, which sometimes appears on the surface of castings and can explode under the impulse of a very minor impact)

SAFEGUARDS

Building Construction

Buildings that house metalworking processes should be of fire-resistive or noncombustible construction with a noncombustible roof deck. If the building is large, it should be subdivided by fire walls to limit the spread of fire.

Buildings in which machining operations are performed should be regularly inspected for the accumulation of oily deposits and/or fine combustible metal particles. Cleaning should be undertaken before hazardous accumulations develop. All electrical control equipment, particularly those for numerical control or computer-directed control of machines, should be housed in vapor-tight enclosures. The equipment itself should be inspected at regular intervals and cleaned when necessary. If possible, control equipment should be located in a separate room, cut off by at least 1-hour-rated walls.

Fire Protection

The need for sprinkler protection should be carefully considered. It will depend largely on the combustible characteristics of the building structure, especially the floors and roof deck, and the extent of the hazard posed by the metalworking machine or raw material as previously discussed. Small fires at machines can be best controlled with portable extinguishers of the correct classification. If proper housekeeping is practiced, the fire hazard from cuttings and turnings can be minimized.

Combustible Metals

The more combustible metals should never be machined unless a suitable fire extinguisher is immediately available to the machine operator. It is important to remember that extinguishers for Class A, B, and C fires are generally ineffective for burning metal or metal dust. Only extinguishers rated for Class D fires should be used on burning metal. When they are used, extreme care must be exercised to ensure that the emergent force of the extinguishing agent or the action of its application to the fire is not sufficient to create an explosive metal dust cloud.

For their own safety, it is most important that all workers thoroughly understand the hazards involved and be properly instructed so that they fully understand the possible consequences of unconsidered or improper action under stress. In many instances, it is highly desirable that local fire fighters, who would normally respond to an alarm, be similarly instructed.

SUMMARY

Metalworking processes do not generally represent a high-hazard occupancy. However, this occupancy can be deceptive as hazards do exist involving the coolants and lubricants used on the tools and in the machines, with some of the metals themselves, and with the support systems for the machining and forming operations. Hazards can also exist for the storage of supplies, such as the cutting and lubricating oils, as well as from the packaging materials used in conjunction with the raw materials and finished products.

Oxyfuel Gas Processes
Thermal Spraying (THSP)
Safeguards
Special Situations and Additional Precautions

Key Terms

cutting equipment, demolition, fire prevention, fuel gas, hot work, oxyfuel, permit-authorizing individual (PAI), thermal spraying, welding and cutting

Hot work is defined by the NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work,* as "Work involving burning, welding, or a similar operation that is capable of initiating fires or explosions." This work can involve temporary or permanent operations that produce flames, sparks, or heat. Some examples of hot work are as follows:

- Cutting
- Welding
- Grinding
- Using powder-driven fasteners
- Thawing pipes
- Hot riveting and allied processes
- Roofings applied by torch and regulated by the requirements of NFPA 241, *Standard for Safeguarding Construction, Alteration, and Demolition Operations*
- Similar applications producing or using spark, flame, or heat

In most cases, damaging hot work fires occur when companies, employees, or contractors fail to follow proper hot work safety guidelines. It is not that individuals performing the hot work are irresponsible. They simply can and do make mistakes, or they are not aware of the hazards and the steps that are necessary to mitigate or prevent a hot work fire.

Torch fires accounted for 1 percent of reported 1999–2002 structure fires in the United States, including 1 percent of home structure fires and 3 percent of nonhome structure fires. Torches were involved in 7 percent of the reported structure fires in industrial and manufacturing properties. Of the torch fires coded by type of torch from 1999–2002, 71 percent of the nonhome structure fires but only 43 percent of the residential structure fires were due to cutting or welding torches. Torches were involved in an average of 74,000 reported structure fires per year. However, education, training, and on-the-job training can significantly reduce the potential for welding, cutting, and other hot work fire.[1]

For related topics, see Section 6, Chapter 10, "Gases"; Section 7, Chapter 3, "Storage of Gases"; and Section 9, Chapter 5, "Metalworking Processes."

PREVENTION GUIDELINES AND SAFETY PRECAUTIONS

Hot work fires are preventable. Established hot work fire prevention guidelines are designed to help people stop and think about the fire hazard potentials that can exist in an area before placing themselves and the facility where they are working in harm's way. These guidelines are as simple as taking the following precautions:

- Implementing hot work permit systems (a precautions checklist highlighting important steps to take during hot work operations)

August F. Manz is president of A. F. Manz Associates, welding technology and safety consultants, Union, New Jersey, and a member of NFPA's 51B Technical Committee on Hot Work Operations.

Mark E. Blank is chief engineering technical specialist at FM Global Chicago Operations, Park Ridge, Illinois, and a member of the NFPA 51B Committee.

- Using alternative methods to hot work
- Relocating the hot work activity to safe/designated areas

In some cases, conditions within a facility are just so inherently dangerous that hot work cannot be conducted safely and should be avoided.

To achieve effective hot work management, proper planning, training of personnel involved, and adequate supervision are necessary components to reduce the risks of hot work. For instance, discussing hot work projects prior to performing any job is a crucial first step. Facility owners and contractors should work together to ensure there is a clear understanding of the fire hazards that exist within the area where hot work will be conducted. Hot work operations should always be supervised by trained personnel to ensure unsafe conditions do not develop. The fire watch should be trained in use of fire protection equipment and facility emergency communication procedures should the need arise.

Due to readily available ignition sources that hot work operations openly create, it is imperative to adhere to every safety precaution, including the following:

- Properly isolating a welding operation with listed/approved welding curtains
- Following hot work guidelines in NFPA 241 for torch-applied roofing systems
- Wearing proper fire-resistive clothing to prevent personal injury

Every hot work safety precaution is important and should be followed. Sometimes hazards within a facility are apparent, like exposed storage or well-labeled flammable liquid operations. But many times, hazards within a facility are not obvious, even to seasoned hot work professionals. Combustible concealed spaces in walls or floors; combustible insulation within walls; heating, ventilation, and air conditioning air-intake vents in floors/walls/ceilings; and open/abandoned piping or conduit extending through walls or between building floors all represent potential hidden fire hazards to hot work operations. Sparks and molten slag can fly or roll long distances, igniting hidden unprotected combustible materials like wall insulation, dust or lint accumulations above suspended ceilings, or flammable vapor accumulations in an adjacent area. Sparks from hot work also can settle into wall or floor openings that are not easily seen, or sparks can be drawn into ventilation ductwork where combustible materials can be ignited and smolder undetected for hours before finally breaking out into fire. The key is not taking any facility hazard for granted and not taking shortcuts in established hot work fire prevention guidelines.

With hot work, four factors must be kept in mind:

1. The two sides of the fire triangle that are always present, that is, a source(s) of ignition and air to support combustion. The other controllable element is the combustible material.

2. The shop's familiarity with hot work as an activity. A shop that performs welding or cutting operations on a routine basis in a fixed location can develop confidence and reinforce safe habits more easily than a shop that performs welding or cutting only occasionally and in a variety of different temporary locations. On the other hand, facilities that conduct hot work on a regular basis need to be careful about becoming complacent of the hot work hazards that are present within their plant.

3. The kind of process and equipment used and their potential fire effect. Cutting, as well as certain arc welding operations, produces literally thousands of ignition sources in the form of sparks and hot slag.

4. The supervision and training of the operator. Is the operator trained in the proper use of the equipment and mindful of the exposure? Who has knowledge of and has assessed the risks involved in bringing a torch into the work area and has authorized its use there? Is there a designated fire watch to support the operator in maintaining the hot work area in a fire-safe condition?

CONTRACT OPERATIONS

The trend toward outsourcing facility maintenance and renovations can influence the risks associated with hot work. A contractor must have the technical expertise to perform hot work, have a full understanding of fire prevention and the specific combustible hazards within a client property. Before starting any hot work job, contractors and their clients should discuss the planned project completely, including the following topics:

- The type of hot work that will need to be conducted
- Procedures for isolating the hot work to prevent fire hazards
- Identification of personnel to be assigned as the fire watch for the hot work operations
- Facility emergency notification procedures
- Available manual fire fighting tools (like portable fire extinguishers and small hose stations)
- Identification of all areas where hot work is not allowed
- Review of any requirements for completion of hot work by a certain time each day

However, it is recognized that premises management might not always have expertise in hot work and therefore would need a knowledgeable designated agent or contractor to act on its behalf. Examples of those who might not have the expertise can include owners of small retail shops, a small apartment complex manager, or a grocery store owner who has no knowledge of hot work safe practices. Management should ensure that the contractor has evidence of financial responsibility, which can take the form of an insurance certificate or other document attesting to coverage or responsibility.

PROCESSES USING ELECTRICITY*

Arc Welding (AW)

Arc welding (AW) applies to a number of processes that use an electric arc as the heat source for melting and joining metals. The arc is a useful tool because its heat can be concentrated

*The descriptions in the sections "Processes Using Electricity" and "Oxyfuel Gas Processes" are adapted from publications of the American Welding Society.

and controlled quite effectively. Frequently, but not always, a filler metal must be used to obtain a good joint. The arc is struck between the metals to be welded and an electrode, which is maneuvered along the joint or remains stationary while the work is moved beneath it. The electrode may be consumable or nonconsumable. If the latter, a separate rod or wire may be used as the filler metal. Consumable electrodes supply their own filler metal by melting. The molten metal and weld zone can be protected from atmospheric contamination by use of a supplementary shielding gas or a shielding atmosphere produced by decomposition of a flux, which is used with certain types of electrodes and wires.

Shielded Metal Arc Welding (SMAW). This simple well-known process is widely used with ferrous-based metals (Figure 9.6.1). It produces coalescence of metals by heating them with an arc between a flux covered metal electrode and the weld pool. The process is used with shielding gases from the decomposition of the electrode covering, without the application of pressure, and with filler metal from the electrode. The process requires an alternating or direct current power supply, power cables, and an electrode holder. Shielded metal arc welding can be performed readily in remote, unusual, or confined locations. Consequently, this process is widely used in such industrial applications as construction, shipbuilding, and pipeline erection. Fairly simple portable units are frequently used in maintenance and field construction work. It is also commonly known as "stick welding," "covered electrode welding," and sometimes simply as "arc welding."

Gas Metal Arc Welding (GMAW). The GMAW process uses a continuous filler metal electrode, which functions as one terminal of the arc, and a gas to shield the arc and the weld metal. The shielding gas depends on the base metal and process variations. It can be an inert gas, such as argon or helium; an active gas, such as carbon dioxide; or mixtures involving these gases with additions of hydrogen, nitrogen, or oxygen. Overall, this process can be used to join just about any metal in any configuration of joint. Gas metal arc welding is commonly referred to as MIG welding, an acronym for metal inert gas welding, even though active gases are also employed. Process variations include short circuiting metal transfer (GMAW-S) and pulse transfer (GMAW-P).

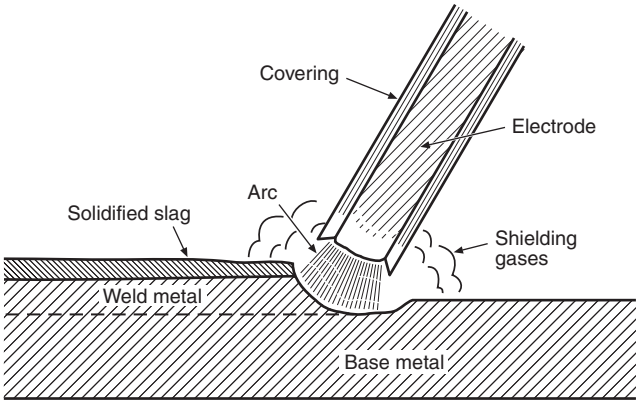

FIGURE 9.6.1 Typical Shielded Metal Arc Welding Operation

Flux Cored Arc Welding (FCAW). Although the FCAW process is similar to gas metal arc welding in equipment used and types of applications, tubular rather than solid electrodes are used. Minerals and alloys in the tube core assist in weld protection, and many such electrodes are intended for use with shielding gases. Other kinds of cored electrodes are self-shielding and produce their own protective envelope without an auxiliary shielding gas.

Gas Tungsten Arc Welding (GTAW). The GTAW process is similar to gas metal arc welding and flux cored arc welding, but it uses a nonconsumable tungsten electrode for one pole of an inert gas-shielded arc. Filler metal may be used. The most common inert shielding gases are argon and helium. Equipment required comprises a power supply, welding torch, source of inert gas, suitable pressure regulators and flowmeters, and connecting hoses. Gas tungsten arc welding is commonly referred to as TIG welding, an acronym for tungsten inert gas welding. It also is called "heliarc" welding and "argon arc" welding. In Europe it can be called WIG welding, where the "W" stands for *Wolfram,* which is the German word for "tungsten."

Plasma Arc Welding (PAW). PAW is characterized by the plasma state, wherein the temperature of a gas is raised until the gas becomes at least partly ionized, enabling it to conduct an electric current. It uses a constricted arc between a nonconsumable electrode and the weld pool (transferred arc) or between the electrode and the constricting nozzle (nontransferred arc). A plasma arc torch incorporates an electrode and an orifice through which a flow of gas forms the arc plasma. Secondary gas, which flows through an outer nozzle cup arrangement that encircles the arc plasma orifice, shields the arc and the weld. Typical shielding gases are argon, helium, and mixtures of argon with hydrogen or helium. Filler metal may or may not be used. Equipment required is not unlike that for gas tungsten arc welding, with necessary differences in power supply and control, torch design, and gas supply and control.

Submerged Arc Welding (SAW). In the SAW process the arc and molten metal are shielded by molten flux and a layer of unmelted flux granules. A continuously fed electrode is submerged in the flux. The arc is submerged below the flux. The process is used without pressure. Radiation and fumes are minimal and fire hazard potential is likewise relatively minor compared to other processes.

Resistance Welding (RW)

Welding heat for resistance welding (RW) is created by resistance to flow of current through the parts being joined. Resistance welding is generally used to join two metal pieces that might have different thicknesses and composition. Electrodes conduct current through the pieces, which are clamped or rigidly held together to provide good contact and pressure at the joint.

Flash Welding (FW)

Although defined by the American Welding Society (AWS) as resistance welding, flash welding (FW) is considered a process unto itself. Heat is created by a flashing action at the interface. Pressure is applied after heating, resulting in the expulsion of metal, formation of a flash, and usually a significant shower of sparks. Applications usually involve butt welding rods or bars end to end or edge to edge. The process is almost always automatic. Flash welding machines vary significantly in size, some being large enough to weld sheets in a steel mill.

Electroslag Welding (ESW)

Electroslag welding (ESW) is a process used primarily for vertical position welding. This process uses a slag, which is electrically conductive while molten, to protect the weld and melt base-metal edges and filler metal. An arc is needed to start the process by melting the slag and preheating the work because the unfused, solid slag is nonconductive. Once the process is started, the arc is no longer necessary, and resistance to current flow through the molten slag produces the heat to sustain the process.

Arc Cutting (AC)

Arc cutting (AC) applies to a group of thermal cutting processes that, like the kindred welding processes, melt the metals to be cut by heating them with an arc struck between an electrode and the workpiece.

Air Carbon Arc Cutting (CAC-A). The CAC-A process uses electrodes comprising a mixture of graphite and carbon, which might also be coated with a copper layer to improve current-carrying capacity. Metal melted by the arc is blown away by a jet of compressed air supplied by conventional compressors, usually at about 80 psi (550 kPa). Current is provided by standard electric welding power supply units rated for CAC-A duty or special power units.

Plasma Arc Cutting (PAC). The PAC cutting process achieves cutting action with an extremely hot jet of ionized gases at high velocity. The high-velocity hot jet is produced by forcing an arc and gas through a small orifice. Arc energy confined to a small area melts the metal, and the jet of highly heated, expanding gases forces the molten metal from the cutting area. High-arc voltages, special power supplies, and water-cooled torches are required. Air, nitrogen, argon-hydrogen, argon-nitrogen, and argon-helium gases are commonly used.

OXYFUEL GAS PROCESSES

Oxyfuel Gas Welding (OFW)

Oxyfuel gas welding (OFW) uses the heat of combustion of a fuel gas and oxygen flame, at high temperatures, to melt the workpiece base metal and filler metal. The flame (except for oxygen-hydrogen) is readily adjusted to provide a "neutral," oxidizing (excess oxygen), or carburizing* (excess fuel gas) environment. The type of flame used depends on the materials being welded.

TABLE 9.6.1 Flame Temperatures of Fuel Gases with Oxygen

Gas	Neutral Flame Temperature °F	Neutral Flame Temperature °C
Acetylene	5589	3087
Methyl acetylene-propadiene (stabilized)	5301	2927
Propylene	5250	2900
Hydrogen	4820	2660
Natural gas-methane	4600	2538
Propane	4579	2526

Acetylene remains the preeminent welding fuel because it has the highest flame temperature of all the fuel gases. Other fuel gases or mixtures, such as methyl acetylene-propadiene (stabilized), have found acceptance. Other hydrocarbons (propane, propylene, butane, natural gas-methane) are not suitable for welding ferrous metals. Hydrogen has a low flame temperature and heat content, and its flame, which is colorless, is difficult to adjust for oxygen-fuel gas ratio. Oxy-hydrogen welding does have application for welding lead, which is frequently but erroneously called lead burning. Table 9.6.1 shows neutral flame temperatures of some fuel gases.

With the exception of acetylene, neutral flame temperatures are significantly lower than the maximums, so it is not possible to melt and control the weld, except perhaps for thin sheet metal. At maximum temperatures, the flames are strongly oxidizing and not usable because of deleterious metal oxide formation in the weld metal. Use of methyl acetylene-propadiene (stabilized) requires special procedures.

Brazing and Braze Welding (BW)

Brazing. This is broadly defined by the AWS as a group of welding processes in which the base metal is heated but not fused and the joining is accomplished with a filler metal having a liquidus temperature above 840°F (450°C) and below the solidus temperature of the base metal. Moreover, brazing is characterized by the filler metal being distributed through a closely fitted joint by capillary action.

Braze Welding (BW). Braze welding is of more significance as it relates to fire prevention because of its frequent use in repair and maintenance activities. It differs from brazing in that capillary action in the joint is not a factor; the filler metal is laid down in a groove or fillet at the point of application. The edges of the joint are heated to a dull red color, flux is used, and filler metal is supplied by a bronze rod. However, the base metal is not melted, only the filler metal melts. The process is widely

*Sometimes carburizing flames are called reducing flames.

used on ferrous metals, as well as on copper and nickel alloys. Sometimes it provides a solution to the problem of joining dissimilar metals.

Hard Soldering. This common but incorrect term is used to describe brazing with a silver-base filler metal. The operation is often performed with an oxyfuel gas torch, as in assembling copper pipe joints with silver brazing alloy. Many times, however, the oxygen is not pure gas but is supplied as air, as in the air-acetylene torch. Thus, only one small gas supply cylinder is needed, enhancing portability.*

Surfacing

In surfacing the oxyfuel gas flame (usually oxyacetylene) is used not in a true welding sense but rather to deposit a layer of filler metal on a base metal to obtain certain surface properties or dimensions. Bronze may be used, but more frequently the process is one of hard facing, where the deposited layer is a special alloy that will greatly prolong the life of parts subject to extreme wear or abrasion. Surfacing can also be accomplished by use of arc welding and thermal spraying processes.

Oxyfuel Gas Heating Operations

There are numerous industrial and commercial operations that regularly employ an oxyfuel or air-fuel flame but do not involve a joining or severing operation. The flame and the nature and location of these operations can, nonetheless, represent an appreciable fire potential. Some such operations are as follows:

Forming. Heating (ironwork, piping, etc.) to facilitate bending, shaping, or straightening

Annealing, flame hardening, flame softening. Use of the flame in a controlled manner to obtain specific properties

Flame priming. Heating to remove scale and rust in preparing metal surfaces for painting

Flame descaling. Heating (generally a steel mill application) to remove scale from bars, billets, slabs, and so on, to facilitate machining or inspection

Other applications. Paint burning, glass finishing, leather edging, babbitting, or antiquing of wood

Oxyfuel Gas Cutting (OFC)

The term oxyfuel gas cutting (OFC) describes a group of oxygen cutting processes named by the specific fuel gas used (e.g., oxy-acetylene cutting, or OFC-A and oxy-natural gas cutting, or OFC-N) for severing metals by the reaction of high-purity oxygen with the metal at elevated temperatures. Burning iron in oxygen produces iron oxide, normally a solid, but the oxide melts at a temperature below the melting point of iron or steel and runs off as slag. A variation in the process is oxyfuel gas gouging, wherein a relatively low-velocity oxygen jet permits gouging or grooving of a metal surface in a reasonably smooth, well-defined manner.

Oxyfuel Gas Welding and Cutting Equipment

Basic elements are fuel gas and oxygen supplies, pressure regulators, conduits (hoses or piping) to convey the gases, and a torch to mix and burn the gases in controlled fashion and provide the oxygen jet used in cutting operations. In its simplest form, the equipment comprises a cylinder each of fuel gas and oxygen, a pressure regulator on each cylinder, hoses, and a torch (Figure 9.6.2). A steel mill, however, might have a major installation for cutting and welding operations (Figure 9.6.3). Fuel gas might be supplied from large multicylinder manifolds (possibly truck mounted and replaceable), from storage tanks for liquefied fuel, or from a public utility natural gas main. Oxygen might be supplied from the mill's own on-site oxygen-generating plant, from storage tanks for liquid oxygen or high-pressure gas or both, or from multicylinder manifolds. A major installation might also have an extensive fixed-piping distribution network and consuming devices running the gamut from simple hand torches to sophisticated steel-conditioning machines.

Auxiliary—but necessary—equipment includes standardized[2] fuel gas and oxygen hose connections, standardized hose,[3] protective equipment for service piping systems, and shutoff valves at points (station outlets) where gas is withdrawn from the piping system. Protective equipment for piping, which may

FIGURE 9.6.2 Portable Welding Outfit with Oxygen and Acetylene Outfits Chained to an Easy-Rolling Cylinder Truck (cutting attachments not shown) (Source: ESAB Welding and Cutting)

*The air-fuel gas flame, particularly air-acetylene, also finds significant use in soldering, commonly called "soft soldering," which by definition involves a filler metal that melts below 840°F (450°C). Plumbing jointwork, refrigeration piping, and heating and ventilating duct assemblies are applications where the air-fuel gas flame is used. Equipment portability is an advantage—but it may also signify access to places where fire prevention is not easily accomplished and is easily overlooked, because a single-joint operation can be done in a matter of minutes.

FIGURE 9.6.3 Large Stationary Oxyfuel Gas Cutting Machine in Operation (Source: ESAB Welding and Cutting)

be installed at one or more locations, should prevent the backflow of oxygen into the fuel gas supply system and vice versa, the passage of flame flashback into the fuel gas supply system, and the development of pressures in excess of system component ratings. In some systems, backflow prevention devices also may be required at station outlets. (See NFPA 51, *Standard for the Design and Installation of Oxygen–Fuel Gas Systems for Welding, Cutting, and Allied Processes.*)

Welding torches have inlet connections and valves for each gas at the rear of the handle (Figure 9.6.4). The gases are controlled by inlet valves and thoroughly mixed before issuing from the torch tip. Cutting torches are similar but provide passageways and separate valving for supplying and controlling the cutting oxygen jet at the center of the tip.

Mechanized cutting is common. Equipment varies from relatively simple, portable machines, used for straightline work and perhaps circles and some irregular shapes, to highly sophisticated multitorch machines that can trace (by photocell, laser beams, or other electronic means) intricate shapes and accurately and simultaneously produce a number of parts of the same shape.

THERMAL SPRAYING (THSP)

Closely allied to welding are several processes known collectively as thermal spraying,* in which finely divided metallic or nonmetallic materials are deposited in molten or near-molten condition to form coatings. Special "guns" are used (Figure 9.6.5). In flame spraying (FLSP), an oxyfuel gas flame is used to melt the coating material, and an auxiliary compressed gas can be used to assist in atomizing and propelling coating material to the workpiece.

Arc spraying (ASP) employs an arc between two consumable electrodes of coating material, plus auxiliary compressed

*"Thermal spraying" is the American Welding Society's preferred terminology for "metal spraying" or "metalizing."

FIGURE 9.6.4 Typical Cutting Torch. All control valves are located at the rear of the body. (Source: ESAB Welding and Cutting)

FIGURE 9.6.5 Thermal Spray Gun (Source: American Welding Society)

gas to atomize and propel the coating particles. Plasma spraying (PSP) uses a nontransferred plasma arc as the heat source and for propelling the coating material. In detonation flame spraying, the coating material is melted and propelled by the controlled explosion of fuel gas and oxygen.

SAFEGUARDS

Although it is beyond the scope of this chapter to describe all the fire prevention considerations that are tied into proper equipment design, installation, and maintenance, some significant items have been selected for specific attention.

Equipment Preparation and Condition

Oxyfuel Gas Equipment. Equipment meeting recognized standards (e.g., torches, cylinder manifolds, pressure regulators, pipeline protective devices, etc.) should be used.

Since oxygen is a far more powerful oxidizer than air, oxygen equipment must be kept clean (i.e., free of oil, grease, and other combustible contaminants). Materials that burn in air will burn violently in pure oxygen at normal pressure and explosively in pressurized oxygen. Also, many materials that do not burn in air will do so in pure oxygen, particularly under pressure. Consequently, it is widely recognized good practice to reserve equipment for oxygen service only.

Proper storage of gas cylinders is important (see NFPA 51). Cylinders should be moved and handled in accordance with recognized practices, for example, those of the American National Standards Institute (ANSI) and the Compressed Gas Association (CGA) (see Bibliography). There are many such recognized practices, and their importance varies with working locations and conditions. However, cylinders should always be supported or located in such a way that they cannot be knocked over. Ruptured cylinders can explode.

Oxyfuel gas cutting and welding equipment should be tested periodically for leaks (Figure 9.6.6). Testing frequency depends on the specific kind of equipment involved and how often it is used. Hose connections are known possible trouble spots. Also, experience has shown that fires can occur at fuel gas cylinder-to-regulator connections simply because someone failed to tighten the joint properly. The ignition of leaking gas at this point can in turn cause the release of cylinder safety devices, especially with acetylene cylinders fitted with fusible plugs, thereby releasing more gas and increasing the size of the fire.

Only standard welding hose should be used.[4] It should be frequently inspected for burns, cuts, worn places, abrasions, and similar defects. Taped repairs are unacceptable. Replace the damaged hose, or, if feasible, cut out the affected area and insert a proper splice. When repairs to equipment such as torches and regulators are required, they should be carried out by trained, skilled mechanics.

FIGURE 9.6.6 Checking Equipment for Leaks Before Operating an Oxyfuel Gas Outfit. After pressurizing both hose lines (with torch valves tightly closed), test for leakage at the following points, using an approved leak-test solution: (1,2) acetylene cylinder connection and acetylene cylinder valve spindle, (3) acetylene regulator-to-hose connection, (4) oxygen valve spindle, (5) oxygen cylinder connection, (6) oxygen regulator-to-hose connection, (7,8) hose connections at the torch, and (9) torch tip (for leakage past the torch valves). Later, after lighting the torch, check for leakage at the throttle valve stems (A,B) and at the welding head-to-torch handle connection (C). (Source: ESAB Welding and Cutting)

Arc Welding Equipment. When using arc welding equipment, the following should be addressed to avoid accidents, electric shock, or equipment damage:

- Use equipment meeting recognized criteria, such as that provided by ANSI, National Electrical Manufacturers Association (NEMA), and Underwriters Laboratories Inc. (UL). Installation, including incoming power lines and grounding of the machine frame or case, should comply with NFPA 70, *National Electrical Code*®, with particular attention to Article 630, "Electric Welders," and with ANSI/AWS Z49.1, *Standard for Safety in Welding, Cutting, and Allied Processes.*
- Proper storage and handling procedures for cylinders of shielding gases should be observed.
- At each work location, cylinders should be supported or located in such a way that they cannot be knocked over accidentally. Precautions must be taken that the cylinders are not grounded.
- Cable sizes should be adequate for current and anticipated duty cycles. Sustained overloading of inadequate cables can burn away insulation. Cables should be inspected frequently for wear and damage and properly repaired or replaced when necessary.

Precautions for the Work Area

Hazardous sparks and globules of molten metal, or hot slag, are produced by welding, cutting, and other hot work operations. Sparks from cutting, particularly oxyfuel gas cutting, are generally more hazardous than those from welding, because the sparks are more numerous and travel greater distances. In a sense, they are jet propelled by the oxygen or airstreams used in cutting processes. Oxyfuel gas flames and electric arcs are inherent and obvious ignition sources, as are hot workpieces or sections cut from the base workpiece.

Isolation of Combustibles. Either isolation or protection of combustibles is essential, for they may be exposed to sparks that fall through cracks or other openings in floors and partitions. If those sparks are of sufficient mass to retain heat for a time, they may ignite combustibles. The following are the minimum recommended requirements for combustible control within a 35 ft (10.6 m) cutting or welding work area:

- Move all combustibles a safe distance away—at least 35 ft (10.6 m)—and be sure that there are no openings in walls, ceilings, or floors within a 35 ft (10.6 m) radius.
- For situations in which combustibles are within a 35 ft (10.6 m) sphere of the point of operation, be alert for cutting conditions that could propel sparks overhead or downward.
- Move the work to a safe location.
- If none of the foregoing steps is possible, protect the exposed combustibles with suitable fire-resistant guards and provide a trained fire watcher with extinguishing equipment readily available.

For situations in which combustible materials cannot be relocated beyond the 35 ft (10.6 m) safe separation distance, the following are some of the precautions that should be implemented:

- Shield combustible flooring with wet sand, listed/approved hot work blankets/pads, or sheet metal.

- Clean up the area, especially oily deposits and trash.
- Cover/shield any storage or other combustibles that cannot be moved with listed/approved hot work blankets or welding curtains.
- Block off any duct openings to prevent sparks from traveling to other areas or to ignite deposits/linings within the ductwork.
- Cover or fill any openings in exposed walls, flooring, and ceiling with noncombustible materials or listed/approved fire-stop material.
- Clean dust and deposits outside and inside enclosures and ducts.
- Close all doors and fire doors around the hot work area.
- Check for gaps under doors or along their sides to prevent sparks from getting through that could ignite combustible material outside the hot work area.
- Relocate combustibles away from the opposite sides of the walls being worked on.
- If hot work occurs at an elevated location (i.e., on the building frame, the ceiling, or the underside of the roof), provide a listed/approved hot work blanket under the work area.
- Relocate the hot work to a designated area devoted exclusively to hot work, which isolates the area from the rest of the facility with noncombustible screens or partitions.

Special Hazards. For operations involving special hazards of combustible dusts, flammable liquids, or flammable gases, special precautions should be taken before any hot work is initiated in these areas. All processing equipment/systems should be shut down, cleaned, and equipment purged of all combustible/flammable contents before hot work is authorized. See appropriate NFPA codes for additional guidance.

Factors to Consider. The steps that have been described are only a partial solution to the problem of preventing cutting, welding, and other hot work fires. There are other important factors to consider. Are there any inconspicuous combustibles in an area proposed for cutting and welding operations? What conditions must be met before cutting and welding operations can take place? Who has the responsibility for authorizing the work to proceed? Are cutters, welders, and their supervisors properly trained in the use of their equipment and in emergency procedures should a fire occur? If an outside firm is engaged to do cutting and welding work, chances are that its employees will be unfamiliar with the premises and its contents. That is why they must be briefed on the conditions in the areas where they will work.

Facility Management Responsibilities. Based on the fundamental but necessary understanding that workers, their supervisors or permit-authorizing individuals (PAIs), and facility management share the responsibility for fire safety, the following paraphrased version of NFPA 51B should be helpful. It is adapted in the following list for convenience; this list should not be used in place of NFPA 51B.

1. Management must establish areas designed and authorized for hot work and/or designate a PAI to authorize hot work in areas not specifically designed for such processes. This management designee must require trained fire watchers where the potential exists for a significant fire to develop. Fire watchers must also be required where appreciable quantities of shielded combustibles are less than 35 ft (10.6 m) away; where wall or floor openings within 35 ft (10.6 m) expose combustibles in adjacent areas; or where combustibles adjacent to opposite sides of partitions, ceilings, or roofs are likely to be ignited by heat from the work. Management must select contractors with a view to their awareness of risks and the quality of their personnel. Management must also advise contractors of the presence of flammable materials or other hazardous conditions on the property work site.

2. The PAI of hot work (e.g., the plant manager, plant maintenance foreman, contractor, or contractor's foreman) in areas not designed for such processes must be assigned the following responsibilities:

   a. Determine what combustible materials are present at the work site.
   b. If necessary, have the work or the combustibles moved, or have the combustibles shielded.
   c. Issue authorization in the form of a written hot work permit.
   d. See that the worker is aware of the authorization and conditions.
   e. See that fire watchers are available when required.
   f. Make a final check for fires one-half hour after completion of welding or cutting operations in cases where a fire watcher was not required.

3. Workers must have the PAI's approval before starting hot work, must handle their equipment safely, and must continue to work only so long as approval conditions do not change.

4. There are a number of precautions to be observed during hot work:

   a. Hot work must not be permitted in flammable (explosive) atmospheres; near large quantities of exposed, readily ignitable materials; in areas not authorized by management; or on metal partitions, walls, or roofs with combustible covering or with combustible sandwich-type panel construction.
   b. Floors must be free of combustibles, such as wood shavings. If the floor is of combustible material, it must be kept wet or otherwise protected.
   c. If combustibles are closer than 35 ft (10.6 m) to the welding or cutting process and the work cannot be moved or the combustibles relocated at least 35 ft (10.6 m) away, they must be protected with flame-resistant covers or metal guards or curtains. This also applies to walls, partitions, ceilings, or roofs of combustible construction (Figure 9.6.7).
   d. Openings in walls, floors, or ducts must be covered if within 35 ft (10.6 m) of the work.
   e. Cutting or welding on pipes or other metal in contact with combustible walls, partitions, ceilings, or roofs must not be performed if close enough to cause ignition by heat conduction.

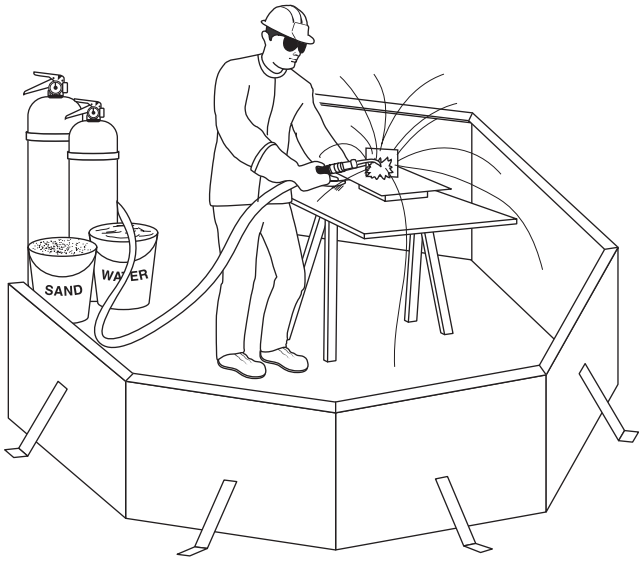

FIGURE 9.6.7 Safe Work Procedures

f. Charged and operable fire extinguishers must be readily available. Trained fire watchers must be posted. In the absence of fire watchers, an important minimum step is to check the work area and adjacent areas carefully for at least one-half hour after completion of welding or cutting to detect possible smoldering fires. Consider extending the time when conditions seem more hazardous.

SPECIAL SITUATIONS AND ADDITIONAL PRECAUTIONS

Containers (Including Piping)

Welding or cutting on containers can cause—and has caused—explosions or fires with potential for deaths or serious injuries. Any container can contain or might have contained a combustible. Therefore, all containers must be considered hazardous unless they have been tested and found safe, cleaned, or rendered inert. Therefore, it is essential that flammable liquids, solids, or vapors be removed from containers by some type of adequate cleaning procedure before welding or cutting.

Depending on the application, it might be necessary or desirable to supplement the cleaning with inerting, water flooding, or periodic testing (for flammables) of the atmosphere within the container. With some materials, water washing or flushing might be sufficient; others might respond to steam cleaning; some might require alkaline cleaners (trisodium phosphate or caustic soda); some might call for more specialized cleaning methods. Heavy, viscous liquids and solids can be especially difficult to remove completely. Residues are especially hazardous because they can volatilize or decompose into flammable products by the heat of the torch or arc. For details concerning these hazards, see AWS F4.1, "Recommended Safe Practices for the Preparation for Welding and Cutting of Containers and Piping."

Jacketed Containers and Hollow Parts

There are some similarities between the hazards of cutting or welding jacketed containers or other hollow workpieces and hazards of cutting or welding containers. Air confined inside an unvented hollow part will expand when heated and pressure will increase. Since hot metal rapidly loses its strength, the container or hollow piece could burst with explosive force at the focus of the cutting or welding work. Be suspicious of closed metal parts that seem unusually light. Drilling a vent hole before heating the part may be necessary (Figure 9.6.8).

Hot Tapping

Occasionally, there are situations in which emergency repair or the complete impracticality of emptying and cleaning demands welding or cutting on a container while it holds flammable gas or liquid (e.g., a natural gas transmission pipeline or utility distribution system). Schemes to accomplish such hot tapping with relative safety have been developed. (See ANSI B31.8, *Gas Transmission and Distribution Piping Systems,* and API Publ 2201, "Procedures for Welding or Hot Tapping on Equipment Containing Flammables.") Needless to say, any such work must be performed only by specially trained and qualified staff, using recognized and authorized methods.

Public Exhibitions and Demonstrations

Special and enhanced fire safeguarding is necessary when welding or cutting is performed at trade shows and exhibitions. Characteristically, places of public assembly, such as auditoriums and hotel exhibit halls, and concentrations of people are involved. When welding or cutting work is planned in such exposures, the fire department must have prior notification, operations must be under the control of a qualified person, gas cylinders must be

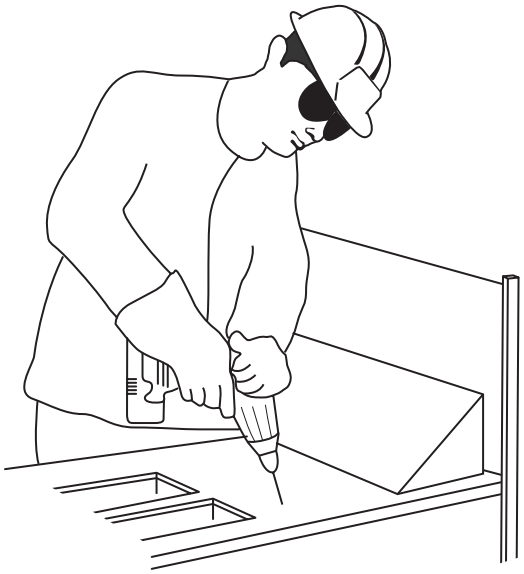

FIGURE 9.6.8 Vent Hole Drilling

charged to only one-half their maximum permissible content, storage sites for gas cylinders must have special restrictions, and fire-extinguishing equipment must be appropriate to the situation.

Personnel Protection and Ventilation

One aspect of welding and cutting fire protection that is sometimes overlooked or inadequately considered is the safety of the operator, helpers, or nearby workers. Flame-resistant gloves and clothing, aprons of leather or other durable flame-resistant material, cape sleeves or shoulder covers with skull caps under helmets or with goggles for overhead work, leggings for heavy work, and high-top safety shoes are generally recommended. Trousers should not be turned up or cuffed on the outside, front pockets on clothing should be eliminated, and sleeves and collars kept buttoned to prevent sparks from entering and lodging in such places. Outer clothing should be free of oil and grease. Cotton clothing may be worn if the cotton is chemically treated to reduce its combustibility (Figure 9.6.9).

Adequate ventilation must be provided wherever welding, cutting, and other hot work are performed to protect the operator from inhaling noxious gases and fumes. Potentially hazardous materials might exist in certain fluxes, coatings, and filler metals. In some cases, general natural draft ventilation is adequate. Other operations require forced-draft ventilation, local exhaust hoods or booths, or personal respirators or air-supplied masks. A good reference for additional information on personal protective equipment (PPE) and ventilation is ANSI Standard Z49.1. It also contains a great deal of general safety information on welding, cutting and allied processes.

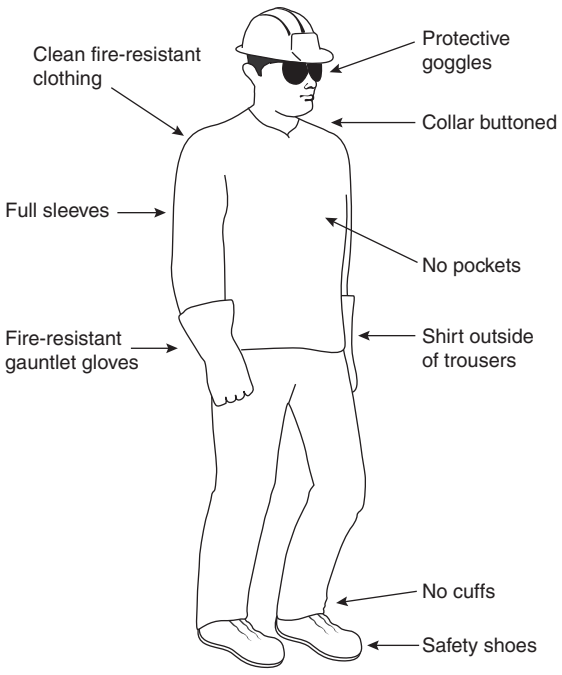

FIGURE 9.6.9 Welder Protection

Oxygen, since it accelerates combustion, must never be used to cool the worker, ventilate a confined space, or dust off clothing. Tests and experience have shown that oxygen-saturated clothing or clothing in an oxygen-enriched atmosphere will literally burn in a flash, with extremely serious and sometimes fatal results.

Manufacturers' Recommendations

Procedures given in manufacturers' instructions for setting up, connecting, lighting or starting, adjusting, and maintaining equipment have specific, safety-oriented purposes. These procedures should be followed. In addition, precautions and safe practices publications with valuable information about fire and personnel safety are available from equipment suppliers.

SUMMARY

Hot work includes welding, cutting, and allied processes that are capable of producing a spark, flame, or heat. Because it is not possible to cover all of these processes, this chapter has focused on the more common ones. First discussed were processes using electricity, such as arc welding, resistance welding, flash welding, electroslag welding, and arc cutting. Next oxyfuel gas processes were described, including oxyfuel gas welding, brazing and braze welding, surfacing, oxyfuel gas heating operations, and oxyfuel gas cutting. Then thermal spraying was discussed. The second half of the chapter examined the recommended safeguards and fire prevention considerations that should be undertaken, including the handling and storage of equipment and various work area precautions. Although the potential for hot work fires is great, education, training, and on-the job practice can reduce the potential significantly.

Modern Elevator Design
Raw Materials
Storage
Handling
Elevators
Dust Control
Fire Hazard
Explosion Hazard
Safeguards

Key Terms

bucket elevator, conveyor, dust collection system, dust explosion, grain, grinding, oilseed

The grain industry includes the movement, storage, and processing of grains—such as wheat, corn, oats, and sorghums—and oilseeds—such as soybeans and sunflower seeds. The industry can be separated into two broad segments: (1) grain elevator operations and (2) millers or processors. Grain elevators are facilities that receive, store, and distribute whole grains and oilseeds for direct use, process manufacturing, or export. Grain elevators receive directly from the farmer and can be classified as either "country" or "terminal" elevators, with terminal elevators further categorized as inland or export facilities. Their end product is virtually identical to their raw material, with only minimal cleaning, drying, and blending and, in some cases, fumigation to preserve and meet product quality standards. Grain millers and processors, on the other hand, take whole grains as their raw material and process these into products, such as animal feeds and feed ingredients, cereals, flour, starch, meal, vegetable oils, corn sugars, and brewery products. The discussion that follows is primarily aimed at the grain elevator segment of the industry and those portions of grain milling and processing that handle and store grains or dry milled products.

For related topics, see Section 2, Chapter 8, "Explosions"; Section 6, Chapter 8, "Dusts"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

MODERN ELEVATOR DESIGN

The growth of the grain industry in the United States has paralleled the phenomenal growth in production, consumption, and export of grains and oilseed products. This growth has been the result of many factors, the most important of which is the ideal temperate climate of the United States for producing these agricultural commodities. The favorable climate combined with the mechanization of farming, the development of high-yielding hybrids, the use of fertilizers, the free market system, and uniquely efficient storage and transportation systems have affected the growth. Table 9.7.1 indicates the dramatic rate of growth in harvested grain and oilseed crops.

In the last three decades there has been much consolidation of the industry, resulting in fewer facilities operating at greater efficiency handling and processing larger crops at a faster rate. Table 9.7.2 gives the structure and productivity of various sectors of the U.S. industry in terms of the number of facilities and their capacity and/or production.[1] All sectors shown in Table 9.7.2 handle grain and grain products and generally have a grain elevator portion in their operations. Figure 9.7.1 shows a major export elevator in the New Orleans, Louisiana, area. The facility was built in the early 1980s to replace a facility that had a major explosion. Many new design concepts were used, including elimination of bucket elevators and use of inclined belt conveyors, and elimination of the headhouse and use of turnheat distributors rather than bin galleries.

James E. Maness is owner and consultant for JEM Safety Consulting, Rehoboth Beach, Delaware. Mr. Maness has been associated with the grain and feed industry for nearly 35 years in the areas of engineering, safety, and dust explosion prevention. He is a member of NFPA's Technical Committee on Agricultural Dusts and is on the technical committees overseeing NFPA 61, 91, 654, and 655.

Lee M. Sargent, P.E., is chair and chief executive officer of Todd & Sargent, Inc., an Ames, Iowa, based company which specializes in the design and construction of feed mills, flour mills, grain elevators, and similar structures. An Iowa State University civil engineering graduate, Mr. Sargent chairs NFPA's Technical Committee on Agricultural Dusts.

TABLE 9.7.1 Production of U.S. Grains and Oilseeds in Thousands of Bushels

Year	*Corn*	*Wheat*	*Soybeans*	*Total (1000 bu)*
1950	3,131,009	1,026,755	287,010	4,444,774
1955	3,184,836	938,159	371,276	4,494,271
1960	4,352,668	1,363,443	558,778	6,274,889
1965	4,084,342	1,315,613	845,608	6,245,563
1970	4,151,938	1,351,588	1,127,100	6,630,626
1975	5,828,961	2,122,459	1,547,383	9,498,803

TABLE 9.7.2 U.S. Grain-Handling Facilities and Capacities as of June 2001

Type of Facility (Commercial)	*Estimated Number of Facilities*	*Annual U.S. Characteristics (Estimated for each industry segment)*
Grain elevators		
Country elevators	10,835	198.8 million tons storage capacity
Terminals	700	42 million tons storage capacity
Export elevators	60	9.3 million tons storage capacity; 120,000 tons/hr handled; exports 115 million tons of commodities
Soybean crushing	93	Crushes 50 million tons of soybeans; daily crush 143,000 tons
Cottonseed crushing	35	Crushes 4.93 million tons
Sunflower crushing	7	Crushes 4,755 tons/day capacity
Feed mills	6,723	Produces 164.7 million tons of feed
Wheat flour mills	237	Mills 31 million tons of wheat; daily production capacity 75,000 tons of flour
Dry corn mills		
Degerminating	15	Grind capacity 3.78 million tons of corn
Full seed	55	Grind capacity 280,000 tons of corn
Wet corn mills	24	Processes 33.6 million tons of corn; produces 15 million tons of corn sweeteners
Total no. of facilities	18,784	

For SI units: 1 ton U.S. = 0.907 ton metric.

The awareness of dust explosion hazards has caused a transformation in the design and construction of grain elevator facilities during the last 20 years, from the totally enclosed concrete structured headhouse (which contains much of the handling and cleaning equipment) to construction of open towers. This awareness has greatly increased because of (1) the severity and frequency of explosions that occurred in the late 1970s and early 1980s,[3] (2) grain industry efforts to research the causes and prevention of grain dust fires and explosions, and (3) the promulgation of the Occupational Safety and Health Administration (OSHA) rule 29 CFR 1910.272 regarding grain-handling operations. Figure 9.7.2 shows the results of a dust explosion at a Houston, Texas, area export elevator in 1976. The facility had two headhouses—one at each end of an array of concrete silos. The building in the foreground was a bagging shed. Figures 9.7.3 and 9.7.4 show the results of other dust explosions.

Information and new concepts learned about grain dust fires are reflected in NFPA 61, *Standard for the Prevention of*

Fires and Dust Explosions in Agricultural and Food Products Facilities, which combines four NFPA standards used prior to 1995, that is, NFPA 61A, NFPA 61B, NFPA 61C, and NFPA 61D.

RAW MATERIALS

Grain and oilseeds consist primarily of starch or carbohydrates, protein, fiber, and various vegetable oils, all capable of burning under very specific conditions. In their raw, whole-kernel states, these commodities are stable and not readily subject to combustion if protected from moisture, insects, and fungi. So-called spontaneous combustion is a product of microbiological spoilage created by fungi combined with certain levels of moisture and temperature.[4] The incidence of this source of ignition of fires and explosions in grain elevators is rare, although it has been known to occur. Good grain industry practice is to store grains at moisture and temperature levels that keep the grain from deteriorating, thus minimizing the possibility of spontaneous combustion.

The probability of fires and explosions at grain-handling facilities is directly related to the increase in the amount of starch and other particles that are released when grain kernels are broken either during handling or processing. For example, artificial drying of corn can introduce stress cracks into the corn kernel, which leads to increased breakage during subsequent handling. Unless controlled, this breakage can result in increased levels of grain dust in the grain and can increase the risk of fires and explosions during grain operations.

As size reduction of the grain kernel proceeds, the susceptibility to fires and explosions increases dramatically.[5] The frequent handling of grain from farm to consumer progressively creates more broken kernels and, hence, more dust. Reduction in particle size also occurs as an integral part of the milling and processing operations.

Since grain is essentially handled as a bulk commodity, the economies of scale continue to dictate larger and more automated handling units. The grain is normally transported in bulk by truck, rail, barge, and ship. Only a small fraction of the grain is bagged, consisting primarily of seed stocks and bagged commodities for export to a few emerging nations that are not equipped to discharge bulk vessels.

STORAGE

There are numerous types and configurations of bulk grain storage facilities. Structures that consist of upright concrete silos, wood bins, steel silos, and steel tanks can generally be unloaded using gravity flow. A combination of traditional elevator design with new concepts to help minimize explosions and limit damage is shown in Figure 9.7.5. The concrete elevator is a traditional headhouse with concrete silo complex. However, bucket elevators have been extended outside and vented. Steel tanks with conveyors are used to store grain. The gallery above the bins houses enclosed drag conveyors.

In addition to conventional warehouse structures, there are structures, referred to as flat storage, which do not totally empty by gravity and require manual labor or special power equipment to remove residual grains. Further, outdoor temporary piles are used during harvest periods to store the grain. Many facilities serve a multipurpose function, including the operation of other related agricultural businesses, such as seed and fertilizer distribution.

The size of the storage structure is determined by the nature of an individual facility's operation. Individual bins may range from 1000 bushels (35.2 m^3) to 2,000,000 bushels (70,400 m^3) or even larger. The largest single facility has a total storage capacity exceeding 45,000,000 (1,524,000 m^3) bushels.

Grain temperature systems are often used to monitor grain temperature and quality and to detect spontaneous heating at facilities that store grains for long time periods. In addition, storage systems are often equipped with aeration systems to help maintain grain temperature, moisture content, and quality.

FIGURE 9.7.5 Combination of Traditional Elevator Design with New Concepts to Minimize Explosions and Limit Damage

HANDLING

The primary function of a grain handler, other than storage and quality preservation, is conveying grain horizontally and vertically into and out of the storage facility. Conveyors common to most bulk handling industries are used in this process. The following discussion shows how these conveyors are used in the grain industry and highlights modified designs tailored to grain industry needs.

Belt Conveyors

The most common conveyor employed to move grain horizontally from point to point is the trough-belt conveyor. By virtue of the wide choices of speeds and belt widths available, any desired volume, within reason, can be accommodated in this manner. Belt conveyors are used to meet large production capacity needs, often exceeding 20,000 bushels per hr (bph) (700 m^3/hr) upwards to 80,000 bph (2800 m^3/hr) at large export elevators. Belt conveyors are generally highly reliable with low maintenance requirements. The fire hazards associated with these conveyors are the combustible rubber belting material, the tendency of dust to be liberated at grain transfer points (belt to belt or to other equipment or storage), and mechanical failure due to poor maintenance. The fire hazard can be reduced with the use of flame-resistant belting[6] and good maintenance procedures. The dust hazard can be mitigated with the use of enclosures, aspiration, belt speed control, or a combination of these. Newer designs often totally enclose the belt with critical bearings kept outside of the enclosure. These designs control the dust by containment and aspiration.

Chain Conveyors

Alternatives to the belt conveyor include the *en masse,* drag, or chain conveyors, which are totally encased in a housing that prevents the escape of dust. These are usually of more limited capacity and convey at reduced linear speeds with much deeper grain depths. Normally, only the loading point or discharge point needs to be aspirated. Their higher energy use (than belt conveyors), increased maintenance, and installation costs are major factors when considering drag conveyors for use.

Screw Conveyors

The helical screw conveyor is a standard for low-volume conveying for short distances. The grain industry generally uses screw conveyors for handling materials such as dust or small product streams. A major drawback to screw conveyors is that they can cause damage to whole grain, adding to grain breakage.

Bearing failure is also a prime concern and requires periodic inspection and lubrication.

Pneumatic Conveyors

The milling portion of the industry uses pneumatic conveying systems extensively. These are especially effective for confinement and movement of finely ground commodities in a complex processing operation requiring multipoint pickup or distribution. There can be some concern about static electricity buildup and discharge if the systems are not properly grounded and maintained.

ELEVATORS

Bucket Elevators

The common principle used in grain elevator design is that of elevating the commodity to the highest optimum point, then permitting the material to flow by gravitational force down through the various garners, hopper weighing scales, cleaners, and finally through spouts into storage compartments (Figure 9.7.6). Use of gravity flow not only makes efficient use of the energy required to move the mass, but eliminates re-elevating and rehandling, which can cause increased breakage and damage to the kernel or seed. Grain quality is often monitored by using automatic grain samplers to collect representative samples during gravitational grain flow. Each subsequent rehandling contributes to reducing the quality of the grain and generation of additional quantities of fine particles and dust. The bucket elevator (or "leg" as it is referred to in the industry) is the primary equipment used to gain these elevations. Inclined belts have been used in several large terminals, but are often impractical for most smaller facilities because of the large amount of land they require.

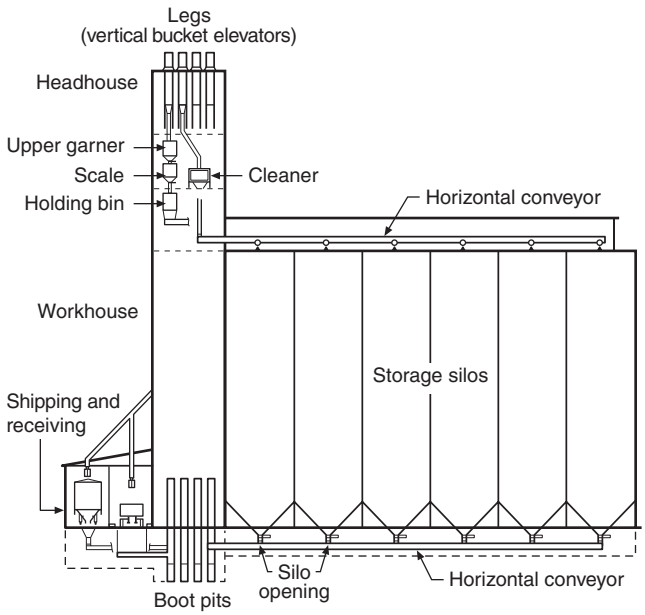

FIGURE 9.7.6 Traditional Concrete Elevator Design

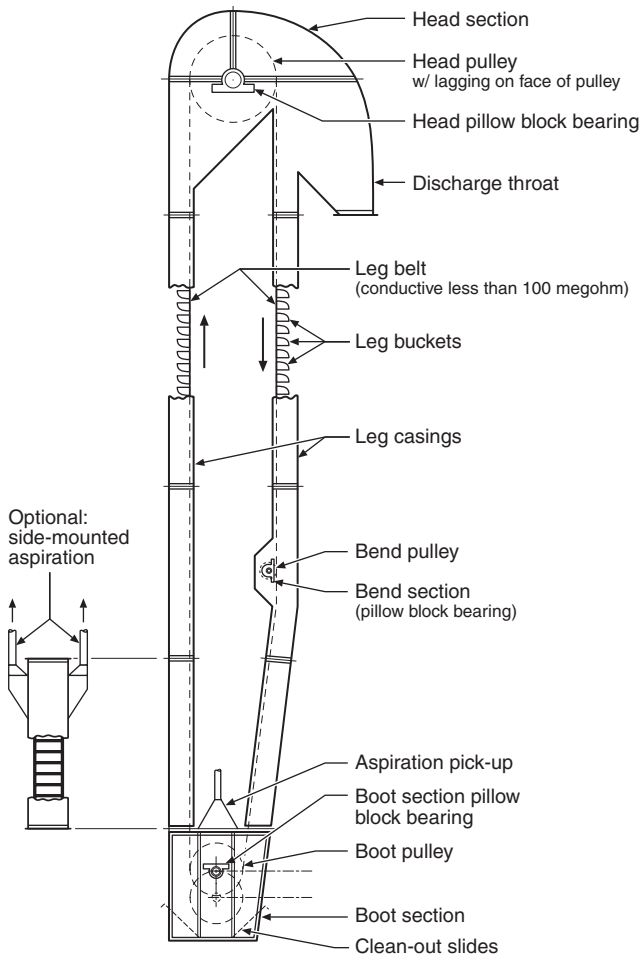
The bucket elevator is the workhorse of the industry and requires special attention as an explosion hazard. The dust concentration within a bucket elevator is likely to be above the minimum explosive concentration (MEC) in some portions of the bucket elevator during normal operations. This combined with the pumping action of the buckets moving in a confined enclosure, mechanical components that can fail (bearings, alignment, etc.) and the high amount of mechanical energy inherent in its operation have led to its identification as the principal ignition source in explosions.[7,8] For these reasons, it is becoming industry practice to locate new bucket elevators outside of totally enclosed headhouse structures (Figure 9.7.7). (NFPA 61 contains explosion venting recommendations for outside-located bucket elevators.) Where "legs" cannot be installed outside, they can be provided with deflagration venting to the outside or be equipped with explosion suppression in addition to other safety devices (Figure 9.7.8).

Spouting and Lining

Grain and oilseeds are very abrasive and can rapidly erode steel conveying spouts used to channel the flow through elevators. For very long grain drops, a grain-retarding device (dead box)

FIGURE 9.7.7 Outside Free-Standing Bucket Elevators with Steel Tank Storage



Notes:

1. Capacity can be a few hundred bushels per hr to 60,000 bushels per hr (2100 m^3 per hr).
2. Belts can have multiple rows of buckets (metal or plastic, plastic is preferred) across them.
3. Take up can be gravity or screw style.
4. Capacity is belt speed x bucket capacity.
5. Head pulley is normally lagged.
6. Legs can be in excess of 200 ft (60 m) tall.
7. Legs interconnect the entire headhouse when placed inside.
8. Slow motion devices are used to detect overload for belt slippage.
9. Bearing and alignment rub blocks with thermocouple establishes temperature monitoring.
10. Casings and head sections can be vented when leg is outside. Head sections of inside legs can often be vented to the outside.

FIGURE 9.7.8 Bucket Elevator

can be used to slow down the grain and reduce breakage and dust generation.

The abrasive nature of grain creates an almost constant demand for maintenance to eliminate leaks and dust emissions. While patching and repair are adequate temporary measures, they seldom fully restore a spout. An alternative has been the wide use of abrasion-resistant liners that can be totally replaced without disrupting the outer spout. Materials most commonly used are abrasion-resistant alloy steel plates and high-density synthetic plastics (most frequently used), such as polyethylene or urethane, and certain ceramics. These can usually be formed or molded to the contour of the spouts and bolted into place without the need for welding or other heating devices. Although the high-density plastics are not easily ignited, they can burn and must be removed or protected whenever welding or cutting is conducted on the spout.

Shipping and Receiving

The first and last adjuncts to a grain storage elevator are the machinery and structures needed to unload or load the grain from and into a carrier. Wherever a truck, railcar, barge, or ocean vessel shipping/receiving system is used, these operations are at ground level, partly or completely in the open, and usually connected to the main storage structure with an underground tunnel beneath the discharge receiving hopper or with an overhead bridge.

The free-fall of grain through open spaces into receiving hoppers presents a unique dust control problem influenced by surface winds and the lack of sufficient enclosures to contain the dust emission. The problem is less of an explosion or fire hazard than a nuisance, as the dust can fly about, since the operation is essentially an open-air one. Environmental laws and regulations have required the same attention to these ground-level emissions as to elevated sources of emissions, which can present greater concerns.

Grain Drying

The principal processing operation at most grain elevators is that of drying the grain to moisture levels low enough to preserve quality during storage or to meet grain standards. Many types of dryers are used in the industry, with batch dryers or continuous flow dryers being the most common. Continuous flow dryers are either column (which allow continuous flow of grain through a screened column while hot air is passed perpendicular to the grain flow) or rack dryers (where grain flows down an air plenum with hot air flowing up through the cascading grain flow) (Figure 9.7.9).

The typical modern grain dryer is direct-fired, that is, the heat of the burned fuel is directed into a stream of air that is passed directly through the moist grain. The fuels used are principally natural gas, fuel oil, or vaporized liquid propane. Although dryers are designed to minimize fire hazards, inadequate maintenance and improper operations can result in ignition of the grain being dried. Examples of causes of these fires are the failure to properly and frequently remove excessive accumulations of dust and combustible materials from the inside of the dryer or the occurrence of blockages to the flow (such as a broken bucket from a "leg"), allowing the grain to overheat.

The resulting "hang-ups" and overdried materials and particles readily ignite when burner temperature gets too hot or small embers are entrained in the plenum air. The multiple severe grain dryer fires and explosions of 20 to 25 years ago have not recurred, reflecting the installation of a number of safety devices and improved operating procedures.

Ideally, a grain dryer should be housed in a structure completely removed from the storage facility. Inside-located bulk

FIGURE 9.7.9 Commercial Column Grain Dryer

grain dryers are prohibited by OSHA in 29 CFR 1910.272(p), unless located in a separate fire area or protected by explosion suppression. Dryers must also be equipped with certain automatic safety controls that shut off fuel for power failure, provide flame or exhaust air movement interruption, and stop the feed to the dryer if excess temperature occurs in the exhaust section of the dryer. The grain is fed to the dryer from an elevated source, and returned from the dryer to storage in a second separate conveyance for distribution into silos. Locating a direct-fired dryer away from the storage unit itself, as well as good operating procedures, minimizes the risk of more serious fires or explosions within the silo structure. In cases where a dryer serves solely to heat grain without cooling, the hot grain is often cooled in the storage silos by fans forcing ambient air up through the grain mass until air-temperature equilibrium is reached. (See Chapter 8 of NFPA 61 for additional dryer recommendations and requirements.)

The grain temperature typically should not exceed 150°F (65.5°C) in a drying operation (corresponding to a hot-air drying temperature between 180 and 200°F [82 and 93°C]), thus avoiding heat damage to the kernels.[3] As the wet grain is heated, the evaporating water at the surface of the kernels has a cooling effect that prevents the kernels from overheating. The heated air leaving the dryer is in a near-saturated state, and some coarse dust and fine particles can escape with it.

Grain Cleaning

Another important activity in some grain-handling facilities is scalping and cleaning of grain through the use of aspiration and/or screening systems to remove extraneous material from the grain, such as bits of stalks, stems, seed pods, husks, corn cobs, weed seeds, or fine broken grain particles. These materials not only affect the quality of the grain but are also more prone to ignition than the grain itself by virtue of their extremely dry state and high fiber content. In some cases, green weed seeds and plant particles can cause additional heating concerns. The grain is cleaned by passing it over vibrating, rotating, or gyrating screening devices or stationary gravity screens for simple size separation. A positive air aspiration system can be used prior to the screening system. Aspiration is often used to remove dust generated by the grain movement within screen-type cleaning systems. Fires associated with cleaners can occur due to lack of maintenance and components coming loose and rubbing, causing frictional heat.

Grinding and Cracking

Some grain facilities serve specialty industries that require grain to be cracked or ground. This entails the use of hammer mills or grinders to accomplish the size reduction, particularly in feed, processing, or milling operations.

Hammer mills can be sources of fires and dust explosions, which can be transmitted through aspiration connections. The hammer mill is frequently used to grind corn and other feed grains in preparing feeds. Care must be taken to remove foreign objects, especially stones and metallic objects, from entering the grinding mechanisms with the use of screening and magnetic devices.

DUST CONTROL

Supplementing the conveying, elevating, drying, screening, sampling, weighing, and storage activities is the dust control process. Each point of grain transfer and handling can produce suspended dust. A complete dust control system at an elevator consists of a combination of methods, such as proper and periodic housekeeping, good maintenance to prevent grain leaks in equipment and spouting, the enclosure of grain-handling equipment to prevent the escape of dust, the reduction of grain-handling speeds, and the use of active dust control provided by mechanical dust collection systems to reduce fugitive emissions. In some cases, oil additives have been sprayed on grain to help reduce grain dust emissions during handling.

Mechanical dust collection continues to be the primary means used to control fugitive dust emissions. The dust collector most commonly employed is the "baghouse" or fabric filter, wherein the dust-laden air is passed through filter media and exits virtually dust-free (up to 99.99 capture efficiency). The dust is recovered in the filter housing, stored in a remote bin or tank, and can sometimes be sold as a by-product of grain for use by the animal feed industry. Often the dust must be given away to avoid disposal and freight costs. Most often the dust is returned to the grain stream in such a manner so as not to create additional airborne dust. However, at export facilities, dust returned to the grain is prohibited once it has been placed in a storage bin or tank. Mechanical dust systems are complex processing operations with self-cleaning devices for the bags, automatic discharge mechanisms, and continuous conveying to disposal points or storage tanks.

The cyclone collector was commonly used prior to clean-air laws, but is used less frequently for controlling dust emissions. Nevertheless, they continue to be relied on for preventing product losses and serve as a separator for dust aspirating systems. Cyclones are not as efficient in capturing smaller particle emissions. Collection efficiencies vary greatly, ranging up to 80 percent for low-efficiency cyclones and up to 95 percent for high-efficiency cyclones. For fine particles, efficiency is only 50 to 60 percent. The cyclone is still often used in conjunction with some dust systems by being located ahead of bag filters to remove and recover very large particles for re-entry into the grain or product streams. The remaining fine dust particles are then collected in bag filters for disposal or for readmission into the operation where circumstances and practices permit.

Dust collection systems can be a fire hazard because they concentrate the dust in specific pieces of equipment and can serve as a path for flame or explosion transmission to interconnecting equipment and areas. For this reason, dust filters should be located outside and should be equipped with deflagration vents to minimize possible damage should an explosion occur. Alternatively, dust systems can be located in separate explosion-vented rooms or be equipped with explosion suppression systems.

Dust systems must be periodically inspected for proper operation. Pressure gauges are often installed to monitor the performance of the unit. Excessive pressure drop across the bags can indicate that filter bags need to be changed or cleaned out. Low pressure can indicate a broken bag or improper operation of the unit.

FIRE HAZARD

Although dust explosions receive the most attention and awareness regarding hazards at grain-handling facilities, there are a number of other fire hazards at these facilities. Fires are much more numerous than dust explosions. Fires often precede a dust explosion; ignition sources include improper welding and cutting, failed bearings, overheated or failed electrical equipment, and mechanical failures.

Fires can occur in nearly any area of a grain facility, particularly where potential ignition sources are present, such as motors, drives, bearings, and electrical equipment. Areas of grain facilities where fires might occur include the dryer, motor control rooms, bucket elevators, conveyors, storage bins, grinding or milling areas, and offices. Potential fuel sources for fires in grain-handling facilities vary depending on construction, equipment, and types of operations.

Generally speaking, grain facility structures are constructed of noncombustible materials, such as concrete and steel. Older facilities may have some wood construction.

The following materials can serve as fuel sources at grain handling facilities: dust, grain, grain screenings, plastics, lubricants and grease, fabric cloth materials, rubber belts, polyvinyl chloride (PVC), conveyor and bucket elevator belting, roofing materials, propane and natural gas, and electrical wiring coverings. Many of these materials are not peculiar to the grain industry and, in fact, are common in most industrial facilities. However, grain dryer fires, conveyor belting fires, bucket elevator fires, and grain fires provide unique fire challenges. Fire challenges can be dealt with as described in the National Grain and Feed Association's publication, entitled *Emergency Preplanning and Firefighting Manual: A Guide for Grain Elevator Operators and Fire Department Officials.* Some typical considerations and factors to consider for several types of grain facility fires are discussed below.

The grain dryer's most potentially severe fire hazard is that of igniting the grain or grain dust and extraneous material that has accumulated on ledges and surfaces inside the dryer. The large amount of heat needed—in some dryers, more than 20,000,000 Btu/hr (21.12 million kJ/hr)—combined with the large size—up to 80 ft (24.4 m) high—requires good operating procedures and proper maintenance of safety devices, such as temperature sensors, UV flame detectors, limit switches, and fuel cutoff devices.

In addition to the preventive measures used to reduce the possibility of a grain dryer fire, each elevator must have an emergency plan for dealing with a fire. The size and unique design of a grain dryer make fighting the fire with hose streams difficult. Probably the most effective consideration in fighting a dryer fire is moving the burning grain to a safe area away from the elevator where water can be selectively applied. In some cases, small smoldering fires in dryers can be removed manually by shoveling the smoldering material into a bucket and removing it to a safe location. For modern grain dryers, a means can be provided for unloading (emergency dumping) of the dryer contents to a safe location so a fire exposure is not created for adjacent buildings, structures, or equipment. One common method is to place a door or chute on the dryer discharge conveyor for emergency dump purposes.

The hazard of grain itself igniting must also be addressed from a preventive, as well as a fire fighting, standpoint. Preventive measures are basically to keep open flame (e.g., welding, torch cutting, cigarettes) and hot surfaces or objects away from the grain. Once grain ignites, it can become quite difficult to extinguish and, if the extinguishing method creates a dust cloud, an explosion is likely. A permit system should be used to control hotwork, such as welding and cutting. The application of large amounts of water in a storage bin will not only deteriorate the grain, but, in the case of soybeans, could cause enough swelling

of the soybeans to rupture the bin itself. A bucket elevator fire is of great concern, since internal dust concentrations can result in a dust explosion. Elevator management should consider meeting with local fire departments to review emergency procedures should a grain fire occur.

Conveyor belting fires are difficult to deal with because of the intensity of the fire and the amount of smoke and vapors given off. Belting fires once ignited are difficult to put out and require large amounts of water to control. If a belting fire cannot be extinguished, consideration can be given to cutting the belt and dropping it to isolate the fire and prevent it from spreading.

Grain bin fires can be particularly difficult to deal with depending on the fire's location and the quantity of grain involved. Bin fires should be approached as a potential explosion hazard. Air sources, such as aeration fan openings and portals, should be sealed off to limit the source of oxygen. If water is applied into the bin, a fog spray is recommended to wet down the dust on top of the bin, including any accumulations under the bin top roof, being careful not to create a dust cloud. Small surface fires can be extinguished using a fog nozzle and removed from the top manually or with the use of a pneumatic evacuator. Fires on the top surface of grain in concrete silos can be controlled by using carbon dioxide to blanket the top of the grain. However, the use of carbon dioxide to extinguish deep-bedded fires is often not successful. If burning or suspect grain is allowed to flow from the bin, it should be directed to the outside by spouting or conveyed to the outside using portable augers or evacuators. Suspect grain should never be handled in bucket elevators or other enclosed equipment. Deep-bedded fires in grain bins or inside large grain storage structures can be the most difficult to deal with because of the amount of grain to be handled and the difficulty of locating and accessing the fire. If a pipe or hose can be probed to the fire area, it is possible to apply water to that portion of the grain mass. It is nearly impossible to apply water to the grain surface to put out deep-bedded fires, and the application of excessive amounts of water can create structural hazards and can destroy grain that can otherwise be reclaimed. In large flat structures, it might be possible to remove the grain with mobile equipment (front-end loaders) or to selectively unload portions of the grain mass to access the fire.

In all cases of dealing with a grain fire in storage structures, a careful plan should first be established to deal with such fires, following these principles: (1) stop the grain flow; (2) seal off all openings that allow oxygen to reach the fire, including shutting down aeration or roof exhaust fans; (3) use fogging nozzles to wet down dust and grain; (4) do not allow high-pressure water streams to be applied that could create dust clouds; (5) carefully consider how suspect or burning grain will be removed from storage; and (6) do not needlessly expose anyone to the fire or a dust explosion hazard.

Another potential fire hazard in grain elevator operations is the use of propane and natural gas. Both are used for grain drying or comfort heating. They present a serious fire hazard in grain operations because of the presence of below-grade areas in grain elevators and because the heavy rail or truck traffic can cause deterioration in underground pipes. If a break occurs, the gas or propane vapors can seep into the below-grade tunnels until discovered or ignited. Elevator management should insist that such gas and propane lines be installed according to NFPA codes, and maintained regularly.

EXPLOSION HAZARD

Dust explosions must certainly be considered the number one hazard in the grain industry. The first recorded grain dust explosion incident is reported to have occurred in 1785.[5] However, recognition of dust explosions was not common until the late 1800s. Figure 9.7.10 shows the number of dust explosions, injuries, and deaths that have occurred from 1976 through 2005. Figure 9.7.11 indicates a trend that the incidence of dust explosions and their severity have continued to decrease from 1976

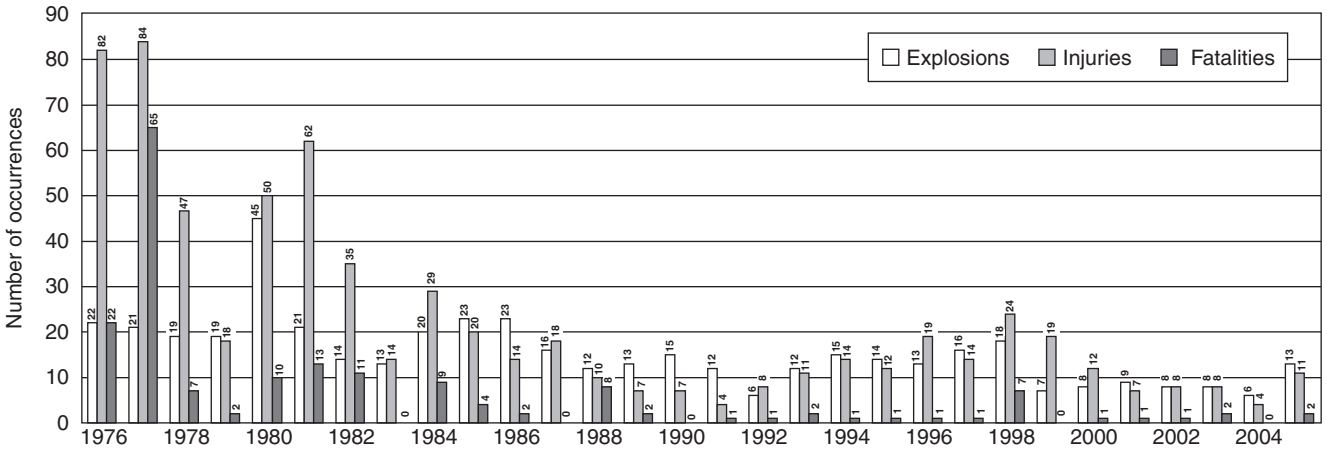


FIGURE 9.7.10 U.S. Agricultural Dust Explosions, 1976–2005 (Source: Schoeff, R. W., Kansas State University, in cooperation with FGIS-USDA)

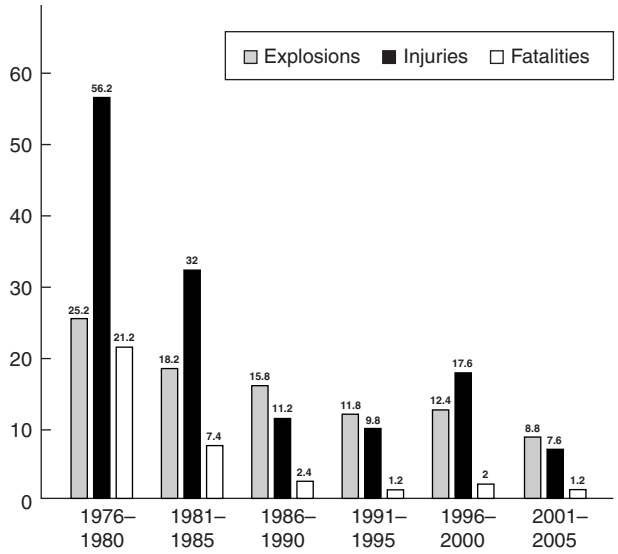

FIGURE 9.7.11 U.S. Agricultural Dust Explosions in 5-Year Increments, 1976–2005 (Source: Data compiled from Jacobsen et al.[9] and Lilienfeld[10])

through 2005. Table 9.7.3 shows the locations of primary dust explosions, indicating that bucket elevators, storage bins, hammer mills, dust collectors, and enclosed equipment are the areas where explosions often initiate. Figures 9.7.2 through 9.7.4 show the severity and type of damage that can occur from grain dust explosions.

Explosion Characteristics

Secondary explosions occur when the primary explosion pressure wave disturbs dust layers, creating a dust cloud that is ignited by the flame front, causing a more severe and damaging explosion. The flame front travels much slower than the pressure wave, which may allow reaction time to avoid fire and explosion hazards. Table 9.7.4 indicates the probable ignition sources that have been identified in the past explosions. Welding and cutting operations, fires, overheated bearings, and electrical failures are among the most frequent explosion ignition sources. An analysis of available information for dust explosions during the period from 1958 through 1995 is presented in Table 9.7.5. Incidents during the time period between 1995 to 2000 appear to show similar trends for probable location and cause of the primary explosion, but evaluation of available data has not yet confirmed this.

Research on Explosions

As a result of increases in grain dust explosion incidents and fatalities in the late 1970s and early 1980s, the industry, through the National Grain and Feed Association, established a Fire and Explosion Research Council to increase the industry's understanding of known causes of explosions and to conduct research into the basic factors contributing to grain dust explo-

sions. This research has revealed a number of options for helping to prevent explosions and created a better understanding of their causes. Major accomplishments of research included better guidelines for venting of explosions in bucket elevators and the use of explosion suppression systems to control bucket elevator explosions. Figure 9.7.12 shows a dust explosion test of a bucket elevator conducted by Fenwall, Inc., for the National Grain and Feed Association in 1979. Vents were located along the "leg" casing and in the head section. The testing determined venting criteria to be used on bucket elevators. Also tested was the use of explosion suppression systems. Explosion venting of grain bins and grain galleries was also studied, resulting in a better understanding of explosions of these structures. Figure 9.7.13 shows a dust explosion test conducted in Norway by Dr. Rolf Eckhoff. The research tested explosion venting of grain bins. The large fireball, at the top, shows the initial venting. The flame beginning to come out of the right side shows the bin splitting open on the side. This illustrates the difficulty of venting elongated grain bins. Because of their large length to cross-sectional width or diameter ratio, these structures are difficult to explosion vent, except for mild or limited explosions.

Bearings were identified as a significant factor in dust explosions, requiring good maintenance practices. Metal sparking and electrostatic sparking were also studied. The research showed that electrostatic sparks were not generally a problem, except under special circumstances where there was high charge generation and poor grounding. The major problem with metal sparking was determined to be high-speed grinding equipment and frictional sparks from mechanical failures or objects becoming lodged in equipment. In addition to the above, the research focused on identifying design methods that could be used to help minimize grain dust explosions.

Elements of a Dust Explosion

The elements of a grain dust fire or explosion are almost axiomatic; namely, that to be initiated and sustained there must be fuel, oxygen, and an ignition source. To have an explosion,

FIGURE 9.7.12 Dust Explosion Test of a Bucket Elevator

a fourth element, confinement (which confines the rapidly expanding heated gases of combustion within a constraining enclosure until the pressures exceed the ultimate strength of the enclosure), is necessary (Figure 9.7.14).

The precise circumstance under which an explosion of a grain dust will occur is a complex combination of dust particle size; concentration in the air (oz/ft^3 [g/m^3]); the energy of the ignition source; and less easily determined factors, such as the moisture content of the dust (or percent relative humidity of the air) and the actual composition of the dust. Dust from each agricultural commodity has its own explosion characteristics. Although researchers have not agreed precisely on the limits of the various characteristics of a particular dust, their conclusions are generally within an acceptably narrow range. Studies of explosibility of agricultural dust show that the minimum explosive

FIGURE 9.7.13 Dust Explosion Fire Testing Explosion Venting of Grain Bins

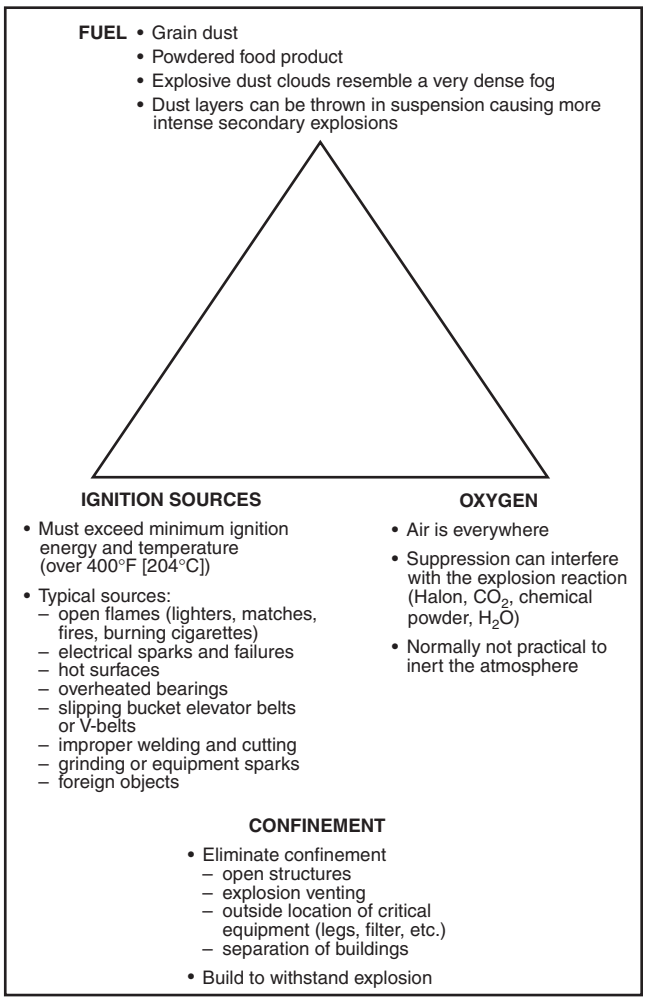

FIGURE 9.7.14 Dust Explosion Elements

concentration needed for an explosion ranges from 0.025 to 0.5 oz/ft^3 (25 to 500 g/m^3).[9] Grain dust generally varies from 0.025 to 0.055 oz/ft^3 (25 to 55 g/m^3) (Table 9.7.6). Suspended dust concentrations of this type represent a severely dense cloud through which a 100 W light bulb cannot be seen at a distance of approximately 9.8 ft (3 m) or one's hand cannot be seen at arm's length. Such dust concentrations make breathing extremely difficult. Some of the highest dust concentrations occur inside bucket elevators, grain bins, scale garners, and other enclosures. Maximum explosive pressures can exceed 100 psi (690 kPa), with the maximum rate of rise of pressure approaching up to 8500 psi/sec (58,608 kPa/sec), which is an indication of the intensity and speed of a grain dust explosion. When the rate of rise of pressure is higher, explosions are more severe.

Fuel. Dust particles emanating from various emission points within a grain elevator are of varying composition and of a wide range of sizes. It is generally agreed by researchers that particle sizes below 100 microns constitute the greatest hazards.[10] A considerable portion of the dust within the elevator environment is smaller than 100 microns. Larger particles tend to settle out rapidly (Table 9.7.7).

Although it seems improbable that such a dense cloud would exist within the ambient space of an elevator structure where personnel are present, such concentrations have been measured within the confines of bucket elevators and can also occur in conveyor housings, bins being loaded, silos, dust collecting systems, and connecting spout work.

The mechanism of an explosion depends on the immediate heat release of a burning particle to ignite and support the burning of adjacent particles.[5] As this rapid spread of flame proceeds from particle to particle, pressure waves and thermal expansion of the air can create an intense shock sufficiently strong to rupture the typical reinforced concrete structure. In studies performed by the U.S. Bureau of Mines,[9] the maximum pressures for corn dust are greater than 100 psig (gauge pressure of 690 kPa). Concrete structures found in elevators can usually withstand no more than 25 psig (172 kPa). Most grain-handling

equipment enclosures fail at pressures less than 6 psig (gauge pressure of 41.4 kPa).

Suspended dust is not the only fuel with which to be concerned. Dust accumulation on floors, walls, rafters, and equipment can become suspended if disturbed by vibration, fires, or small explosions. If this accumulated dust is suspended in sufficient concentration, the resulting explosive dust concentration can become ignited and progress into an explosion. This resuspended dust can encompass large volumes and propagate explosions through an entire elevator. This illustrates the importance of keeping overhead surfaces and ledges clean of excessive dust accumulations.

Ignition Sources. The second most important element of a grain dust explosion is ignition of the suspended dust cloud by a source of energy of sufficient intensity and duration. One ignition source is improper use of welding and cutting equipment. Other potential ignition sources include fires and heat caused by the frictional energy of mechanical equipment, such as bucket elevators, bearings, and belt drives. Heat or arcing caused by the failure of electrical equipment, such as lighting, motors, and wiring, has also been identified as an ignition source. Miscellaneous ignition sources include open flames from matches or smoking, space heaters, lightning, and internal combustion engines on vehicles such as industrial trucks.

Torches and electric arcs used for hot work represent one of the most intense energy sources used at grain facilities. These sources can quickly ignite dust and construction materials. Welding and cutting is also a concern in the grain industry, because many elevators do not have full-time maintenance personnel. This results in unsupervised contractors performing welding operations within the grain elevators. These contractors might be unfamiliar with the fire and explosion potential of grain dust and need to be monitored by elevator management. A formalized hot work welding and cutting work permit should be established to help control hot work operations.

The majority of known locations of explosions in grain elevators stem from the bucket elevator, so it would follow that this single piece of equipment presents the most serious ignition hazard to the grain handler.[7,8] This conveyance produces ignition energy in a number of ways. Overloading or stalling of the belt generates intense frictional heat on the revolving drive pulley. This has been known to burn the belting to the point of failure, allowing the severed and flaming pieces to drop within its housing. Failure of belt splices could lead to the same results.

Misalignment of belts can cause the "leg" casing to become hot enough to ignite combustible materials, such as dust or lubricants. The misaligned belt itself probably does not get hot enough to ignite while it is moving, since it has the chance to cool as it moves, but might ignite after the equipment is turned off and the belt is stationary next to the hot casing.

Another potential ignition source associated with bucket elevators is overheating bearings. Some older conveyor designs have tail or head pulley bearings located inside of the casings. If these bearings overheat, they can provide sufficient heat for ignition of static or suspended dust. Even bearings located outside of casings can ignite layered dust, which can be drawn into the "leg" casing by the dust collection aspiration or the "air pumping" action of the "leg" itself.[7]

Extraneous foreign material, such as scrap metal, tools, wood, stones, or pieces of concrete, is also a concern within a bucket elevator. Such material might or might not produce sparks with sufficient energy to ignite dust, but certainly can result in plugged spouts, damage to the belting, or deformation of the elevating buckets. When this occurs, the chances of belts stalling or continuous frictional rubbing are increased. The use of grating to reduce foreign objects from entering the grain receiving pit and subsequent handling equipment is common at most facilities. Most grates are set 2½ in. (63.5 mm) apart, with varying lengths of the opening. The grate size can be adjusted for the commodity; for example, a smaller opening can be used for wheat than for soybeans in southern locations or for receiving corn cobs. Many processors, millers, and grain export facilities rely on magnets on the receiving grain stream to capture tramp metal.

Nonconductive belting moving over the pulleys in bucket elevators can create significant static electricity on the buckets. Research indicates that sufficient energy to initiate a dust explosion is not released from this static discharge, but prudent practice is to reduce this static accumulation by using electrostatically conductive belting and good grounding practices.[14] OSHA calls for belting to have a surface resistivity less than 100 megohms. Rubber belting has typical resistivity of 1 megohm, and PVC belts are typically 15 megohms in resistivity.

The energy inherent in electrical systems is extremely high, but can be minimized as an ignition source by strict adherence to the provisions of NFPA 70, *National Electrical Code*® for the appropriate hazardous area classification. For areas that have an exposure to higher levels of airborne and layer dust, electrical equipment is normally rated as explosion proof for Class II, Division 1, Group G areas. Other areas can be rated for electrical equipment that is suitable for Class II, Division 2 (dust-tight), Group G locations. Many in the industry choose to utilize electrical equipment that has a dual rating for Class II, Divisions 1 and 2, Group G areas to avoid the problem of the wrong equipment getting in an area. The importance of proper electrical equipment applies to both fixed and portable equipment. This consideration is important for portable electrical devices, lighting, low-voltage control circuitry, extension drop-lights, and communications equipment.

Oxygen. The oxygen concentration required for a dust explosion is the same as that found in the atmosphere. Using inert gases in equipment to reduce the oxygen concentration enough to prevent explosions has been suggested, but has limited application due to the large size and volume of grain-handling equipment. Processing equipment, such as hammer mills, may be more likely candidates for inerting.

Confinement. As with all dust explosions (except detonations), the pressures generated after ignition of a grain dust explosion increase until the fuel or oxygen is consumed or until the explosion is vented. If there is no confinement (i.e., unlimited venting), explosion pressures are minimal and the incident should more properly be called flash fire. On the other hand, as confinement increases, the explosion pressures can build up to levels over 100 psig (690 kPa). Grain elevator structures and equipment cannot withstand pressures anywhere near these levels, so considerable damage will occur, unless these pressures can be vented. Due to structural considerations, most existing grain elevators would be nearly impossible to retrofit with adequate venting, but newly designed elevators are adaptable to increased venting and the resulting reduction in explosion confinement. Deflagration venting must be done to the outside of the facility to avoid secondary explosions or danger to personnel. Although the levels of recommended venting are not always possible, some venting is better than no venting when feasible to help eliminate pressure development during an explosion.

An alternative to deflagration venting is explosion suppression, during which a chemical is injected into equipment during the early stages of explosion development to stop the process. The chemical can interfere with the combustion reaction, or inert the environment (CO_2), or cool the process with a water spray. Suppression systems can be specifically engineered for a piece of fixed equipment.

The construction of structures and equipment that can totally contain an explosion is generally not practical, with the exception of hammer mills, which can often withstand the explosive pressures. However, the transmission of pressures and flames to connecting equipment can present explosion problems.

The only other means of dealing with confinement is to provide separation between buildings and structures to help minimize the propagation of an explosion. NFPA 61 recommends that a separation of 100 ft (30.5 m) be provided between personnel-intensive areas and concrete elevator headhouses and silos. Some exceptions are allowed, based on the location of bucket elevators (outside), type of construction (damage limiting), or property size. The concept of separation can be taken into account for major modifications or new facilities, but is often impractical for existing facilities.

SAFEGUARDS

Building Design

NFPA 61 can assist designers of grain-handling facilities. The standard devotes considerable attention to the physical structure. NFPA 61 is not intended to apply to existing facilities, which might have been constructed prior to its publication; however, major modification or expansion made to an existing facility should enhance safety to life and property. The following discussion summarizes industry trends concerning the design of new facilities.

The traditional design approach to grain elevator facilities has been to construct upright storage silos of reinforced concrete or steel. The facility has a high contiguous structure known as a headhouse, with inside-located bucket elevators to elevate the grain high enough to pass through necessary scales, samplers, garners, cleaners, and distributors by gravity into the storage bins. Figure 9.7.6 illustrates the traditional grain elevator design. Structures are constructed of noncombustible materials. There has been a constant evolution of facility design to meet the larger grain productions and to be able to handle higher flow rates with more automation. Higher throughput facilities have evolved to load unit trains in excess of 100 railcars (3300 bushels [119 m^3] per railcar) or several barges (up to 60,000 bushels [2160 m^3] each) a day. Equipment has also changed to meet these new demands. Facility owners have also been concerned with safety and the elimination of fire or dust explosion hazards and make changes, as resources permit.

Modern design has moved toward the elimination of the enclosed elevator headhouse.[15,16] Bucket elevators are placed outside the facility or inside structural steel or reinforced concrete frameworks to eliminate the element of confinement (Figure 9.7.15). The bucket elevators then elevate the grain to the top of storage to distributors that connect to turnheads, which spout directly into bins or to enclosed conveyors, which move the grain to bins, eliminating the enclosed gallery above the bins (Figures 9.7.16, 9.7.17, and 9.7.18). Some large terminals, particularly export facilities, have used inclined belt conveyor systems in lieu of bucket elevators (see Figure 9.7.1). These incline designs convey the grain to separate weighing and cleaning towers. Enclosures, such as dust collectors, bucket elevator housings, and ancillary structures, are often designed to relieve explosion pressure waves as much as possible, should such an incident happen. This is not always physically possible, because of the very nature of the configuration of the enclosure.

FIGURE 9.7.15 Open Tower Structure and Deflagration Relief Venting in Corpus Christi, Texas, Public Elevator

FIGURE 9.7.16 Headhouse Concept Eliminated in This Superior, Wisconsin, Elevator

According to NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* numerous methods have been proposed for calculating the vent area for an enclosure. Some venting models have used the surface area of the enclosure as a basis for determining vent area. Analysis of available data shows that such methods overcome certain deficiencies of previous methods of calculating vent area.

The use of doors, windows, multiple explosion-relief panels, and light-gauge structural coverings on steel structures is a

FIGURE 9.7.17 Naples, Illinois, Terminal Elevator Company with Deflagration Venting Technology Incorporated on Bucket Elevators and Headhouse Structure Left Open on One Side

practical approach to an acceptable design. Stairwells and elevator shafts, where they are enclosed, should be protected with approved fire doors.

Fire walls of approved design can be provided to separate the grain-handling function from adjoining grain-processing operations, such as flour milling, preparation for oil extraction, feed milling, or grinding. Where tunnels, basements, or other underground structures can be avoided, the alternate use of ground-level or aboveground structures can give opportunity for maximum openings to the atmosphere.

Where sufficient land area is available, the placement of structures for weighing, cleaning, and other operational functions can be remote from silo storage and interconnected with inclined belt systems.

All surfaces, bin bottoms, and spout inclinations should be designed to be self-cleaning when the grain or grain products flow. Structural ledges, beams, or other horizontal surfaces should be designed, where practicable, with an inclination of a minimum of 60 degrees from the horizontal to prevent gradual buildup of static dust. Where possible, design should accommodate the washing down of accumulated dust on vertical walls and overhead structures with water.

Where possible, the placement of bucket elevators, in open air, apart from the structure should be considered. Additionally, office buildings, employee break rooms, maintenance shops, inspection labs, and control rooms should be located remote from concrete structures when constructing new elevators.

Mechanical Design

Many devices are available to detect, warn, and control faulty operation of mechanical equipment or their components. Many of these systems were neither available nor sufficiently developed for use in Class II, Group G, dust atmospheres until recent years. Among them are hot-bearing sensors, speed indicators, alignment devices, level-sensing gauges, slowdown detectors, overflow alarms, and pressure gauges, all of which can serve to indicate or react to malfunctioning units. Particularly important among these are the speed indicator and alignment devices for monitoring bucket elevators. If properly designed, installed, and monitored, these devices can prevent ignition from stalled and rubbing belting.

A combination of mesh screens, grating, scalpers, or magnets will prevent large extraneous material and metal from entering into the grain handling machinery. Depending on individual elevators, permanent or electromagnets, large-mesh screening, grizzlies, and specific gravity separators might be appropriate. Their use is particularly important just prior to the point where the grain enters hammermills or other types of grinders.

Dust Control Measures

The need for adequate dust control has been established. Dust control in elevators, however, should not be limited to installation of dust collection systems, but should be a systematic approach to dust control. This systematic approach should include designs that limit the amount of dust liberated from the grain, mechanical dust collection at grain transfer points where dust occurs, containment of dust to selected points where mechanical dust collection can be effective, reduction of dust concentrations within equipment, maintenance of dust collection equipment, and manual housekeeping to complement mechanical dust control.

The design of dust collection systems must provide sufficient capture velocity at the point of emission, particularly at conveyor loading and discharge points. Design must also provide sufficient air velocity (typically between 3500 and 4000 ft/min [1068 to 1220 m/min]) within the ducts to prevent settlement of the particles and subsequent plugging. Blast gates and fresh-air inlet dampers are necessary to balance the airflow to all points served by the system so that starving of some remote emission points is avoided. Operators must understand the dust collection systems, so that they can monitor and maintain their effectiveness on a daily basis.

If a baghouse or fabric filter is used, the porosity of the filter media must be maintained to avoid diminishing the airflow. High humidity and fine dust particles can form a cake on the bags and reduce the air passage. In such instances, replacement or laundering of the bags is necessary (see NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids,* and NFPA 654, *Standard for the Prevention of Fire and Dust Explosions from the Manufacturing, Processing, and Handling of Combustible Particulate Solids,* for further information on the application and design of air-moving systems).

Containment of dust to selected points or the proper return of the dust downstream of the capture point not only makes the mechanical dust collection system more effective, but also limits the amount of manual housekeeping effort needed to reduce accumulated dust.

Typical methods to reduce dust liberation from grain include reducing the distance and velocity grain is allowed to free fall onto conveyors or from spouting. (Choke feeding, where possible, is the best approach to limit grain velocity). Reduction of conveyor belt speeds and adequate belt tension can both be effective dust control methods where horizontal belt conveyors are used. Well-designed transition points that do not have abrupt changes in direction can also limit the amount of dust liberated from the grain. Additives, such as soybean or mineral oil, are used as an additional method to control dust.

Regardless of the facility design or amount of mechanical dust collection, manual housekeeping efforts are important in grain elevator facilities. Although safe levels of accumulated dust are impossible to determine, housekeeping programs at each facility should be designed to keep the dust accumulation at the lowest feasible level. This housekeeping program should focus on not only grain dust but also any type of combustibles to reduce the possibility of their providing an ignition source for a dust explosion. Good maintenance to spouts and other equipment leaking grain dust is also an essential element to explosion prevention. In addition, proper safety procedures must be followed to avoid ignition sources while blowing down overhead ledges. Some facilities use vacuum systems to clean overhead and floor areas in lieu of blow down or they use periodic wash down of some areas, such as reclaim tunnels. Further, new techniques are sometimes used to pressurize key areas of a facility to prevent dust from escaping the equipment.

Electrical Design

Electrical wiring and equipment in grain dust environments should be installed in accordance with the appropriate articles in NFPA 70. These articles need to be thoroughly understood by those installing or maintaining electrical equipment in a grain

elevator facility. Individual paragraphs in these articles cover equipment requirements for maximum surface temperature, transformers and capacitors, surge protection, wiring methods, switches/breakers, and so on; motors; ventilating piping; utilization equipment; lighting equipment; flexible cords; receptacles and plugs; signal and communication systems; live parts; and grounding. No attempt is made here to paraphrase these articles. The reader is encouraged to review the most current edition of NFPA 70.

Away from the technical requirements of NFPA 70, the development of economical and miniaturized electronic components for use in Class II, Group G atmospheres has made the operation and control of grain elevators more sophisticated and less labor intensive. Remote control of the entire facility from a centralized control center is now a reality in new installations. This technological advance has dictated the need for redundant detection of malfunctions, since people are no longer in an operating area to observe the minute-by-minute activity.

The more common safeguards include electrical interlocking to simultaneously shut down all activities in a sequenced fashion when one unit of a sequentially connected operation fails. Annunciator panels can display the exact cause of shutdown to the operator. Ammeters and load indicators can depict the exact weight being carried by conveying equipment. Spring-return pneumatic devices can activate shutdown conditions even in a total power failure. Fully electronic scales now safely transmit millivolt differentials, detected by a load cell or strain gauge, to a remote amplifier for direct conversion into information on weight.

Maintenance

A preventive maintenance program is essential not only to ensure trouble-free operation and to minimize breakdowns, but, in grain elevator facilities, it is also a critical safeguard for eliminating ignition sources. This preventive maintenance program should include lubrication of bearings, checking of belt splices, replacement of bent or missing bucket elevator cups, and the early remedy of leaking, worn-out spouting.

Dust filters should be checked frequently for plugging, excessive pressure drop, and worn or poorly sealed rotary airlocks. Ductwork in the aspiration system should be free of plug-ups and bent ducts, and blast gates should be opened or closed consistent with system balancing.

Electrical junction boxes should be kept closed and lighting fixture protective globes kept in place. Whenever maintenance work on the electrical systems is performed, qualified personnel should ensure that the power is disconnected or that hazardous dust concentrations are not present.

Welding and any other hot work should be rigidly controlled by facility management. The use of a written "hot work permit" is generally the best system to ensure that hot work is not performed in the presence of explosive dust concentrations. This is particularly important with contractors whose employees might not be aware of the dust explosion hazard.

Improved maintenance diagnostic equipment can also be effective in monitoring equipment that could become an ignition source for an explosion. This diagnostic equipment includes bearing temperature monitors, bearing vibration monitors, and infrared analysis of electrical and mechanical equipment.

Fire Control Systems

Grain elevators have few applications where traditional automatic sprinkler systems would provide much protection. The nature of the explosion hazard is such that, even if sprinklers are installed, the lines would likely be ruptured by the shock waves. Additionally, explosions are normally initiated so rapidly that fusible links would have insufficient time to react. Combine this ineffectiveness with the lack of combustibles present and the catastrophic damage that could result from water leaks sweeping into grain storage bins, and it becomes clear that general-purpose automatic sprinkler systems would do little to mitigate damage from an explosion hazard. There are, however, several specific applications where sprinklers, fixed water spray nozzles, and explosion suppression systems can be effective. Strategic location of fire extinguishers throughout the facility and near major potential ignition sources, such as major drive units, is important to allow personnel to deal with small incipient fires before they create more serious concerns.

Wood elevators, which have a significant fire hazard potential, as well as the explosion hazard, are the major exception where automatic sprinkler installation can be justified. Additional specific applications where sprinklers or fixed water spray nozzles can have some benefit are (1) within the drive pulley enclosure of bucket elevators; (2) at remote, elevated belt gallery structures where manual fire fighting would be impossible; (3) in some tunnel areas where access is difficult; and (4) within some grain dryers in which, because of design, it would be impossible to use hose streams effectively.

Explosion suppression offers the grain industry a possible tool to reduce the number of explosions. Explosion suppression technology (i.e., rapid detection of incipient explosion and immediate introduction of suppressing agent) has been used effectively in other industries for some time. Recent research efforts directed at applying the technology to the grain industry have resulted in the development of self-contained explosion suppression devices that are suitable for installation on bucket elevators.[17] Application of hose streams within an elevator where the possibility of a dust explosion exists must be a well-considered endeavor. Any application of high-pressure water or use of a fire extinguisher that disperses accumulated dust must be avoided to prevent an airborne dust concentration that could be ignited.

SUMMARY

Much of the preceding discussion is a reiteration of concepts and principles known by the grain-handling industry. The devices, systems, and machinery now available are much more extensive than in earlier years. There are over 10,000 grain elevators in the United States, ranging from crossroad country stations to newly constructed export facilities. Many of these newer facilities have incorporated the devices mentioned above.

In spite of this, grain dust explosions still occur although at a lower incidence rate than in past years. In many instances, the

exact location of the primary explosion and ignition source are not precisely known. However, this much is known: the initial explosion has the characteristic of transmitting pressure waves, vibration, and air movement throughout the facility, which could result in other deposited dust being thrown into suspension. This additional dust might have been lodged on the ledges, beams, walls, floors, and inaccessible places and is exposed to the progressing flame front. The result is a series of additional explosions known as secondary explosions.[18]

In summarizing the potential hazards associated with the handling and storage of grain, one must remember that dust is a powerful fuel. Constant awareness and proper training of all who work in the facilities is essential to continue the recent trend of reduced numbers of explosions. Prudent consideration of the inherent dangers requires respect, care, and adherence to building codes and regulations in the design and construction of each facility. Once the facility is built and operating, each day requires positive management appreciation of the inherent dangers, and action to ensure that all those working in the facility understand the basics of proper operations, maintenance, safety, housekeeping, and training.

If it is assumed that some dust will always be present within the grain elevator facility, the elimination of the explosion hazard can only be accomplished by controlling the dust and removing its ignition sources.

Although the explosive growth in the use of personal computers promised us a "paperless office," the reality is a massive increase in the total volume of paper records that are generated, plus an acceleration of electronic records. This increase has intensified the problems involved in protecting records from fire. Traditional fire-resistive containers, such as insulated file cabinets, safes, and vaults, have not lost any of their capabilities to protect paper records. In fact, recent advances have introduced devices that can safeguard magnetic and photographic records. In many cases, however, the volume of records material has become so great that it is considered impractical to invest in either the devices or the space that is required to safeguard all the records to the level of protection that is justified. New methods of records storage have been developed that use the maximum cubic capacity of the area assigned to records storage. Some of these storage arrangements not only place the records at risk but also contain sufficient fire potential to be a danger to the structure and all other operations housed in it.

This chapter discusses ways of identifying and classifying valuable records to determine the amount of protection, justified by their value, against fire and its associated perils. The relative susceptibility of various records to flame, heat, smoke, and water exposure is discussed. Because water damage can be a serious by-product of fire containment efforts, information on salvaging water-soaked documents is provided. The different ways in which the risk of extensive loss of valuable records can be mitigated are considered. Protection against perils not associated with fire is not discussed.

Detailed discussions of the best ways to provide maximum reasonable protection for records are contained in NFPA 232, *Standard for the Protection of Records,* most recently updated in 2007. NFPA 232A, *Guide for Fire Protection for Archives and Records Centers,* was discontinued. The material suitable for enforcement or guidance has been incorporated into NFPA 232. Further information can be found in "Protecting Federal Records Centers and Archives from Fire,"[1] and the reference book *Protecting the Library and Its Resources.*[2]

Adequate provisions must be maintained for the safety of persons in records storage facilities. This can be a particularly difficult task when the facility is designed to provide maximum security of its contents against illegal entry. However, emergency exits are necessary to ensure life safety for persons in the records area in case of fire, even at some compromise in security.

For related topics, see Section 16, Chapter 5, "Sprinkler Systems for Storage Facilities"; Section 17, Chapter 1, "Carbon Dioxide and Application Systems"; Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems"; Section 19, Chapter 2, "Structural Integrity During Fire"; Section 20, Chapter 16, "Storage Occupancies"; and Section 20, Chapter 17, "Library and Museum Collections."

STORAGE OPTIONS

Bulk Storage

Bulk storage of records creates a fire hazard in itself. Bulk storage describes any sizable collection of records not contained in vaults, safes, or insulated cabinets. This includes collections of

James A. Beals is a senior fire protection engineer in the Arlington, Virginia, office of Jacobs Engineering. He has over 27 years in the practice of fire protection engineering and serves as the chairman of the Technical Committee for the Protection of Records.

records ranging from small file rooms to the largest archives or records centers. Storage methods include, but are not limited to, file cabinets; various types of shelving, including open shelves and mobile shelves; palletized cardboard boxes; transport cases; miscellaneous cardboard boxes; and devices for unusually shaped records, such as blueprints, magnetic tapes, photographic film, and other media. Locations range from an area within a general office complex to specially built records facilities. It is not uncommon to house record collections in basements or attics of public buildings, in office buildings, in converted factory or warehouse buildings of various constructions and levels of quality, in public warehouses, underground, including storage in mines, and in facilities protected against war-time perils.

Open-Shelf Storage

The trend toward making the maximum use of available space in buildings has often resulted in using open-shelf storage methods, normally with the records held in either file folders or various kinds of cardboard boxes. Typically, the racks of records face each other across 25 to 30 in. (600 to 750 mm) aisles. The aisle exposure presents a wall of paper made up of the sides of boxes or loose ends of paper sticking out of file folders. They can be easily ignited by any ignition source, such as a match, a cigarette, a portable heater, faulty fluorescent ballast, or by an exposed incandescent lightbulb. Paper ignites at a relatively low temperature. Ignition of a few pieces of paper on a filing cart, for instance, can readily transmit ignition to the boxes.

Attempts have been made to develop economical methods for increasing the flame resistance of the typical records center cardboard boxes. A popular method is coating the box with an intumescent type of fire-retardant paint. Such paint, properly applied, will substantially delay actual ignition of the cardboard box material. However, since intumescent paint does not effectively react to heat under about 400°F (204°C), the temperature of any modest exposure fire (such as might occur on a file cart) will weaken the paper in the box to the point where the box will break open under the weight of the paper it contains and expose the ordinary combustible contents of the box to ignition.

An additional consideration for fire protection and storage professionals is the lack of control of the contents of the cardboard boxes used for storage. Typically the owner of the records to be stored packs the boxes off site. The boxes are then picked up, transported to the storage site, and placed onto shelves or racks by the storage provider. The boxes are most likely never inspected as to contents and arrangement. Regardless of any contractual requirements that may exist between the owner of the records and the storage provider, effective control of what is actually in the storage box is not with the parties responsible for storage and protection.

Full-scale fire tests were conducted in December 1974 in untreated boxes of paper records stored on open steel shelves 13 ft (4 m) high.[1] Sprinklers were adequate to control the fire, but the fire developed very rapidly anyway. From a small ignition source, flames reached the top of the rack in 4½ minutes. Eight seconds later, the facing array of boxes across the 30 in. (0.75 m) aisle flashed into flame from top to bottom. The first sprinkler had a 286°F (141°C) rating* and activated in a little more than 5 minutes. By then, the ceiling temperature directly over the fire had reached 1900°F (1038°C). The direct cause of the intense fire was rupture of the walls of the cardboard cartons and the release of the contents. Paper records exfoliated into the aisle and many burned while falling. A test was conducted with an identical arrangement, except that unboxed files were oriented perpendicular to the aisle, which exposed the edges of paper to easy ignition. In this test, fire spread at a leisurely pace and did not develop into an intense fire. The basic difference in the rate of fire growth between these two fire tests was that in the second test, the paper could not exfoliate into the aisle and no fire storm resulted. The progress of the fire can also be dramatically changed by changing sprinkler temperature ratings, response time, and sprinkler drop size characteristics.[3] Some sprinklers especially designed for fast response to fire exposure would be expected to reduce fire spread, heat rise, and extent of fire damage under similar conditions.

It is important to note that many agencies, both public and private, require that records stored on their behalf be oriented perpendicular to the aisles. However, effective control of the paper arrangement within the boxes is given to the individuals actually placing the files in the storage boxes. The people who develop economics associated with efficient box placement and storage configurations give little thought to the arrangement of the paper files within the boxes.

During a test conducted in December 1999[4] in 30 ft (9 m) high shelving, a single ½ in. (12.5 mm) 155°F (68°C) quick-acting in-shelf sprinkler controlled the fire, which at the time of sprinkler activation had a flame height of 12 ft (3.7 m) above the floor on each side of the aisle. Box fronts were failing and exfoliation of records was in process. The operating sprinkler was located above the lower catwalk, but flaming had not reached the lower catwalk; exfoliation had not started above the catwalk and falling paper was limited to the building floor.

This test was successful in meeting the test criteria of controlling the fire with considerably fewer destroyed records than allowed in the test criteria. It is quite possible that a rerun of this test could result in ignition and exfoliation above the catwalk and operation of two or three additional sprinklers and still have a perfectly acceptable outcome. Quick-acting water spray sprinklers are very well suited to controlling a records fire. The trickiest part is locating in-stack sprinklers so they are activated

*Bulk storage of records has generally been classified as warehousing occupancy and having little need of life safety provisions. Automatic sprinkler protection is usually optional. Prior to the Military Personnel Records Center (MPRC) fire,[1] the U.S. National Archives was setting a trend by providing sprinklers in new storage facilities and retrofitting existing facilities as funds became available. At that time, archivists were extremely nervous about installing water pipes above their valuable paper records. In the effort to alleviate their concerns, fire protection engineers offered sprinklers of low sensitivity (286°F [141°C]), which allowed larger fires to develop but were unlikely to operate accidentally on hot days. Such a system, designed to prevent fires from crossing aisles and jumping to the third row, was perfectly acceptable to archivists. Today, most archivists accept sprinkler protection as a given and show interest in low-temperature (155°F [68°C]) quick-acting sprinklers that may limit fire damage to 50 boxes or less.

by the strong thermal columns early in a records fire, while not having solid ceiling as a heat collector.

In other tests of high-piled storage conducted by Underwriters Laboratories Inc. (UL)[5] and tests of 6 ft (1.5 m) high archival shelving arrangements conducted by the GSA, the fire, at the end of an early and relatively short development stage, preheated a sufficient amount of the exposed boxes so that fire development characteristics changed suddenly, temperatures rose quickly, and the flame enveloped large areas. Neither of the tests involved exposed loose paper typical of systems with open-shelf filing.

In open-shelf storage, the close proximity of the opposing sides of the aisle can result in increased radiant heat feedback and flaming ignition of evolved gases across the narrow aisle. The severity and rapidity of fire development are accelerated by increased stack height and slowed by increased aisle width. Fire development is highly influenced by the amount of open space in the shelving; no means of estimating the effect of vacant space has been suggested.

Properly designed automatic sprinklers will control the fire, but factors that speed fire development and penetration increase the amount of information loss and the amount of irrecoverable damage.

Mobile Shelving

A class of storage devices, known variously as mobile shelving, track files, compaction files, moveable files, and so on, consists of open-shelf units mounted on tracks. In use, all of the shelves are pushed together except that one aisle is left open for access to two units. To access another unit, shelf units are moved on the tracks until access to the desired unit is gained. Units can be designed to move electrically or manually. The shelves that are pushed together form continuous horizontal tunnels through which fire can communicate, except where shelves are built with continuous transverse dividers. Mobile shelving containing combustibles should be protected by overhead sprinklers.

A fire in the open aisle of mobile shelving is similar to a fire in open-shelf storage of comparable height and is readily controllable by overhead sprinklers. When a fire elsewhere in the mobile shelving array is sheltered from sprinkler application, it is a deep-seated burrowing fire. Full-scale fire tests conducted in 1978 indicate that a fire in a tunnel formed by shelving can develop and spread very slowly. When shielded from direct sprinkler discharge, fire is likely to continue spreading through the entire array unless the shelf unit has internal metal dividers.[6] Although protection by sprinklers alone might permit fire involvement of the entire array, the fire is very likely to be confined to that single array. Overhead sprinklers provide adequate protection for a building containing mobile shelving and they prevent fire from jumping to other arrays.[7]

In addition to sprinkler protection, a smoke detection system is suggested in mobile shelving areas not continuously occupied to provide a fire warning well in advance of sprinkler operation. Early-warning smoke detectors can help limit the extent of fire damage in mobile shelving if skilled forces are quickly available during nonoperating hours.

The U.S. National Archives and Records Administration has opened a very large facility in College Park, Maryland, employing state-of-the-art mobile shelving. The facility is about 1.9 million ft^2 (176,500 m^2) in size, protected throughout with wet-pipe automatic sprinklers, augmented in records storage areas with smoke detection. Approximately 520 mi (840 km) of mobile shelves are provided for records storage. Typical shelving units are 8 ft (2.4 m) high and about 20 ft (6.1 m) in length. Shelves are electrically propelled, opening at the selected aisle, but during closed hours and during a fire alarm, shelves are automatically parked a few inches apart. Each shelf is thereby directly accessible to sprinkler water from overhead sprinklers that will operate by heat from a fire in the array. Smoke detectors ensure prompt response to an incipient fire and open the array to sprinkler control and extinguishment.

Automated Files

Program libraries (e.g., open-reel tapes, tape cassettes, etc.) are normally stored in a separate room adjoining a main-frame computer room. A code-conforming library has its own fire separation walls, protected openings, and separate fire extinguishing module(s). Program tapes are manually accessed. Automated file systems are in use, in which a relatively unlimited number of cassette-type programs or record tapes are stored in a series of modules within the computer room. At the command of the computer, a desired tape is mechanically accessed from storage, transported and installed in the proper slot in the computer, removed, and returned to storage. NFPA 75, *Standard for the Protection of Information Technology Equipment,* requires that these tape libraries, being a severe unprotected hazard to the computer and peripherals, be sprinklered internally.

Plastic Media

The combustibility or flammability of magnetic media and its containers is a prime concern when such media are stored in bulk quantities. Generally, acetate and polyester-based tapes do not present a hazard any more severe than paper. Polystyrene cases and reels, however, present a severe fire hazard condition because they have a high fuel value, a high heat release rate, and shed water. Storage systems designed to safeguard materials of cardboard or paper composition cannot be relied on to adequately protect materials involving large quantities of polystyrene. If the containers are made of another plastic, the condition might vary, although most thermosplastics exhibit similar properties. In any case, it is necessary to limit the height and extent of the storage of reels encased in plastic or to design special protection systems for them.

Fortunately, it appears that open-reel data storage is a declining technology, but huge quantities remain in storage and constitute a major self-exposure and exposure to other records. Computer records are being stored on an increasing variety of magnetic and optical media in widely varying formats. The main trend is the dramatic increase in information density each change involves. This factor has serious implications for the archivist, for fire prevention/control, and for the owner of the information. Loss of a records box or its volume equivalent filled with records

on paper would approximate the contents of a file drawer. Loss of an equal volume of CD-ROMs might represent the loss of an entire vault filled with paper records. The current format of DVD-ROMs is up to 70 times the data density of CD-ROMs. The increase in information density also implies that minor dimensional changes (e.g., due to slight overheating) could make the information forever unreadable. Even minor smudges can make some media unreadable until cleaned. It is evident that reasonable protection can be achieved only by storing duplicate records in widely separated locations not subject to a single fire.

DAMAGEABILITY AND SALVAGE

Ordinary paper records survive reasonably well when exposed to most of the effects of fire, except direct exposure to flaming. With rare exceptions, burned paper records represent a total loss, whereas a high recovery rate is practical where the records have been exposed only to water, high humidity, smoke, and moderately high temperatures of about 350°F (177°C). While exfoliated pages burn nearly instantaneously, packed paper files burn slowly at the edges. Prompt extinguishment of packed files leaves the information largely intact, and near total recovery of wet paper with charred edges is possible. Nonpaper records media tend to be more susceptible to damage than paper.

Photographic Records

Photographic records, whether they are on traditional acetate, glass base, or any special base, consist of an image held in place by an emulsion. The image can be distorted or destroyed under any condition that loosens the emulsion. Tests have demonstrated that these emulsions will not withstand high temperature and humidity conditions, and that they are particularly susceptible to steam.[8,9] The traditional insulated safe or insulated filing device depends on the water of crystallization in the insulation material to limit the internal temperature and might be vented into the interior of the device. Therefore, it is expected that a steam atmosphere at 212°F (100°C) or higher will exist within the records protection equipment under severe fire exposure. The tests demonstrated that such exposure would damage or destroy the information on photographic media. A high degree of safety, however, can be achieved by placing the photographic media inside a steel can and sealing it with a moisture-resistant tape before storage within a record container.

The fire problem with photographic records that are stored in bulk facilities is similar to that encountered with paper records, except in salvage efforts it is important to give priority to the photographic records. While the cold water used in extinguishing the fire will not immediately attack the photographic emulsion as would steam, it will tend to cause some softening. If salvage efforts are not undertaken immediately, there is a tendency for the emulsion to stick to adjacent material and damage the image.

Magnetic Media

The more common magnetic records consist of magnetic impulses retained in an iron oxide or similar deposit held to an acetate, polyester, or similar plastic-based material. The tapes are usually wound on polystyrene or similar plastic reels and contained in polystyrene cases. This is particularly true of many tapes used with electronic computer systems. The security of the record is primarily related, as with photographic records, to the stability of the emulsion. Even minor distortion is severe in the case of magnetic records, since machines cannot make subjective judgments regarding distortion. If the emulsion is softened by the heat from fire, for example, there is a tendency for the layers of tape to stick to each other on the reel and to be destroyed in efforts to unreel. A tape can be considered safeguarded only up to temperatures in the range of 125°F (52°C) and in relative humidity not exceeding 85 percent.

Salvage

The problem of recovering wet records is the same whether they are damaged by a fire, or some other source, such as flood, hurricane, heavy rainstorm, roof leakage, spilled liquids from operations located above, or a breakdown of any of the numerous water or steam systems in the building. It is generally recognized that virtually any wet paper records can be recovered, provided prompt and proper action is taken.

Good sources for further information on salvaging records are contained in NFPA 909, *Code for the Protection of Cultural Resource Properties—Museums, Libraries, and Places of Worship,* as well as "Salvaging and Restoring Records Damaged by Fire and Water,"[10] *Managing the Library Fire Risk,*[11] "After the Water Comes,"[12] and *Procedures for Salvage of Water-Damaged Library Materials.*[13]

RECORDS STORAGE

Factory-Built Devices

Limited quantities of valuable records can be stored in factory-built records protection equipment, such as insulated records containers, fire-resistant safes, insulated filing devices, and insulated file drawers. These devices are available in varying degrees of resistance to fire, heat, and impact, and the degree of protection to be specified for a particular application will depend on the severity of the exposure and the items to be stored. The test procedure applicable to this equipment and the ratings employed are described in UL 72, *Tests for Fire Resistance of Record Protection Equipment.*[14]

Records protection equipment is classified in terms of two elements: (1) an interior temperature limit and (2) a time in hours. Three temperature limits are employed: 350°F (177°C), regarded as a suitable limit for paper records; 150°F (66°C), regarded as a limiting temperature for photographic records; and 125°F (52°C), regarded as suitable for most magnetic media. The time limits employed are ½, 1, 2, 3, or 4 hours. The complete rating, consisting of the two elements, indicates that the specified interior temperature limit is not exceeded when the record container, safe, or filing device is exposed to a standard test fire as described in UL 72,[14] for the length of time specified.

Ratings are assigned to the various categories, as follows:

Insulated Records Containers

Class 125—4 hours
Class 125—3 hours
Class 125—2 hours
Class 125—1 hour
Class 150—4 hours
Class 150—3 hours
Class 150—2 hours
Class 150—1 hour
Class 350—4 hours
Class 350—3 hours
Class 350—2 hours
Class 350—1 hour

Fire-Resistant Safes

Class 125—4 hours
Class 125—3 hours
Class 125—2 hours
Class 125—1 hour
Class 150—4 hours
Class 150—3 hours
Class 150—2 hours
Class 150—1 hour
Class 350—4 hours
Class 350—3 hours
Class 350—2 hours
Class 350—1 hour

Insulated Filing Devices

Class 125—1 hour
Class 125—½ hour
Class 150—1 hour
Class 150—½ hour
Class 350—1 hour
Class 350—½ hour

Insulated File Drawers

Class 125—1 hour
Class 150—1 hour
Class 350—1 hour

Insulated records containers and fire-resistant safes must protect contents from heat to an extent described in the requirements, before and after a fall from 30 ft (9 m). Insulated filing devices, which are not drop-tested, are not required to have the strength to endure such an impact.

Insulated records containers, fire-resistant safes, insulated filing devices, and insulated file drawers must sustain sudden exposure to high temperatures to an extent described in the requirements without the unit exploding as a result of such exposure.

Ordinary uninsulated steel files and cabinets provide only a limited measure of protection from an exposure fire, as heat sufficient to char contents is quickly transmitted to the interior. However, they can be very useful where the major fire exposure is from the records themselves. They are commonly used for records having no extraordinary value. They are also used for the organized storage of valuable records in protected facilities, including vaults, file rooms, and document buildings. A records vault or file room in which all records are kept in metal file cabinets is much safer than one in which the records are kept in cardboard boxes on open shelves. If an ignition occurred in an open file drawer, fire development would likely be very slow. An ignition in open-shelf files, however, could be beyond manual control within a few minutes.

Files and cabinets made of wood, fiberboard, or other combustible materials can release their contents in a fire, adding to the fire hazard. They should not be used in valuable records storage.

Vaults and File Rooms

Standards for the construction of fire-resistive vaults and file rooms are contained in NFPA 232. The term "vault" refers to a completely fire-resistive enclosure up to 5000 ft^3 (142 m^3) in volume, used exclusively for records storage, with no work to be carried on inside. It is equipped, maintained, and supervised to minimize the possibility of a fire starting within and to prevent a severe fire of long duration on the outside from entering, provided the vault door is closed. Vaults are designed to fire resistance classifications 4 and 6 hours, indicating that, under standard test conditions, heat will not rise above a specified temperature inside and the construction will withstand both the exposure fire and the application of fire hose streams during that period. Vaults are constructed in the field and do not carry a testing laboratory label. Vault doors, however, are laboratory tested and carry ratings conforming to the vault construction in which they are to be used. (See NFPA 232.) Unlike some other fire doors, vault doors limit the temperature on the interior face to 350°F (177°C) during fire exposure, so that paper stored in contact with the door would not be in danger of ignition. Provisions in NFPA 232 require sprinklers in vaults.

Vaults usually contain a substantial fuel load and by their nature are normally used to store only vital and important records. The internal contents of some vaults are more of a fire hazard than any external exposure. In recognition of this situation, vault standards permit sprinkler systems, lighting, and low-energy circuits, with suitable safeguards. Installation of smoke detectors and/or sprinklers to detect and extinguish a vault fire impose a minor permissible increase in ignition sources. A fire within an unprotected vault can be disastrous unless it is immediately discovered and extinguished with portable fire-fighting devices. Fire extinguishers of the water type or fire hose, or both, should be outside the vault in an accessible location near the door.

Additional protection is gained by storing particularly sensitive documents in protected filing devices *inside* vaults. Be careful that fire exposure is not increased thereby, such as installing the safe in a vault occupied by open-shelf filing.

A standard fire-resistive file room is defined as an enclosure not exceeding 50,000 ft^3 (1416 m^3) in volume and 12 ft (3.66 m) in height, designed to a fire resistance classification of 2, 4, or 6 hours. The volume and height limitations restrict the quantity of records exposed to destruction by fire in a single enclosure and reduce the possibility of fire originating within the enclosure.

File room doors are labeled as to their fire resistance following a laboratory test under the procedures of UL 155, *Tests for Fire Resistance of Vault and File Room Doors,*[15] but the ratings are only for ½ or 1 hour. Door openings shall be protected with listed file room doors that have a minimum rating that is equal to the rating of the walls. These ratings anticipate that paper and other combustibles will not be stored nearer than 3 ft (0.9 m) from the unexposed face of the door, nor 6 in. (152 mm) to the side from the door jambs.

Lighting, heating, ventilation, and so on are permitted inside file rooms, as are filing cabinets and furniture, provided they are noncombustible. Although it is not to be used as a working space for other than filing purposes, the file room is more susceptible to a fire ignition than a vault. Due to this vulnerability, installation of automatic fire detection and fire control systems should be considered in relation to the values involved. Automatic sprinklers are required in file rooms having open-shelf filing, unless all storage is held in records protection equipment.

Records Centers and Archives

Bulk storage of records in buildings set aside for the specific purpose or in major portions of other buildings (in rooms exceeding the 50,000 ft^3 [1416 m^3] fire-resistive file room limitation) should comply with the recommendations set forth in NFPA 232. For facilities of this size, where the most severe hazard might not be from a fire exterior to the facility but from a fire starting and spreading entirely within the records storage area, the level of fire-resistive construction and protection must be individually determined. Within such a facility, secondary operations might have to be segregated from the actual storage by fire-resistive construction. Full-scale fire tests of 14 ft (4.3 m) high open-shelf records storage in a sprinklered facility indicated the likelihood of ceiling temperatures in excess of 1200°F (649°C) for periods of up to 8 minutes when using standard 286°F (141°C) sprinklers.[1] Lightweight bar joist roofs often present in records centers are vulnerable to early collapse unless additional precautions are taken, such as might be provided by developments in large-drop sprinklers, quick-response sprinklers, or fireproof coatings for the steel. In a full-scale test in 30 ft (9 m) high storage, a single quick-operating, 155°F (68°C) sprinkler held the fire in check for an extended period of time before extinguishment was completed with a handheld hose.[4] A thorough fire risk analysis by qualified personnel should be conducted due to the high fire potential from the concentration of combustibles and the probability of loss of large volumes of valuable documents.

Recent changes in the rack and storage arrangements for records centers have led to several important changes to NFPA 232. Records centers have been defined as being of two types: compartmented and noncompartmented. A compartmented records center is defined as having a storage compartment area of less than 40,000 ft^2 (3715 m^2). Fire separation between compartments should have no less than a 2 hour fire resistance rating if the area does not exceed 40,000 ft^2 (3715 m^2), and 3 hour fire resistance rating if the area exceeds 40,000 ft^2 (3715 m^2). Noncompartmented records centers should have height and area limitations as determined by the applicable building code.

FIRE RISK ANALYSIS

Maximum possible protection is not desirable for the bulk of what comprises records storage. Most records can be reconstructed, duplicates are often available in other locations, and their loss might not create any substantial hardship. The value of certain irreplaceable documents warrants especially sophisticated protective measures to preserve a single sheet of paper. The great majority of records in a particular collection, however, might dictate consideration of less-than-optimum methods of records protection and anticipation of potential small fire losses, yet still provide a high degree of assurance against a significant loss.

Classification of Records

A records protection program should be based on an inventory that determines type, volume, rate of acquisition, duplication of data, rate of disposal, and class of importance of the records. The responsible party, records manager, or archivist should determine which, if any, of the records need a higher level of protection as provided by the different classes of records storage. Valuable records can be generally classified in one of two ways to assess their value:

1. *Vital and archival records.* These records are irreplaceable; records having high historic value (archives); records where reproduction does not have the same value as an original; records that give direct evidence of legal status, or ownership; records needed to sustain a business or avoid delay in restoration of production, sales, or service; and records of accounts receivable.
2. *Important records.* These are necessary records that can be reproduced from original sources only at considerable expense or loss of time.

Other records might be useful but should be kept well separated from vital and important records because they could constitute a fire exposure in and of themselves.

Fire Risk Evaluation Factors

In considering the protection of valuable records, the following four basic items must be evaluated:

1. The probability that the building containing the records, as well as neighboring operations, will have a fire outside the records storage activity that will spread to the records. Determining the probability of such fire hazards will involve consideration of building construction, contents, possible fire causes, and general features of fire protection that might stop a fire that originated elsewhere before it reaches the records. (See Section 19, Chapter 2, "Structural Integrity During Fire.")
2. The probability of a fire starting within the records storage activity. This includes assessing the ignition sources, vulnerability to arson, the susceptibility of the records or their containers to ignition, and factors facilitating the spread of fire.
3. The quantity of fuel the records represent, particularly as it relates to available or proposed capability for fire extin-

guishment, and the structural stability of the storage arrangement and the building enclosure.
4. The susceptibility of the records to damage from fire, fire effects (heat, smoke, vapors, etc.), and fire-extinguishing efforts (principally water damage and impact damage from hose streams and other extinguishing devices, and physical disruption from manual fire fighting).

When records must be housed in a building that might burn around them, properly rated vaults and containers can give reasonable protection against the external fire exposure. The hazard of the records themselves, such as those stored within a vault, file room, segregated floor or section of a fire-resistive building, or records center, can be substantial. For example, a fire involving military records of 19 million U.S. servicemen occurred in an unsprinklered, six-story, fire-resistive building. The top floor, where the fire started, was completely destroyed. Fire-fighting efforts prevented the fire from spreading downward. Had the fire started on a lower floor, it is likely that the entire building would have been lost.[1]

The protection methods described in this chapter yield protection guidelines commensurate with the hazard and the sophistication of the protection systems. The degree of fire risk and the potential for loss in collections not suitable for cabinet or vault storage may require evaluation by a person knowledgeable in this type of analysis.

FIRE RISK REDUCTION

Since most records media are combustible, 100 percent effective protection is not feasible and efforts should be directed to reducing the risk of fire and its associated effects. One of the most effective means for limiting the disastrous effects of a fire in a records storage facility is to prepare duplicates and store them away from the originals where they will not be subject to the same incident. Often the duplicate copy is on microfilm, which is inexpensive, easily transported, and easily stored at a remote facility. Once a duplicate has been prepared, the value of the original is reduced considerably, unless the original document is required for legal purposes or is of intrinsic or historic value. If the duplication is complete, up-to-date, and easily accessible, then reduced protective measures may be justified for both the original and the duplicate collection.

If the prior generation of computer records is stored remote from the current generation, the effect of loss of the current records in use at a computer center would be reduced. Although they are not exact duplicates, the existing earlier records still greatly simplify the task of reconstructing current records.

Protective Containers

Heavily insulated, massive vaults, safes, and filing cabinets are the traditional way to safeguard vital and archival records against the effects of fire. The practice of encapsulating the records so that they are fully protected against the greatest potential fire exposure is still viable. Containers are available that will keep the internal temperature and humidity as low as necessary to retain the data on magnetic tape and other temperature-sensitive media.

Vaults are usually used where the volume of valuable records is large. They are often the only practical method of protection in non-fire-resistive buildings where the probable fire severity exceeds the rated endurance of 4 hour safes. Safes are used for smaller volumes of records where it is necessary to have records near their point of use, where the cost of vault construction would be prohibitive, or where the building does not lend itself to vault construction.

Protective containers for records are rated by tests under standard fire conditions. They are rated according to the time elapsed before the interior of the container reaches 350°F (177°C). This time factor provides a measure of safety, since the ignition temperature of most paper is somewhat higher.

Records containers rated for interior temperatures that do not exceed 150°F (66°C) and relative humidity that does not exceed 85 percent at temperatures above 120°F (49°C) are available. Containers rated with these more stringent requirements are intended to provide protection for films, magnetic tapes, plastic media, and similar materials. The development of new and different records materials, however, requires a careful evaluation of their characteristics to ensure proper protection. An important limitation on this type of container is that it is not subjected to the traditional drop test while containing magnetic or similar media records. The device should not be considered capable of safeguarding magnetic and similar records in any building that could collapse in a fire and cause debris to fall on the container, nor should the container itself be subject to falling several floors.

Table 9.8.1 indicates the approximate fire resistance that can be safely expected from various types of records containers exposed to a fully developed fire. The protection provided varies considerably, depending on design and materials. Thickness of insulation alone does not give a reliable indication of fire resistance, which can be determined accurately only by tests.

Patterns of records container performance in real fires were analyzed in depth in a special five-year study done by NFPA five decades ago.[16] Although the statistics from that era might no longer be representative, the leading factors of

TABLE 9.8.1 Fire Resistance of Records Containers

Insulated records vault doors	2, 4, and 6 hours
Insulated file room doors	½ and 1 hours
Steel-plate vault doors with inner doors	About 15 minutes
Steel-plate door without inner doors	Less than 10 minutes
Modern safes	1, 2, and 4 hours
"Old-line," "iron," or "cast-iron" safes, 2 to 6 in. wall thickness	Uncertain
Insulated records containers (files and cabinets, etc.)	½, 1, and 2 hours
Containers with air space or with cellular or solid insulation less than 1 in. thick	10 to 20 minutes
Uninsulated steel files, cabinets, wood files, wood or steel desks	About 5 minutes

For SI units: 1 in. = 25.4 mm.

contents destruction are probably the same ones one would find today. They are listed next in order of frequency from the old study:

- Container exposed to fire beyond its capacity to withstand (mostly unlabeled containers, some 1 hour containers, a few 2 hour containers, no 4 hour containers)
- Obsolete design or construction of unlabeled container
- Container submerged in water
- Container door left open

The first two of these were cited much more often than the second two, which underlines the importance of selecting the right containers for the fire hazard in the first place. As one might expect, the longer the time rating, the more likely the container was to preserve the contents.

Early Warning Concept

Records administrators might consider a sprinkler system as optional when they plan records protection. A smoke detection system coupled with manual response, once highly favored by archivists and librarians as a full substitute for sprinkler protection, is now considered to be only a useful supplement to sprinklers under favorable conditions. In a slowly developing fire, a well-designed smoke detection system can give an advance warning before heat-responsive devices, such as automatic sprinklers, operate. If manual fire extinguishment is mobilized by a manned emergency center, it might be able to attack the fire before it gains headway. Whether manual extinguishment causes more or less damage than sprinklers depends on the skill of the responding force and how the fire progresses while the responding force is mobilizing. In any case, although automatic detection and manual extinguishment can be valuable adjuncts to automatic sprinklers, they would not constitute an acceptable alternative to automatic sprinkler protection under most conditions found in records storage.

Smoke detectors in records storage are particularly useful when the area is unoccupied. Spot-type detectors on high ceilings are unlikely to be activated until smoke from a smoldering fire completely permeates the air, or flaming fire gains sufficient headway to drive a column of smoke and heat to the ceiling. Therefore, in-rack detection or projected beam detectors should be considered.

Smoke detection systems might not be appropriate in open-shelf records storage, where fire development is likely to be very rapid. They might provide supplementary protection in high-value collections, particularly if measures have been taken to slow down development of a fire (such as storage in totally closed metal containers), or burning material is prevented from falling off shelves. Smoke detection equipment can be useful in unoccupied areas of mobile shelving or other arrangements in which combustible contents are sheltered from sprinklers, or storage arrangements slow the spread of fire. Heat detection, either spot type or line type, can be located near or in the racks. This type of detection might be more suited where a rapidly spreading fast-burning fire is expected, and especially if the smoke or heat detection system is connected to activate an extinguishing system.

Smoke detection systems are also used to activate extinguishing systems, such as carbon dioxide, halon, water mist or high-expansion foam. They are used to activate preaction sprinkler systems, which are sometimes installed to prevent accidental water damage.

Duct detectors are used to shut down fans, activate dampers, or initiate smoke control measures. Detectors are also used to cause held-open doors to close and to stop conveyors, in a variety of single-purpose actions.

Heat detectors can perform most of the same duties as smoke detectors but usually with a much longer time lag. An extended time lag is sometimes desirable, such as in the opening of a sprinkler, or the release of a special extinguishing agent.

Handheld Extinguishing Appliances

Even if the facility is equipped with an automatic extinguishing system, manual fire control devices should be provided for staff use. Fire extinguishers are most often encountered. The preferred types are those containing clear water as the extinguishing agent. Although carbon dioxide extinguishers do not leave a residue or dampen documents, they are not effective on the deep-seated fires likely to occur in records storage. Although the use of halon extinguishing agents is being phased out worldwide, they are still used extensively in record storage systems. Halon extinguishers have the same limited extinguishing ability as carbon dioxide, in that they are ineffective on deep-seated fires. The user of halons should also be aware of the toxicity of the agent and avoid high concentrations of it. Although national standards rightly limit human exposure to the various halons, there is no mechanism, except the knowledge and alertness of the extinguisher operator, to manage the extent of exposure to halon. Most extinguisher users, however, are unaware of this hazard and are at risk of overdose. Multipurpose dry chemical extinguishers can be provided, but they leave considerable residue and have only limited effectiveness on deep-seated fires.

Water hose lines can supplement, or be used instead of, fire extinguishers. To minimize water damage, rubber-lined hose with an adjustable water spray, straight stream, and shutoff nozzle is preferable in records storage areas. Its use greatly expands the fire-fighting capabilities of the staff. Hose lines connected to carbon dioxide or halon storage tanks or cylinders have been used. However, these systems should not be undertaken without extensive training and appropriate protective equipment because the danger to the fire brigade is much greater than with the use of hand extinguishers containing the same agent.

AUTOMATIC EXTINGUISHING SYSTEMS

A variety of automatic fire extinguishing systems are suitable for records storage protection; the choice depends on the economics of a particular situation and the degree of sophistication desired. All of the extinguishing systems described are loss initiated; the system does not detect and begin extinguishment until a fire is established and a fire loss has occurred. Systems that are more sensitive and reactive are available for highly specialized requirements. A large increase in cost and rate of false operation should be expected. Increased maintenance is usually required

in more sophisticated systems to attain the reliability inherent in standard sprinkler systems.

Automatic Sprinklers

Automatic sprinkler systems are the most common type of automatic protection. They are effective in records storage fire incidents in limiting both fire and water damage. Water is discharged only in the immediate vicinity of the fire and salvage techniques have been perfected to the point where recovery of wetted items is no longer unusual. Accidental opening of a sprinkler is rare. The probability of water damage from an accidental discharge can be further reduced using a preaction sprinkler system where water does not enter the piping until a fire detector operates. Preaction systems introduce additional failure modes, which could be unacceptable. A more sophisticated variation is a system where the water supply valve cycles on and off, depending on the actual presence of fire as sensed by a detector in the fire area. Also available are sprinklers that cycle on and off individually, but the piping remains filled with water. However, the increased cost of these systems must be weighed against the value of the records being stored. "On-off" sprinklers have a troubled record in long-term use.

Water Mist Systems

"Mist" nozzles, long used in cotton processing factories to raise humidity, reduce static electricity sparking, and reduce incidence of flash fire in accumulations of fine fibers, are being used in a relatively new type of sprinkler system. Parallel developments are being pursued for two types of application. In one model, a small array of open mist nozzles are supplied through a valve controlled by heat or smoke detectors. Many arrays are installed in a large area. In another model, individual nozzles are activated by an internal valve controlled by an integral heat detector.

Installation of a water mist system should be undertaken only under a person experienced in design, installation, and testing of water mist protection for records storage facilities.

Foam Systems

High-expansion (hi-ex) foam can provide some credible assurance of controlling a fire that might escape sprinkler control. Hi-ex foam has the ability to overcome a well-established fire. Like gas extinguishment, to do its job hi-ex foam must fill the entire fire compartment, totally submerging the fire, and continue refilling at a rate adequate to completely replace the foam broken down by the fire. Water damage to any single item will be low, but all items within the room or fire area involved will be affected.

If provided to justify the use of caverns and multistory buildings for records centers, hi-ex foam should be required to demonstrate, by full-scale testing, the ability to overcome a fire spreading beyond sprinkler control in a 250,000 ft^3 (7100 m^3) records module. (Caution: A previous full-scale test was fully successful except that all the records box identifying labels slid off onto the floor—a disaster for records keepers.[17])

Hi-ex foam can be used as a backup for sprinkler failure if adequate reliability factors are built into the design of the system. Inadequate water supply is an important cause of sprinkler failures; such a lack would also cause a hi-ex system failure. Closed valves are the leading cause of sprinkler failures and are a symptom of poor maintenance, which could affect a hi-ex system at a number of points (e.g., water valves, foam valves, air fans, and directional dampers). All sorts of failure modes affect foam systems. Whether to rely on the sprinkler waterflow alarm for activating the hi-ex system or to provide an entire separate heat detection system is a design decision. A smoke detection system designed to activate hi-ex foam seems to be much too reactive.

Carbon Dioxide Systems

A few automatic total flooding carbon dioxide systems having a high rate of discharge have been installed in records storage or library areas. A properly designed system should promptly control fire with limited damage. To be successful, a high concentration of gas must be maintained for an extended period. The concentration must be maintained until a deep-seated fire cools below its ignition temperature. The operation of such systems, however, involves a hazard to life and must be delayed until the area to be flooded is cleared of people. See Section 17, Chapter 1, "Carbon Dioxide and Application Systems," for additional information.

Halon Systems

The manufacture of Halon 1301 (bromotrifluoromethane) and various related Freon™ gases (used in fire protection, refrigeration, and air conditioning) are being phased out rapidly by international treaty because of concern for ozone depletion in the upper atmosphere. Several substitute gases have been proposed for fire extinguishment, none of which has so far received universal acceptance.[18] See Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems" for additional information.

Existing automatic total flooding halon systems utilize flame-inhibiting liquefied gas under pressure. Halon 1301 is being marketed for use in specially engineered systems for the protection of valuable records. The primary advantages are that the gaseous agent leaves no residue and is only mildly toxic in the concentrations in which it is used. Occupants, however, should not be unnecessarily exposed to Halon 1301. Deep-seated smoldering fires will not be extinguished by halon, as it inhibits flaming only.

System Reliability

All fire control systems are subject to failure when various conditions are exceeded or not met. Gaseous systems have a number of possible failure modes that are unique to them, although this does not necessarily imply an unusually high failure rate in practice. An independent detection system must work and must be correctly linked to the gas release. Usually, electric power is required for the detection system, linkage, and release to operate. The gas containers must be filled and connected to distribution piping. If the room has been enlarged since the system was installed, the gas volume applied may be inadequate. If any of

the doors fail to close properly, a critical amount of gas may escape. If the ventilating system continues to operate, critical duct dampers fail to close, a window remains open or gets broken, or walls are breached for construction, a critical amount of gas may escape. If fire fighters open doors to assist in extinguishment, a critical amount of gas may escape. If deep-seated fires are not extinguished prior to gas dissipation, rekindling of the fire may be beyond the control of manual forces if no connected reserve gas supply is available for reapplication.

High-expansion foam systems have similar detection and activation vulnerabilities. They are especially vulnerable to loss of power because substantial power is required to operate the large fans used to generate the foam. Foam is also subject to blockage by doors, walls of stock, and fabric curtains. It is also somewhat vulnerable to loss of containment, although not nearly to the extent of gaseous systems.

Water-based systems (sprinklers, foam, water mist, etc.) are subject to failure because of closed water supply valves, pipe obstructions, and lack of adequate water pressure. Pumper connections are provided for the fire department to supplement the water supply, especially to restore pressure loss caused by other fire department operations.

FIRE PREVENTION AND EMERGENCY PLANNING

Although detection and extinguishing systems are important, particularly for the bulk storage of valuable records, the first line of defense remains a good fire prevention and risk reduction program. Good housekeeping, orderliness, maintenance of equipment, and prohibition of smoking in records storage and handling areas are fundamental principles of good records management.

An emergency action plan that is kept current and practiced is essential to limit damage in case a fire occurs. Staff personnel cannot be expected to approach a fire and use extinguishers or hose lines effectively without adequate training. Fire-resistive containers and vaults are of much greater value if there has been training in procedures for fire emergencies. The following suggestions apply:

1. Records should be returned to their places of safety accurately, quickly, and without confusion or oversight. If there is no standard records protection, the best plan is to have the most important records carried out of the building. Drills are valuable to train employees to meet emergencies.
2. Records belonging in vaults or safes should never be left out overnight.
3. Important materials that belong under protection should not be allowed to accumulate on desks.
4. Because records normally safeguarded are often unprotected while temporarily on loan, copies instead of the originals should be loaned, and the originals retained in safe storage.

PROTECTION LIMITATIONS

The prototypical records center used to be a single-story warehouse complex consisting of 40,000 ft^2 (3715 m^2) modules separated by 4 hour rated brick fire walls, sprinklered and unsprinklered. Wide roadways separated the warehouses in all directions; an uncontrolled fire in any warehouse was unlikely to be transmitted to any other warehouse. Also, if a fire grew out of control in any one module, the fire department could breach the walls and roof of the unit out of control to reduce the heat acting on the fire wall separations and allow water applied externally by hose streams to cool the exposed fire walls, providing a good chance of saving the contents of the rest of the warehouse.

In multistory warehouses, basement storage, and especially mine storage, these options are severely limited. A fire that has grown, for whatever reason, out of control of sprinklers and of inside fire fighting is not likely to be stopped at the fire barriers of the module. Available heat and smoke venting is not at all likely to be adequate, and there is no place for a fire department to combat the fire from outside.

Now, records storage centers are growing bigger and taller, as structural rack assemblies change and automated storage and retrieval equipment is developed. Fire fighting operations can be inhibited by the sheer size of a facility and the associated difficulty in physically finding and getting to the fire.

Multistory Buildings

Success in limiting the fire to a segment of the multistory building by fire department activity is dependent on the fire location. No traditional fire-resistive building will survive a module burnout (a 7 to 15 hour fire exposure); an exception was the top floor MPRC fire.[1] (Even in that fire the 10 in. [250 mm] reinforced roof was destroyed by the fire, which performed the useful task of greatly increasing the venting performed by the windows.) Fire fighters prevented the fire from propagating downward. Had the fire originated on another floor, the unsprinklered, heavy reinforced concrete building would have collapsed because of impact loading caused by floors above collapsing into the fire. All the records in the building would have burned completely. Because of lack of sprinklers, a fire starting on the first floor would have been out of control by manual fire fighting by the time the fire department arrived and the kind of success enjoyed in the Chicago fire would have been negated from the outset.

Modules are generally inaccessible from the outside; an exception was the ground floor of the Chicago Records Storage Facility fire.[19] The fire department was able to breach the entire south wall and apply hose streams from the outside to control and eventually extinguish the fire, while maintaining sufficient control for other fire fighters to defend fire doors on each end of the fire module and to cool the floor above the fire to prevent paper ignition. In a multistory building, providing ventilation is difficult on any story except the top floor and the first floor.

Cavern Storage

Caverns selected for records storage are clean and dry, with essentially no air movement. They are prized as low-maintenance facilities with no heating or air-conditioning required. Lighting is limited to task lighting and safety lighting; therefore, ultraviolet light exposure is not a problem. A minimal water supply is maintained for the comfort of a small staff. The location is

usually remote, reducing security requirements and simplifying visitor control.

Basic fire protection features, however, are lacking. Open-shelf records storage requires the following:

- A professionally designed sprinkler system
- Reasonably sized fire-resistive subdivisions
- A robust water supply, such as 250,000 to 1,000,000 gal (946,350 to 3,785,400 L) of water in a ground tank or reservoir, pressurized by two or more automatic fire pumps of 1000 or 1500 gpm (3785 or 5700 L/min) capacity or pressurized by elevation
- A large professional fire department with strong backup
- The capability of ventilating large amounts of smoke and heat to the outside

Providing the sprinklers and the subdivisions is the easy part. The remaining fire protection features are difficult or impossible to attain in cavern settings; nevertheless, they are vital to the safe storage of records.

After a fire is controlled by sprinklers, it requires the following:

- Overhaul and extinguishment by the fire department
- Smoke removal by the fire department and the small environmental system
- Data recovery by the staff and outside auxiliaries

For a fire beyond control with sprinklers or an unsprinklered fire, the fire walls should contain the fire in the module of origin for 4 hours; however, before the fire spreads throughout the module of origin, smoke and heat will migrate, filling the cavern and making it dangerous and eventually impossible to remain in. Because of limited means to dump smoke and heat to the outside, the fire will continue to grow until it involves all the cavern contents. The cavern might be inaccessible for months. Nothing will remain to salvage.

Caverns are usually remote from any substantial water service. (A credible private water service would consist of the storage supply and fire pump capacity stated earlier.) Caverns are also usually remote from the services of a large, well-organized fire department. This may be a superfluous problem, because there is no safe place for a fire department to operate inside a cavern, and there is little a fire department can do from outside a cavern.

Caverns have no outside venting capacity. Without the possibility of massive smoke and heat venting, a hi-ex foam system might be designed to provide adequate backup fire extinguishment.

Burnout of a module releases massive quantities of heat and smoke that must somehow be vented directly to the outside to avoid a total cavern burnout. Venting into the cavern itself does not permit manual fire fighting. Hi-ex foam is a candidate for limiting a fire to a module, given sprinkler failure, because there is no possibility of adequately venting a module fire to the outside and there is no natural drainage for sprinkler discharge. Failure of sprinklers to control a fire for any reason would likely result in quick abandonment and total burnout of the entire cavern contents unless hi-ex foam provides adequate backup.

None of the mine storage locations assessed for records storage occupancy show potential for venting facilities.

Basement Storage

Basements have all of the downside features of caverns, with two exceptions. They are not necessarily located in remote places; they might be served by superior fire departments and perhaps a strong water supply. The fire department can operate to some extent from the outside, with limited inside travel. Otherwise, basements are very difficult to ventilate in a fire and, given a serious fire, can be very dangerous to fire fighters.

Failure to control a records fire in a basement creates a very serious risk of the loss of the building and all the contents. Existing multistory buildings might be candidates for high-expansion foam backup, in which a single hi-ex system with automatically controlled directional ductwork is designed to protect one of a group of modules.

RELEVANT FIRE EXPERIENCE

Military Personnel Records Center (MPRC) Fire[1]

The unsprinklered Military Personnel Records Center (MPRC) fire in Overland, Missouri, where the service records of 19 million World War II military men and women were destroyed was not the ultimate records center fire—not even for that building. The MPRC fire was limited because it occurred on the top floor. Had it occurred on a lower floor, the building windows could have permitted it to spread to the upper floors. The floors above the out-of-control fire could have been too much of a hazard for fire fighters to occupy, to prevent flames outside the windows from igniting paper stacks inside the windows. Later in the fire, the flooring directly above the fire could have actually become too hot to stand on. The atmosphere could have been too hot to endure, and the floor could have begun to fail and sag, precipitating imminent total collapse of the building. Descending floor and heavy stacks of paper could have imposed impact loading on the floors below. Partial or total building collapse could have broken the building apart and spread the fire to all floors, at which time the loss of the building and all the contents could have been assured. This description was taken from a report about the MPRC building 6 months before the actual fire. The fire that subsequently occurred in July 1973 was on the top floor and relatively easy to prevent propagating downward. Although the entire top floor was destroyed, the fire was fortunately never a serious threat to the rest of the building.

Chicago Records Storage Facility Fire[19]

On Tuesday, October 29, 1996, an alarm was sounded for a fire in an automatic sprinkler–protected records archive building shortly before 2 p.m. Before the fire was declared under control nearly 10 hours later, it had reached the fourth alarm level with a commitment of 17 engines, 9 trucks and tower ladders, a squad, and several additional special pieces of equipment. The last fire company left the scene about 5 p.m. on November 7, 1996, and a full box alarm assignment was involved in overhaul operations for over 24 hours after the fire. Damage consisted of the total loss of thousands of record storage boxes and their contents,

water and smoke damage to thousands of other boxes, the loss of steel storage racks, and structural damage to the fire area and adjacent fire divisions. The value of the lost records and the cost to restore salvageable records were still being determined at the time this investigation was conducted. The loss of the racks and storage boxes themselves is estimated at over $3 million. The cost of structural damage and replacement of the destroyed front wall has been estimated at over $2 million. Early assessments of the total dollar loss have been set at over $50 million.

Aggressive fire department interior and exterior operations contained the fire to the 35,000 ft^2 (3250 m^2) compartment of origin. The fire area contained storage of cardboard-boxed records in approximately 28 ft (8.5 m) high metal racks with solid shelves. Automatic sprinklers were provided at the ceiling level only. Salvage of records had not been decided at the time of this report.

The successful control of this fire can be attributed to the performance of the fire separation walls supported by a large fire suppression force. Effective pre-incident planning and standard operating procedures also contributed. Companies supported the automatic sprinkler systems by supplying pressurized water at siamese connections and protected openings in the fire separation walls with hose streams. The availability of a good water supply to support the numerous hand lines and master streams as well as the automatic sprinkler systems was important to the overall tactical plan. The fire report did not emphasize removal of an outside wall as a key element in saving the facility.

In this fire the Chicago Fire Department kept the automatic sprinkler system operating for days. The sprinklers were still discharging water as outside contractors were overhauling and removing the building contents with heavy equipment. Their tactics and support of the sprinkler system are good examples for other fire departments to study.

Iron Mountain Fires, South Brunswick, New Jersey[20]

After the fire in Chicago, serious fires occurred in four other records storage facilities. Two of these fires also resulted in the total loss of the contents, even though both buildings were protected by automatic sprinkler systems. In addition to the loss of the contents, both of these buildings were destroyed.

Three of the fires, all determined to be the result of arson, occurred between March 10 and March 19, 1997, in two adjacent records storage buildings in South Brunswick, New Jersey. Both buildings were operated by the same company and were part of 117 record storage sites operated countrywide. One building with its contents was totally destroyed.

The first two fires occurred on March 10 and 17, 1997, in the same building, which contained an estimated 250,000 record storage boxes. Both of these fires were controlled by the automatic sprinkler systems and fire department operations. The automatic sprinkler protection included a strong hydraulically calculated overhead system and in-rack sprinklers. Boxes were stored on steel shelves and racks in a similar configuration to that used in Chicago. The exact storage height was not available. The Monmouth Junction Fire Department was still on the scene of the March 17, 1997, fire when the third fire occurred.

The March 19, 1997, fire was reported at 10:20 a.m. in a building located around the corner from the one above. The building, constructed of concrete walls and metal roof, contained an estimated 850,000 record storage boxes. Storage was on steel shelves and racks with intermediate catwalk levels. The exact storage height was not available. Automatic sprinklers were installed at the ceiling and in the racks following the same design that controlled the previous fires. Flames penetrated the roof of the building by early afternoon in the third fire and reached 100 ft (30 m) in the air by 8 p.m. that night.

West Pittston, Pennsylvania, Records Center Fire[21]

A records center fire occurred on May 5, 1997, in West Pittston, Pennsylvania, located between Scranton and Wilkes-Barre. The center was a single-story, 44 ft (13 m) tall, noncombustible building with a ground floor area of about 78,000 ft^2 (7250 m^2). The original section was built in 1995; an addition was completed approximately 6 months before the fire. The center was protected throughout by a ceiling-level-only dry-pipe automatic sprinkler system.

Record storage boxes were arranged on solid metal shelves in double- and single-row metal racks to a height of 42 ft (12.8 m). Intermediate-level grated metal walkways were provided to access the boxes. The arrangement was similar to the rear section of the Chicago Records Center building. The company operated nine other records storage buildings throughout four states.

The building had ceiling-only automatic sprinklers (none in the racks). The sprinklers did not control the fire; it spread throughout the structure resulting in a total loss.

National Archives Fires[22]

Two recent fires at the Washington Regional Records Center serve as a demonstration of the combination of records protection based on research, outstanding disaster planning, local fire department involvement, employee dedication, and official support. A midafternoon fire on February 29, 2000, was controlled by joint action of automatic sprinklers and elements of the Prince George County Fire Department. While the fire was still underway, employees were spreading salvage covers, directing fire fighters to ventilation equipment, moving out smoldering boxes, and beginning records salvage. As soon as the fire was out, salvage and cleanup were started, fire watches were set, and drying equipment was ordered in. Although about 3500 ft^3 (100 m^3) of records were wet down, only about 50 boxes were lost. On April 5 another fire occurred, about quitting time, this time affecting about 700 ft^3 (20 m^3) of records with much the same employee response. Cleanup was quicker because the specialized equipment was still on the scene from the first fire. The cause of both fires was arson by a part-time employee.

SUMMARY

Protecting records from fire and other hazards has become more challenging in recent years because of the increase in the vol-

ume of records and the frequent necessity to use the maximum cubic capacity of storage areas. Provisions must be taken not only to minimize the risk to records but also to protect the safety of persons in records storage facilities. The provisions taken depend on the nature of the records themselves and on the means of storage used. Since there is no 100 percent effective way to provide protection or to salvage damaged records, it is recommended that duplicates be stored at another site.

It is vital that effective maintenance and service of all passive and active fire protection systems be provided on a regular basis. Impairments to any system must be corrected in a timely manner.

Vinnie DeGiorgio ❏ Heron Peterkin

Chapter Contents

Preproduction Process
Production Process
Semiconductor-Related Developments and Guidelines
Hazard Control in Semiconductor Manufacturing
Fire Hazards
Health Hazards

Key Terms

cleanroom, integrated circuit, mask production, pyrophoric gas, semiconductor, silicon

Producing a state-of-the-art semiconductor device, also known as an integrated circuit (IC) or chip, is truly an extraordinary process. Integrated circuits are based on silicon, a fundamental component of sand, which is a tetravalent, nonmetallic element that occurs in combined form as the second most abundant element in the earth's crust next to oxygen. It is processed through several hundred steps into devices that are used in a wide range of applications.

Silicon has the same crystalline structure as diamond, but is only as hard as glass. It is also a semiconductor, which means it is halfway between a conductor, which carries electricity easily (like the copper wire used in domestic lighting circuits), and an insulator, which prevents electricity from flowing (like the plastic sheath around the wires). Its conductivity can be easily altered by adding minute quantities of other chemicals (called "dopants") to its crystalline structure. Other semiconductor materials include gallium arsenide, germanium, indium arsenide, and a combination of sapphire and silicon. The use of silicon is currently the most popular, but gallium arsenide technology continues to gain popularity. This is because gallium arsenide can move electricity faster than silicon and can generate light impulses, which silicon cannot do.

In addition to the production of electronic circuits, electrooptical and electromagnetic devices are also produced. These devices are made on wafers in cleanrooms with similar processes. Photocells for converting light energy to electrical energy and sensors for measuring ultraviolet (UV), visible, and infrared (IR) electromagnetic waves are made using the deposition, photolithography, and etching processes. Electromagnetic devices, such as read-write heads for magnetic disc drives, are also made using similar processes in clean rooms.

The loss potential as the result of a fire in a semiconductor manufacturing plant can be enormous. A large facility can cost $2–3 billion to construct and equip. Add to this the value of completed and in-process wafers, which are very susceptible to damage from fire and smoke, and the potential disruption in production schedules, product distribution, and business interruption, and the potential for loss can be staggering.

The in-process or finished devices generally present no unique hazard. In contrast to this, the manufacturing process presents several unique hazards to production workers and fire fighters. Acids, alkalis, flammable liquids, flammable gases, pyrophoric gases, and toxic gases are common in semiconductor manufacturing facilities.

For related topics, see Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 3, "Storage of Gases"; and Section 9, Chapter 12, "Fire Protection of Laboratories Using Chemicals."

PREPRODUCTION PROCESS

Semiconductor devices have extremely small circuit patterns. A single particle of microscopic dust can ruin a chip. Because of this, the devices are fabricated in a cleanroom. A room can be considered a cleanroom if it can maintain a particle level of fewer than 100,000 particles larger than 0.5 µm

Vinnie DeGiorgio is the semiconductor principal engineer with FM Global, based in Johnston, Rhode Island. He is a member and secretary of the NFPA 318 Technical Committee.

Heron Peterkin is field engineering group manager with FM Global.

(0.00002 in.) in size per ft^3 (0.028 m^3) of air. Such a room would be designated a Class 100,000 cleanroom. The most advanced semiconductors today require cleanrooms of Class 1 design. This means the room frequently is designed to a specification of fewer than 1 particle larger than 0.12 µm (0.000005 in.) in size per ft^3 (0.028 m^3) of air. In contrast to this, normal urban air has particle counts in the range of 5,000,000 particles per ft^3, and smoke generated from a fire can have 1 trillion particles per ft^3. The human body can release up to 2,000,000 particles per minute into the atmosphere.

Crystal Production

Crystal production involves the growing of silicon crystals in electrically heated, argon-atmosphere vacuum furnaces operating at a temperature above 1400°F (760°C). As with all crystal growing, a seed crystal is required to set the process in motion. When the growing process is complete, the silicon ingot is brought to room temperature and the seed is removed from the crystal. Years ago the diameter of the ingot was only ½ in. (13 mm). Today, 6 in. (150 mm) and 8 in. (200 mm) ingots are common and 12 in. (300 mm) versions are now widely used.

In the cut and grind operation, the ends of the polysilicon crystal are removed and the uneven exterior is ground to achieve uniformity. The silicon ingot is then sliced into wafers with a multiwire saw that make numerous cuts at once or with a diamond-edge circular saw. The saw slices the ingots into 14 to 30 mil (0.36 to 0.76 mm) wafers (i.e., about the thickness of a business card). About 28 wafers are cut from each inch of the ingot.

After being sliced, the wafers are lapped to remove the saw marks. The wafers are mounted to the lapping equipment, which features an abrasive slurry on a revolving disc. An acid etch process performed in plastic wet benches follows to remove the lap marks.

Wafers are then polished with a diamond paste to a mirrorlike finish. Finally, the wafers are given a thin surface layer of either silicon dioxide, in an oxidation furnace (metal oxide semiconductor [MOS] process), or silicon, in an epitaxial reactor (bipolar process). At this point, the wafers are ready for building of the circuits on the silicon substrate. Most chip manufacturers purchase wafers from an outside supplier, but some facilities make a small number of wafers needed for processing.

The gallium arsenide crystal is more brittle and it is more difficult to grow a single gallium aresenide crystal than a silicon one; therefore, 2 in. (50 mm), 3 in. (75 mm), and 4 in. (100 mm) wafers are typically used. Gallium arsenide circuits are sometimes grown on germanium wafers because the cost of germanium is lower. Crystals and wafers are generally not produced at the semiconductor manufacturing site. Raw wafers are purchased from outside vendors.

Mask Production

Mask production involves transferring a large circuit drawing to a glass plate called a mask. The mask may contain hundreds of exact reproductions of the original art work and is used later to recreate the pattern on the surface of the wafer. Each mask contains the pattern for a single layer of the circuit; therefore, many individual masks are used to fabricate the entire integrated circuit or chip. The mask surface can be an emulsion, chrome, iron oxide, or silicon monoxide. Most masks are fabricated from chrome on glass. Reticle and electron beam technology are two different techniques used to produce masks. Companies that specialize in mask making supply the majority of masks to the semiconductor industry. Several large semiconductor manufacturers fabricate their own masks.

The circuit design process starts with determining the intended function of the circuit. A logic diagram of the circuit is developed and then translated to a schematic diagram that shows the location of the various components. The circuit components are then translated to their relative final dimensions, as they will be formed in and on the surface of the wafer. A sophisticated computer-aided design (CAD) system then draws a composite picture of the circuit surface, showing all the sublayer patterns.

Reticle Technique. A reticle, which is an emulsion or chrome photoplate that is selectively exposed to light in a pattern generator, is a miniaturized reproduction of one layer of the circuit. The actual size of the pattern on the reticle is normally 10 times the final size of the pattern on the wafer. The computer tape from the digitizing operation instructs the shutter system to open and close, exposing the reticle in the exact pattern of the original drawing.

The pattern on the reticle is transferred to the mask in a step-and-repeat operation. The reticle is positioned over one corner of the photoresist coated mask blank, and a light source transfers the pattern on the reticle into the photoresist. After the first pattern is transferred, the machine "steps" the reticle to the next position and repeats the pattern in the next location. This process continues until the entire mask surface is filled with the reticle pattern.

Electron Beam Technology. Electron beam technology is used to make masks that produce more advanced circuits. An electron beam writer is similar to a scanning electron microscope. The coated mask is placed in a vacuum chamber and an electron beam is directed at it. The pattern information stored on the tape at the digitizing operation is used to direct the electron beam to the correct locations to expose the photoresist. The pattern is written onto the mask without a reticle.

PRODUCTION PROCESS

In the manufacturing or fabrication process, selected areas of the integrated circuit chip are made to be either conductors or insulators, thus creating electrical circuits, transistors, capacitors, and so on. Highly sophisticated manufacturing techniques allow circuit patterns as narrow as 5 millionths of an inch (⅛ µm) in width. The circuit patterns are applied in sequential layers, one on the other. Forty or more layers of circuit patterns might be combined on a single chip, depending on chip design. A modern microprocessor chip might contain over 10 million individual transistors and capacitors per square centimeter of silicon wafer. See Figure 9.9.1 for an illustration of the general production process.

Fabrication Process Steps

The fabrication process involves repeated steps of applying photoresist, photomasking, developing, etching, doping, and deposition. These processes are typically performed in cleanrooms.

Applying Photoresist. Photoresist and its developer are the largest volume solvents within the fabrication area. Negative photoresist, a photosensitive polymer suspended in a flammable organic solvent base such as xylene or toluene, is used to coat the wafer in preparation for transferring the pattern of the circuit from the mask to the wafer. The wafers are coated with a small quantity of photoresist and then rapidly rotated on a spinner, which spreads the photoresist into a thin uniform layer on the wafer. Photoresist materials are classified as either negative or positive, depending on whether the solubility in the developer decreases (negative) or increases (positive) on exposure to an ultraviolet (UV) light source. Since photoresist is sensitive to light, it is shipped and stored in and dispensed from brown glass or plastic bottles.

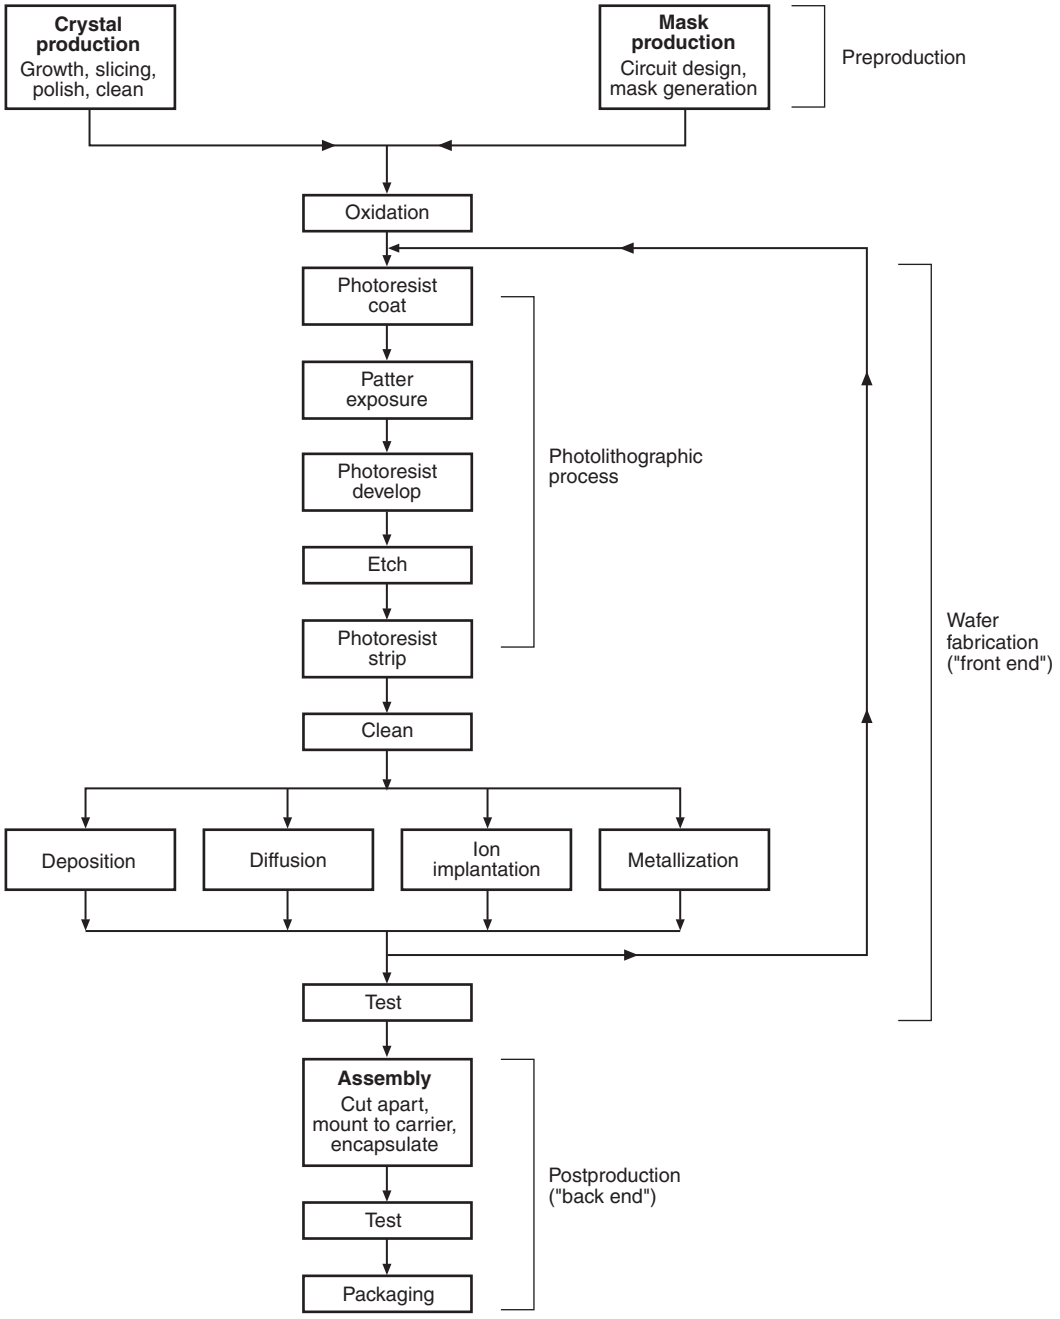

FIGURE 9.9.1 Semiconductor Manufacturing Process

Photoresist adjuncts, which consist of a variety of chemical liquids and gases, are used to promote the adhesion of the photoresist coating to the wafer. Hexamethyldisilazane (HMDS) is the most widely used chemical for adhesion and is spun onto the wafer surface prior to photoresist application.

After the wafers are coated with photoresist, they are "soft baked" to cause a portion of the solvents in the photoresist to evaporate. Methods used to soft bake include hot plates and the following types of ovens: convection, vacuum, moving belt IR, microwave, and conduction belt. After the baking has been concluded, the actual photomask process takes place.

Photomasking. Photomasking is a process of alignment and exposure. The types of equipment used for this process can vary in size, overall appearance, method of operation, and equipment cost. Equipment includes contact aligners, projection aligners, wafer steppers, and wafer scanners. The wafer is placed onto the machine and a specific patterned mask plate is placed over the wafer. The wafer is then aligned with the mask plate and exposed through the action of the shutter of the machine, which opens to allow UV light to hit the unmasked portion of the wafer.

Developing. After the wafer has been aligned and exposed, the next step is developing it. In the development process, a machine similar to a spinner is used. The developing is done by chemicals, which are sprayed onto the wafer. The spray washes away the nonexposed resist (areas where the light was not allowed to pass through the mask plate) while the exposed, or polymerized, resist remains. The preferred developing chemical for negative photoresist is xylene. A Stoddard solvent may also be used in certain cases. Positive photoresist is developed in an alkaline solution, such as potassium hydroxide, sodium hydroxide, or tetramethyl/ammonium hydroxide.

Other flammable solvents also used in the wafer fabrication process include butyl acetate and isopropyl alcohol, which are used as washes for wafers after they have been developed with negative resist. Deionized (DI) water is more commonly used with positive photoresist as a postdeveloping wash.

Etching. Etching removes layers of silicon dioxide, metals, and polysilicon, as well as photoresists, according to the desired patterns delineated by the photoresist. The two major categories of etching are wet and dry chemical, with wet etching used predominantly. Wet etching involves solutions containing etchants, usually acid mixtures at the desired strength, which react with the materials to be removed. Plastic wet benches and plastic exhaust ductwork are typically used in wet etching operations. Dry etching involves the use of reactive gases containing chlorine or fluorine under vacuum in a highly energized chamber, which also removes the desired layers not protected by photoresist.

Doping. To form the junctions where current will flow, a controlled number of impurities or dopants must be introduced into a selected region of the wafer by either diffusion or ion implantation. Diffusion is a high-temperature (1652 to 2372°F [900 to 1300°C]) process in which the dopants are introduced into the surface layer of the semiconductor material to change its electrical characteristics. Diffusion is the most established method of applying dopant material.

Ion implantation is a technique for doping impurity atoms into an underlying substrate by accelerating the selected dopant ion toward the silicon target through an electrical field. Ion implantation is often preferred over standard diffusion methods because it is more precise, faster, and less expensive. Annealing is usually required following ion implantation because of the structural damage caused by bombardment of the substrate by the accelerated ions.

The need for annealing after ion implantation has led to the development of a technology called rapid thermal processing (RTP). This process, which takes place in seconds, eliminates the need for a minutes-long process in a tube furnace, which has undesirable side effects of migration of dopant atoms within the wafer. Also, every time a wafer is heated near diffusion temperatures and then cooled down, crystal dislocation occurs, which can result in circuit failures. In the single wafer RTP tool, radiation heating (usually from tungsten halogen lamps) is very rapid, and the body of the wafer never comes up to temperature. Annealing can take place without undesirable side effects. The trend to small feature sizes on wafers has also lead to thinner layers. Thermally grown gate oxide layers now can be less than 100 Å thick. Rapid thermal oxidation (RTO) tools are similar to the RTP annealing tools, but they have an oxygen atmosphere in the chamber rather than an inert gas. RTP technology is used in various oxide, nitride, and silicon layer processes.

Deposition. Deposition is the process of placing additional layers onto the wafer surface, either by chemical vapor deposition (CVD) or physical vapor deposition (PVD). CVD is the process of causing a thin film to form on a substrate through the chemical reaction of various gases. CVD is usually promoted by the heating of the substrate, either at atmospheric pressure or at low pressure (LPCVD). Epitaxy, which represents a special form of chemical vapor deposition, is the process of depositing a crystalline layer having the same structure as that of the substrate. Often, epitaxial layers are grown with intentionally added impurities, such as boron or phosphorus. These impurities change the electrical conductivity of the crystalline silicon.

The photoresist application, photomasking, developing, etching, doping, and deposition processes are repeated many times until the complete circuit is produced. A typical photolithographic sequence using negative photoresist is shown in Figure 9.9.2. The sequence is as follows:

1. A pattern is etched onto a silicon dioxide layer that has been grown on to the surface of the wafer.
2. The wafer is coated with photoresist.
3. The coated wafer is exposed to ultraviolet light through the patterned mask.
4. Exposure renders the exposed photoresist insoluble. The unexposed photoresist is removed in the developing process, leaving a patterned area of silicon dioxide exposed.
5. The exposed silicon dioxide is removed by etching. The remaining hardened photoresist protects the unexposed silicon dioxide from the etchant.

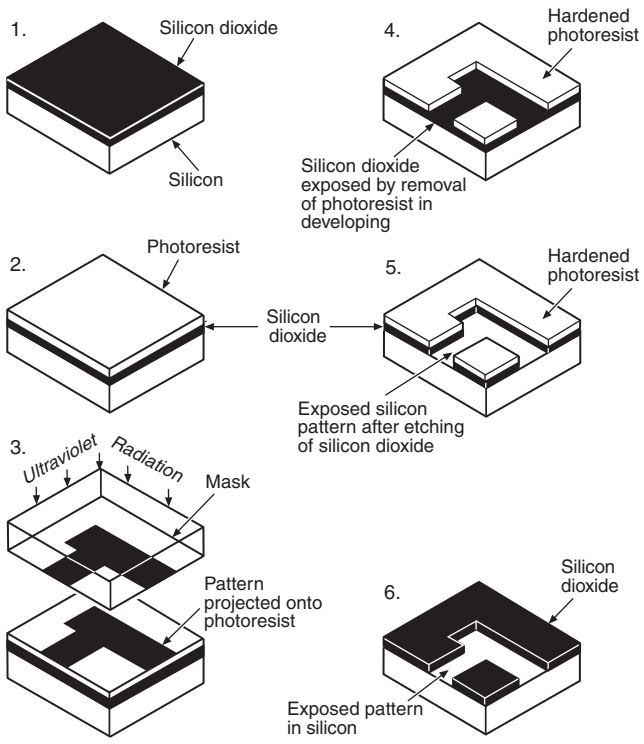

FIGURE 9.9.2 Photolithography

6. The remaining photoresist is stripped away in a chemical bath leaving a pattern on the surface of the wafer.

Metallization. After the final diffusion step, the devices that have been fabricated into the silicon wafer must be connected to perform circuit functions. This process is known as metallization. Metallization provides a means of wiring or interconnecting the uppermost layers of integrated circuits by depositing complex patterns of conductive material, which route electrical energy within the circuits. To do this, a PVD process is used in which a conductive metal is either sputtered or evaporated over the front of the wafer. A photoresist pattern is then aligned over the metal and some of it is etched away, leaving the desired metal coverage. The most common metals used for metallization are aluminum, nickel, chromium, gold, copper, silver, titanium, tungsten, and platinum.

Testing

The final step in the wafer form of integrated circuit manufacturing is testing. During the electrical test (e.g., die sort, wafer sort, wafer probe), each integrated circuit or chip is tested for its ability to perform the operations for which it was designed. As each chip is tested, a computer records information about it. If a chip is not acceptable, that is, if it fails any one or more of the tests, a small droplet of ink is automatically placed on the chip so that the bad, or inked, chip can be discarded when the wafer is separated into individual chips.

300 mm Wafer Processing Fabrication Facilities

Semiconductor manufacturing using 12 in. (300 mm) wafers are now common with over 40 such facilities now operating. The ability to fabricate more than twice as many chips on a 300 mm versus 200 mm wafer has led to significant cost savings per wafer. Many new 300 mm facilities are under construction and discussions have begun regarding the move to 450 mm wafers.

Front-Opening Unified Pod (FOUP). The main differences in 300 mm versus 200 mm fabrication facilities (fabs) are related to the high level of automation. Whereas interbay (between bays) material handling systems are common in 200 mm fabs, 300 mm fabs have automated intrabay (within bays) material handling systems. Due to the weight (8 kg) of a 24-wafer lot front-opening unified pod (FOUP), personnel movement of the FOUPs will generally not occur. Overhead hoist vehicles (OHV), automated guided vehicles (AGV), or rail guided vehicles (RGV) are used for intrabay transport.

FOUPs are staged in stockers (Figure 9.9.3) which are self-contained vertical storage units located inside cleanrooms. FOUPs in use today are generally constructed of combustible plastics and represent a significant fire hazard when located inside a stocker as confirmed by large-scale fire testing conducted by FM Global.

Fire protection options for stockers include automatic sprinkler protection, high-sensitivity smoke detection/gaseous fire suppression, or nonfire propagating FOUPs. FM Global Test Standard 4911, *Approval Standard for Wafer Carriers for Use in Cleanrooms,* provides test criteria for the rating of a FOUP as nonfire propagating. Special engineered plastics are needed to pass the requirements of Test Standard 4911.

Ceiling Heights. The minimum requirement for ceiling heights in 300 mm fabs is 14.8 ft (4.5 m) and can reach as high as 22.9 ft

FIGURE 9.9.3 Wafer Stocker and Associated Automated Materials Handling System (Source: Copyright FM Global. Reprinted with permission. All rights reserved.)

(7 m). The minimum height is necessary to allow move-in clearance for tools with heights approaching 11.5 ft (3.5 m). Ceiling heights lower than 14.8 ft (4.5 m) do not allow adequate automation track clearance configurations so that tools can pass without track removal.

In the event of a fire, these higher ceiling heights would result in a longer response time for a typical fab sprinkler system. In addition, the fire will actually be larger in terms of heat release rate (HRR) at the time of sprinkler response. This situation should be reviewed to ensure sprinkler arrangements take into account the longer response times.

Processing Tools. 300 mm processing tools are 1.0 to 1.5 times larger than comparable 200 mm tools. In addition, subfab support equipment is also greater in size. This will result in greater amounts of tool construction materials. If noncombustible and/or fire safe plastics are not used for tool construction, this will result in an increase in fire loading.

Electrical Demand. Another change is increased electrical demand for major tools, particularly in the etch area (208V and greater than 250A), which is driving more 480V supply and distribution to tools. Electrical interconnects between tools and support equipment are major considerations in equipment facilities routing between floors. The increase in power creates greater fire ignition source energy. This and the fact that there are fewer operators in the fab increases the likelihood of potential fire ignition along with delayed discovery by operators.

SEMICONDUCTOR-RELATED DEVELOPMENTS AND GUIDELINES

NFPA 318, *Standard for the Protection of Semiconductor Fabrication Facilities*

NFPA 318 was first published in 1992 and is currently a 2006 edition. The standard applies to any semiconductor facility that contains a cleanroom or "clean zone" and it provides a set of reasonable requirements to protect such facilities from a fire or related hazards. The standard includes requirements for the following:

- Construction, including seismic protection
- Fire protection, including sprinkler system design criteria and detection system design criteria
- Ventilation (air supply and recirculation) systems and local exhaust systems
- Production and support equipment, including required interlocks, electrical system design, and specific requirements for process liquid heating systems

NFPA 318 also addresses the storage and handling of chemicals used in semiconductor manufacturing processes. Topics include delivery systems for flammable and combustible liquids, both bulk and containers, as well as disposal of waste liquids. Particular attention is paid to storage and handling of cylinders of hazardous gases and bulk silane storage systems. NFPA 318 contains extensive references to relevant standards and guidelines of other organizations, such as FM Global and Semiconductor Equipment and Materials International (SEMI), as described later in this chapter.

The 2006 edition of NFPA 318 contains a new chapter addressing quantity limits for hazardous materials following coordination of this information with *NFPA 5000®, Building Construction and Safety Code®*.

NFPA 1, NFPA 318, and *NFPA 5000®*

There are cross references among NFPA 1, *Uniform Fire Code™*, NFPA 318, and *NFPA 5000.* NFPA 318 references NFPA 1 and *NFPA 5000* relative to hazardous materials storage, usage and handling, fabrication area separation walls, emergency power requirements, and hazardous chemical/gas room separation walls. NFPA 1 references NFPA 318 relative to new and existing facility compliance to NFPA 318. *NFPA 5000* states that buildings in semiconductor fabrication facilities that contain cleanrooms must be constructed in accordance with NFPA 318.

Semiconductor Equipment and Materials International (SEMI)

Semiconductor industry organizations such as the Semiconductor Equipment and Materials International (SEMI) also produced fire protection guidelines. Up to the year 2000, the industry has followed Section 19 of SEMI S2-93, *Safety Guideline for Semiconductor Manufacturing Equipment,* which provided a prescriptive and limited scope regarding fire protection. Most operators were accepting the use of UL 94 V-0, developed for small plastic appliances, to evaluate the combustibility of their large polypropylene plastic tools. UL 94 V-0 was never intended to be applied to semiconductor manufacturing tools, especially those enclosed in present-day huge minienvironments. The plastic tools in these chambers can be constructed of thousands of pounds of plastics, which in most cases is shielded from the facility automatic sprinkler systems.

SEMI S14. SEMI S14-0200, *Safety Guidelines for Fire Risk Assessment and Mitigation for Semiconductor Manufacturing Equipment,* was originally published in February 2000. The purpose of the document is to assess the risks to equipment that might be created by fire and to allow for performance-based alternative methods to reduce or mitigate those risks. The guideline is intended to apply to all semiconductor manufacturing equipment in the fabrication area air-flow space, possibly including the subfabrication area. The document is intended to be used in the design of new equipment, but can also be used to categorize and report the risks for existing equipment in a facility. It is not intended to be used to evaluate the fire sources that can start outside of a piece of equipment. The document does not assess or review any regional or local regulations and is not intended to be used as a code document. The following hierarchy, or cascade, of correction should be used whenever possible, as this emphasizes the concept of a proactive rather than a reactive solution:

1. Taking steps to eliminate the hazard or to replace combustible material with noncombustible material

2. Using a nonpropagating material of limited combustibility
3. Reducing the hazard by using detection, suppression, or another mitigation method, including power shutdown

S14 provides a formalized approach to evaluating various potential fire hazards and their risks, provides a standardized method of categorizing and reporting those risks to the user, and gives some minimum requirements for risk reduction or mitigation methods. SEMI S14 has been revised several times and the most current version is SEMI S14-0704.

SEMI S2. SEMI S2, *Environmental, Health, and Safety Guideline for Semiconductor Manufacturing Equipment,* is a safety guideline intended as a set of performance-based environmental health and safety (EHS) considerations for semiconductor manufacturing equipment. SEMI S2-0703A contains an extensive section on fire protection. According to SEMI S2-0703A's Section 14, equipment fire risk is to be assessed and reported, as are the risk mitigation features that are incorporated. It allows for optional fire risk reduction features, depending on the plant's level of risk acceptance. The prescriptive components are limited to those the supplier and user communities consider common to most equipment. There is also a description of how some of the features are to be provided, but the direct inclusion of these is only prescribed if risk assessment finds them to be necessary.

When risk reduction is considered, materials of construction are high on the list. Noncombustible material should be used whenever possible, with the second choice being materials that do not propagate flame. It advocates that the selection of materials be based on minimizing fire risk, but also recognizes that materials must be compatible with process chemistries. The hazards from the materials of construction might be reduced, for example, by using barriers of noncombustible materials to separate combustible materials from sources of ignition.

Another method of risk reduction is a fire detection and suppression system, which is to be included only if the need is indicated by the risk assessment. The components of the fire detection and suppression system should be suitable for use in process equipment, certified by an accredited testing laboratory, installed in accordance with appropriate standards, and capable of interfacing with the facility systems.

HAZARD CONTROL IN SEMICONDUCTOR MANUFACTURING

Most of the potential hazards encountered in semiconductor manufacturing plants are commonly found in other industries as well. Plating operations, crystal growing, flammable liquids, and flammable gases all present hazards that are widely recognized and for which effective loss prevention controls are established.

There are, however, several hazards that are not widely encountered in other industries. Pyrophoric gases, toxic materials (gases, liquids, and solids), radio frequency fields, ionizing radiation, and special handling techniques required for certain chemicals due to purity constraints are examples of uncommon potential hazards that might be encountered in semiconductor manufacturing facilities.

General Safeguards

Semiconductor manufacturing cleanrooms should be located in buildings of fire-resistant construction and must be equipped with a fully automatic, fast-response sprinkler system. The cleanroom should be cut off from other areas of the plant by fire-rated construction having a minimum rating of 1 hour. Because of the high values present, additional compartmentation is highly desirable. Ventilation systems, including recirculating and exhaust systems, should be independent of ventilation systems in adjoining compartments.

Recirculating air systems should be designed with the flexibility to shut down in the event of a fire or chemical spill. Exhaust systems serving processes using toxic materials should continue running during such incidents. This will allow continued removal and treatment of potentially dangerous fumes and vapors from the cleanroom, as well as assist in smoke removal. Most of these exhaust systems contain treatment processes to remove or neutralize the chemical(s) in the exhaust stream. Caution should be used in placing automatic sprinklers inside ducts used for fume and vapor exhaust, because sprinklers may significantly reduce the exhaust flow through the duct when sprinklers are operating. This could be undesirable in exhaust systems handling toxic fumes or vapors.

Fire extinguishers and hose stations should be provided. The minimum extinguisher capability should be distributed on an extra-hazard schedule in fabrication areas. (See NFPA 10, *Standard for Portable Fire Extinguishers.*) Carbon dioxide (CO_2) fire extinguishers are the most common type used in cleanrooms. Dry chemical extinguishers are not recommended for use in cleanrooms, because the powdered extinguishing agent used in these extinguishers will contaminate an area of the cleanroom where it is discharged, causing many wafers in the area to be contaminated beyond salvage. Most of the equipment will require meticulous and expensive cleaning to remove the powder, and the high-efficiency particulate air (HEPA) filters will probably have to be replaced at great expense. In specific isolated situations, combustible metal extinguishing powders, such as MET-L-X, might be appropriate for processes using combustible metals.

Selected process equipment or wet benches may be considered for protection with fine water spray or gaseous extinguishing systems (such as CO_2 or FM-200). However, process constraints should be evaluated when this option is considered.

Cleanroom Overview

The fabrication or main part of the semiconductor manufacturing process is performed in Class 1–10,000 cleanrooms (Figure 9.9.4). The two basic methods of constructing a cleanroom are the built-in-place method and the modular method.

Built-in-place rooms are based on a custom design and all construction is on site. These rooms are the most practical approach for larger, permanent installations. Prefabricated or modular construction uses manufactured, modular components that can be connected to one another in a variety of ways.

FIGURE 9.9.4 Clean Bay Service Aisle (Source: Copyright FM Global. Reprinted with permission. All rights reserved.)

In either modular or built-in-place construction, the mechanical systems must be custom designed and installed. The cleanroom air-handling system includes the make-up air system and the recirculation system. The concept of laminar air flow is used in nearly all semiconductor cleanrooms. Laminar flow occurs when air is made to flow in unidirectional layers. The air flow velocity in a cleanroom ranges from 40 to 100 ft/min (0.2 to 0.5 m/sec). Depending on the velocity, up to 10 air changes per minute might occur. Typical air flow volumes for new cleanrooms, whether recirculated at work stations, modules, or large global air systems, range from about 20 to 50 cfm/ft^2 (6 to 15 m^3/min/m^2) of clean room. This assumes that 60 percent of the cleanroom is made up of service corridors with less stringent requirements.

The method of returning the air from the cleanroom to the recirculation fans is accomplished through sidewall vents, a perforated raised floor, or a perforated raised floor opening into a basement plenum. Sidewall returns are openings in the walls of the work area that are used as the path for return air. A perforated raised floor is a perforated deck raised 1 to 4 ft (0.3 to 1.2 m) above the structural floor of the room. The space between the perforated deck and the solid floor forms a path for air return. In the last case, perforations in the structural floor allow air flow directly into the basement of the building, which is used as an air return path.

The air supplied to the cleanroom is usually a mixture of recirculated air and make-up air that compensates for leakage and exhaust losses. Since the recirculated air is cleaner and closer to the desired temperature and humidity, a high ratio (80 to 95 percent) of recirculated-to-make-up air is provided.

The cleanroom is typically kept under a slight positive pressure of about 0.15 in. (40 Pa) water. This is done to maintain airflow from the cleanroom to the outside if there is any air leakage or if a door or other passage is opened. If outside air were to rush in, it would bring millions of airborne contaminants with it.

FIRE HAZARDS

Flammable Liquids

A number of fairly common flammable liquids are used in chip fabrication processes. Most are alcohols and alcohol-based mixtures. When these liquids are to be used in direct wafer processing (i.e., in contact with the wafer), absolute purity of the liquid must be maintained. As in the cleanroom atmosphere itself, a single microscopic particle can contaminate the chip, rendering it useless.

Storage and handling of flammable liquids should generally follow the principles outlined in NFPA 30, *Flammable and Combustible Liquids Code.* Special precautions are necessary to handle flammable materials safely. These include carts designed specifically to transport containers safely from the flammable liquid storage room to the cleanroom. These carts hold the containers firmly upright and can even contain the contents in the event of leakage. Regardless of container construction, flammable liquids not being used should be stored in listed flammable liquid storage cabinets. Personnel training and restricted travel routes for the carts between storeroom and cleanroom should be provided.

In some cases, the flammable liquid is piped into the process equipment. The bulk supply will vary in size and location according to process requirements. Appropriate safeguards must be taken to ensure stability of the pipe system. Bulk dispensing in closed, dual-contained systems is prevalent throughout the industry.

Flammable and Pyrophoric Gases

Some of the gases used in semiconductor manufacturing are either flammable or pyrophoric (i.e., ignite spontaneously on contact with air). The gases might be pure, or they might be found as mixtures, with a carrier gas such as hydrogen or nitrogen. Pyrophoric and toxic gases should be placed outside the plant. Gas may be piped to the cleanroom in welded, stainless steel tubing. Process equipment using high concentrations of pyrophoric gases, such as silane, should be equipped with exhaust gas conditioning in the exhaust stream. The exhaust systems should be equipped with continuous monitoring devices to warn of abnormal conditions.

The burning characteristics of pyrophoric gases, such as silane, dichlorosilane, diborane, and phosphine, are not fully un-

derstood, mostly because the engineering controls provided for these processes have been so successful in eliminating uncontrolled releases. Experience has shown that when a leak occurs in an unconfined area (e.g., outdoors), pyrophoric gases usually ignite on release and subsequently burn in a manner similar to other flammable gases.

The use of the pyrophoric gas silane as a source of silicon in semiconductor manufacturing has grown greatly over the years. The hazards of this material are noteworthy due to the ability of the material to self-ignite with visible flame on release or, in other cases, to be released with either no ignition or delayed ignition occurring, possibly resulting in a detonation explosion. When released into a confined area, such as a gas cabinet, silane has been known to detonate.

Studies conducted by the Compressed Gas Association (CGA) on the release of large quantities of silane have produced technical data. These data have resulted in a CGA publication P32-2000, "Safe Storage and Handling of Silane and Silane Mixtures." The data in P32 have been used to establish minimum separation distances for system installations. These distance limitations minimize risk in the event of an inadvertent release. The distances determined recognize the probability for immediate ignition as well as the probability of latent ignition with its potential explosive effects. It also includes guidance on siting, design of equipment, piping, and controls, fire protection, gas detection, ventilation, and related safeguards. The P32-2000 document has recently been revised and now is called G-13, "Storage and Handling of Silane and Silane Mixtures."

NFPA 318 contains new performance-based guidance on silane gas cabinet ventilation rates, based on FM Global Research testing. Figure 9.9.5 gives average silane concentrations in a ventilated enclosure, and Table 9.9.1 shows silane flow rates through restrictive orifices.

Explanatory appendix material in NFPA 318 gives additional guidance (based on the Compressed Gas Association studies on releases of silane) on separation of bulk silane systems from buildings. The guidance uses performance criteria based on the pressure in the system and the size of the pressure relief valve.

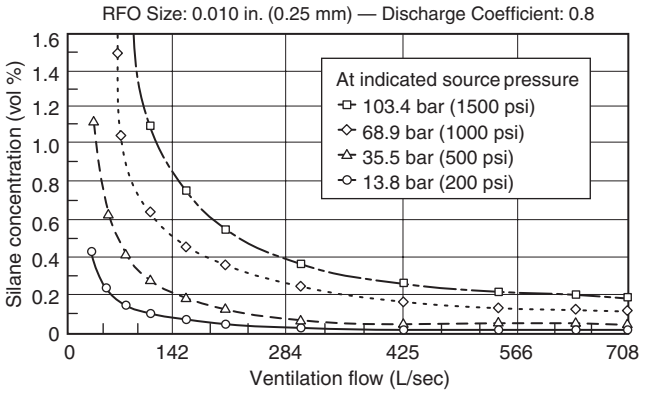

FIGURE 9.9.5 Average Silane Concentration in a Ventilated Enclosure. Notes: 1. If RFO = 0.36 mm (0.014 in.), multiply silane concentration by 2.0. 2. If RFO = 0.51 mm (0.020 in.), multiply silane concentration by 4.0. 3. If RFO = 0.15 mm (0.006 in.), multiply silane concentration by 0.36. (Source: NFPA 318, *Standard for the Protection of Semiconductor Fabrication Facilities,* Figure 8.5.3(C), 2006, p. 318-17)

Cleanroom Furnishings

Workstations, wet benches, and other equipment used in fabrication areas are specially designed to reduce dust accumulation and release of particulates (from the finish treatment) into the room and for compatibility with the chemicals used in or around the equipment. Fiberglass-reinforced plastic ducts for exhaust of corrosive fumes are usually present.

NFPA 318 contains major modifications dealing with fire protection for the tools in the semiconductor cleanroom, which could well be the most significant change to the standard. The requirement says that tools should be of noncombustible construction. An existing exception has been deleted and three new exceptions have been added. The first exception states that small

TABLE 9.9.1 Silane Flow Rates Through Restricted Flow Orifices

RFO Diameter		Source Pressure (bar) (psi)								
mm	*in.*	*103.4 (1500)*	*82.7 (1200)*	*68.9 (1000)*	*55.1 (800)*	*41.3 (600)*	*27.6 (400)*	*13.8 (200)*	*6.9 (100)*	*3.5 (50)*

parts are excluded. The second exception allows the use of listed nonfire propagating materials that are acceptable without internal fire detection and suppression. The third exception allows the use of other control methodologies, such as fire sprinklers or detection and suppression systems. There is also extensive new appendix material regarding the second exception that adds references to the FM Global Test Standard 4910, *Cleanroom Material Flammability Test Protocol,* and UL 2360, *Test Methods for Determining the Combustibility Characteristics of Plastics Used in Semi-Conductor Tool Construction,* for listing materials acceptable for use in cleanrooms without internal fire detection and suppression.

FM Global Test Standard 4910 provides guidance for assessing the fire hazard of materials used in environments highly sensitive to thermal and nonthermal damage, such as within cleanrooms in the semiconductor industry. The test apparatus is recognized in ASTM E2058, *Standard Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus (FPA),* and the fire test methodology is recognized in NFPA 287, *Standard Test Methods for Measurement of Flammability of Materials in Cleanrooms Using a Fire Propagation Apparatus (FPA).* The protocol uses three small-scale tests and, if needed, a large-scale validation test. Small-scale tests are performed in a flammability apparatus, which includes a fire products collector and data evaluation equipment. The tests include ignition tests, fire propagation tests, and combustion tests.

Based on results of the three small-scale tests, the following indices are determined for each material tested:

1. Fire propagation index (FPI): This index is determined by the fire propagation tests and represents the ease or difficulty of fire propagation on the surface of the material, as expected in large-scale fires. Nonpropagating materials have FPI values at or below 6.0.
2. Smoke development index (SDI): This index is defined as the product of the FPI and the yield of smoke for a given material and represents the rate at which smoke is expected to be released during fire propagation. Materials expected to restrict smoke development have SDI values of 0.4 or less.

Materials that meet the flammability protocol criteria require high heat fluxes to be ignited; once ignited, these materials can burn locally in the ignition area, but they will not propagate a fire beyond the ignition zone. Smoke and corrosive products generated from the combustion of these materials are reduced, minimizing nonthermal damages.

Underwriters Laboratories has also developed a cone-calorimeter-based test method as an alternative to the FM Global 4910 oxygen-enriched fire propagation apparatus test protocol. The cone calorimeter is the basis of ASTM E1354, *Standard Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter,* and is widely available. It is also the referenced instrument of ISO 5660 and NFPA 271, *Standard Method of Test for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter,* and resulted in UL 2360.

The plastic materials tested are identified as nonpropagating—Class 1; limited propagating—Class 2; and slow propagating—Class 3. The individual classifications are defined as follows:

Class 1. Materials that ignite with limited propagation of flame and a demonstrated flame propagation index of 6 or less in the cone calorimeter and flame propagation in the parallel panel test of 4 ft or less. Smoke damage index is 0.4 or less.

Class 2. Materials that ignite with limited propagation of flame in the parallel panel test of less than 8 ft. Smoke damage index is 0.4 or less.

Class 3. Materials that ignite with maximum flame propagation in the parallel panel test of less than 8 ft in the first 10 minutes of the test. Smoke damage index is 1.0 or less.

HEALTH HAZARDS

Although health hazards are also present in semiconductor manufacturing, they are beyond the scope of this handbook. They are mentioned briefly only to acknowledge their existence. For additional information concerning any particular hazard, an industrial hygienist or safety engineer should be consulted. Semiconductor plants should have persons on staff trained in these disciplines.

Several of the gases used, such as arsine, phosphine, and diborane, are highly toxic. The toxicity hazards must be monitored on a continual basis and controlled. In addition to the piping and control systems, the exhaust systems from the process tools should include treatment processes for these materials to avoid release into the atmosphere.

Many of the liquid and solid chemicals used in semiconductor manufacturing are also toxic. Examples include arsenic, various acids, and solvents. Safety considerations including ventilation and employee training are required.

In addition to chemical hazards present in the fabrication area, there are sources of ionizing radiation, laser radiation, radio frequency (RF) energy, and exposure to UV radiation. The machines should have appropriate safety devices and controls incorporated into them and follow the SEMI recommendations for cleanroom equipment.

SUMMARY

Silicon, a fundamental component of sand, is processed through many steps in order to manufacture semiconductor devices, also known as integrated circuits or "chips," which serve a variety of purposes. Several types of fire hazards are associated with semiconductor manufacturing, including hazards that are commonly found in other industries such as flammable liquids and gases. Other hazards are pyrophoric gases, toxic materials, radio frequency fields, and ionizing radiation. General safeguards include cleanrooms located in buildings of fire-resistant construction, fully automatic, fast-response sprinkler systems, recirculating air systems, exhaust systems, fire extinguishers,

hose stations, and specially designed cleanroom furnishings and semiconductor manufacturing equipment.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on the processes and protective systems for semiconductor manufacturing discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 1, *Uniform Fire Code™*
NFPA 10, *Standard for Portable Fire Extinguishers*
NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems*
NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances*
NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems*
NFPA 30, *Flammable and Combustible Liquids Code*
NFPA 70, *National Electrical Code®*
NFPA 75, *Standard for the Protection of Information Technology Equipment*
NFPA 86, *Standard for Ovens and Furnaces*
NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems*

Solvent Extraction Process
Hazards of Solvent Extraction
Fire Protection

Key Terms

desolventizer-toaster (D-T) unit, flammable solvent, hexane, oilseed, rotary cooler, rotary steam tube dryer, solvent extraction process

Oilseeds that contain approximately 20 percent oil by weight, such as soybeans, are usually extracted directly. Seeds containing more than 20 percent oil usually are prepared by prepressing to reduce their oil content to 10 to 20 percent. Facilities employing this step are called prepress solvent extraction plants. Some major oilseeds processed this way are cottonseed, rapeseed, flaxseed, corngerm, sunflower, safflower, peanuts, and copra.

Additional information relevant to the solvent extraction process can be found in the following chapters: Section 6, Chapter 8, "Dusts"; Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 9, Chapter 7, "Storage and Handling of Grain Mill Products"; and Section 11, Chapter 1, "Waste Handling and Control."

SOLVENT EXTRACTION PROCESS

Solvents Used

Commercial hexane is the solvent exclusively used in oilseed extraction because it is relatively easy to desolventize from the extracted meal and oil products, making them nontoxic; it is essentially immiscible with water; and it can be produced from petroleum at a relatively low cost. Commercial hexane consists of a mixture of these petroleum solvents: normal hexane with a weight ranging from about 53 percent to 85 percent (60 percent by weight is a normal average); methylcyclopentane, about 13 percent to 15 percent; methylpentanes, about 22 percent to 25 percent; and dimethylbutanes, about 1 percent. The major disadvantage of commercial hexane is the danger of fire and/or explosion. This danger is overcome by careful design, construction, and operation of the solvent extraction plant.

Other flammable solvents, such as mixtures of aromatic hydrocarbons, are used for extracting lignite, Douglas fir bark, and other special raw materials whose end products are not used by humans for internal consumption.

Description of the Process

Unit operations for extracting all oilseeds are similar, and usually the same equipment can handle the flakes or cakes from these materials. A flow diagram for a typical extraction process is shown in Figure 9.10.1.

For safe storage, oilseeds are brought into the processing plant, checked for moisture content, and dried in a flue gas dryer to about 10 or 11 percent moisture content by weight. To eliminate fire hazards in both the dryer and in the preparation step of the extraction process, seeds are cleaned to remove trash, dirt, and foreign material before they are dried.

The solvent extraction process is continuous. Its rate is usually controlled by measuring at the weigh scale and adjusting the cracking mill feed rolls. The cracking mill splits the hulls and breaks the seeds. Screens and aspiration remove hulls. The seeds are flaked between rollers after passing through a rotary steam tube conditioner. Here they are heated to temperatures between 140 and

C. Louis Kingsbaker is president of C. L. Kingsbaker, Inc., consultants to the oilseed industry.

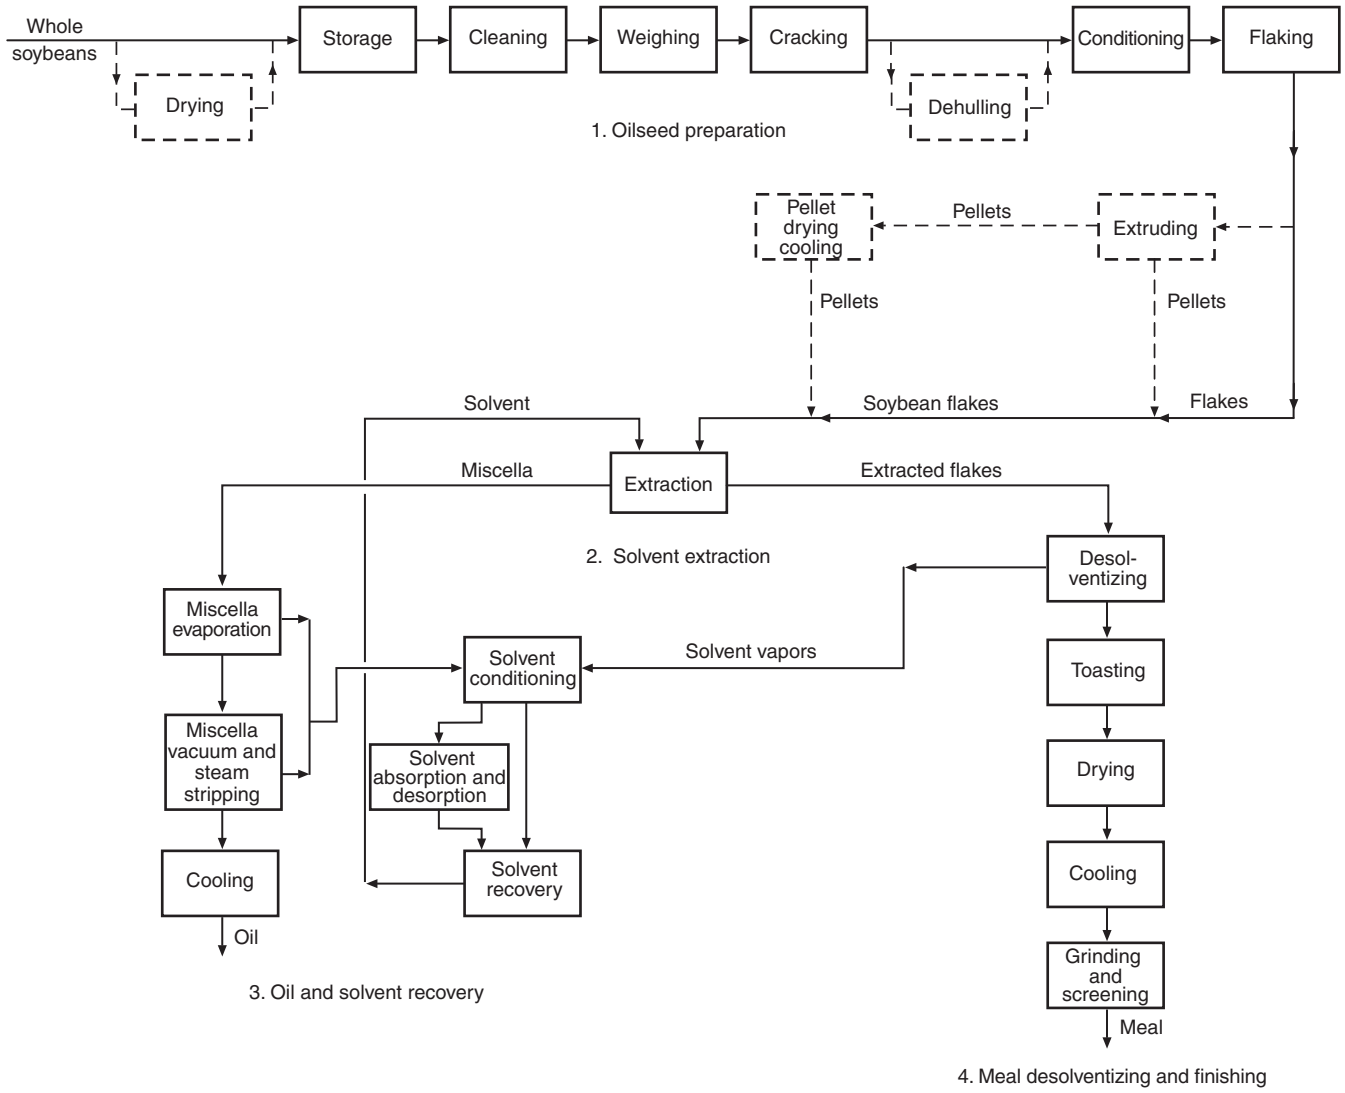

FIGURE 9.10.1 Soybean Solvent Extraction Process

165°F (60 and 74°C) and the moisture content is adjusted to between 10 and 10½ percent.

Due to the demand for high protein soybean meal for poultry and other animal feeds, most U.S. extraction plants remove hulls from cracked soybeans using sifters and aspirators in the separation step. To achieve good separation of hulls from bean meats, typically the bulk moisture is reduced to about 10 percent by weight. The beans are then stored for several days in "tempering" silos to allow the residual moisture to equilibrate. A newer method is to process the beans directly from storage at their normal moisture content by heating them quickly in a fluidized bed dryer. Then the beans are cracked and dehulled while still hot. The meats are then conditioned in a second fluidized bed dryer prior to flaking.

Within the past 15 years, many processors have installed equipment to produce pellets or collets from soybean flakes and other oilseeds. This machine is called an expander and consists of a tubular barrel, a feeding device that takes material into the barrel, a cut flight screw inside the barrel, bolts that protrude from the barrel into the spaces between the discontinuous flights to add shear to the material inside, a die plate at the outlet of the barrel through which the extruded material leaves the machine, and a large motor and drive that powers the unit. Live steam injected into the barrel heats and cooks the oilseed and raises its moisture content. The purpose of using an expander is to rupture additional oil cells and increase the pellet's density when compared to the flake. However, the most important benefit is to greatly improve the drainage of the solvent and miscella (mixture of extracted oil and hexane) streams added to the extractor. With better drainage in the extractor, material leaving the extractor has a lower solvent holdup, which reduces the desolventizing duty in the desolventizer-toaster and saves considerable steam energy. Some plants only expand about 20 to 25 percent of the incoming flakes, whereas others expand 100 percent of the stream. As long as no more than about 30 percent of the flakes are extruded, the pellets can be fed directly back

into the remaining flake stream. But if more than 40 percent of the flakes are pelletized, a dryer-cooler must be provided to reduce the pellets' moisture content and cool them to about 165°F (74°C). Higher oil content oilseeds, such as cottonseed, can be extruded and then extracted without first prepressing them in a screw press.

Hot flakes are delivered to the extractor, which is usually of the continuous percolation type. The liquid solvent enters above the flake bed and drains or percolates through the bed to a compartment below the flakes to be recycled by a pump to another stage of the extractor. Most percolation extractors have six or more extraction stages.

The many types of percolation extractors include vertical basket, rotary, stationary bottom, sliding cell, perforated belt, and rectangular loop extractors. Figure 9.10.2 shows a rectangular loop extractor. Fresh, recovered hexane solvent, heated to about 140°F (60°C), contacts flakes near the extractor's discharge end to remove the remaining oil from the flakes. This solvent, which now contains some oil, is pumped from stage to stage in a direction counter to the flakes' flow and becomes richer in oil with each successive stage. Oil extracted from the flakes and mixed with hexane, which is called miscella, usually has a concentration of 25 to 30 percent by weight when it exits the extractor. The amount of hexane solvent added to the extractor is one part solvent to one part flake, by weight. This is the solvent ratio and ranges from 0.85 to 1.10. The extractor normally operates at 140°F (60°C) and at either atmospheric pressure or at a slight vacuum of ½ in. water gauge (gauge pressure of 124 Pa). A variable-speed drive, or variable-speed motor, controls the extractor speed for changes of plant rate and also bed height in the extractor.

After the flakes move beyond the solvent addition point in the extractor, time is provided for hexane to drain. Extracted and drained flakes are conveyed to equipment to desolventize, toast, dry, and cool the material. Two processing systems are used to accomplish this. The first, which is now being phased out in older plants, requires three individual equipment items: (1) the desolventizer-toaster (D-T unit), (2) a rotary steam tube dryer (D), and (3) a rotary cooler (C) using ambient air to cool the meal. The second system, the counter current D-T-D-C, is normally installed in extraction plants. This single piece of equipment achieves the four processing steps (Figure 9.10.3). It consists of eight trays: two predesolventizing trays (1 and 2); two hollow staybolt trays, often called countercurrent trays (3 and 4); one sparge (5); two drying trays (6 and 7); and one cooling tray (8). Additional trays can be provided for each processing step as needed, depending on plant capacity, or the type of oilseed processed.

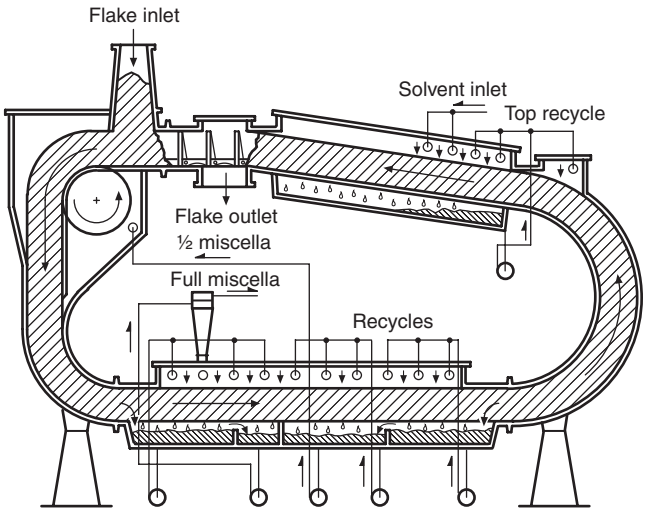

FIGURE 9.10.2 Rectangular Loop Extractor

The processing principles are the same for each type of seed. Open or sparge steam in the desolventizer strips solvent from the flakes. Toasting is accomplished by indirect contact with high-pressure steam in trays 1, 2, 3, and 4 and the open steam. The D-T-D-C is a vertical, cylindrical unit consisting of multiple trays or decks. Flakes drop from tray to tray. Open steam in the top five trays removes solvent. Steam condenses in the flakes, raising the flakes' moisture content. Toasting is also done in these trays, which are also heated by indirect steam.

Usually, the desolventizing step uses about 10 percent excess sparge steam. The D-T-D-C dome's normal operating temperature is about 158 to 165°F (70 to 74°C). The outlet temperature from tray 5 must be at least 221°F (105°C). Lower flake outlet temperature indicates that not all solvent has been removed, which could present a potential safety hazard. Operating pressure at the top of the D-T-D-C should be lower than the pressure in the extractor. This prevents steam vapor from flowing back to the extractor and stops solvent vapor from flowing downward through the outlet of the toasting section. Solvent and excess sparge steam vapors leaving the top of the D-T-D-C are scrubbed with liquid hexane to remove any fine particulates that might be entrained in these vapors, and are condensed, recovered, and reused in the extraction step.

The specially designed rotary valve located at the outlet of tray 5 has a variable speed drive. Its speed controls the operating levels in trays 1 through 5. It also seals tray 5 from tray 6 to prevent drying air from blowing into tray 5 from tray 6. Tray 6 has a much higher operating pressure than tray 5. The rotary valve is a safety device that prevents explosive mixtures of hexane and air from forming in the unit's top five trays.

The desolventized material drops into trays 6 and 7, where it contacts hot air. As the water-moist meal proceeds downwards, heated air is injected through holes in the top of these two trays. The hot air evaporates excess moisture in the meal, and as water evaporates from desolventized meal, its temperature drops. A fan sends atmospheric air through a steam coil air heater and into the trays for drying.

The outlets from trays 6 and 7 each have a gate and sail arrangement. The gate is normally closed until the level in each tray rises high enough to contact a sail at the top of its tray. The sail, located inside the tray, has a shaft that extends through the D-T-D-C shell; the end of the shaft connects externally to the gate at the tray's outlet. When the meal contacts the sail, the sail opens the gate to permit material to exit the tray. This automatically maintains meal levels in the trays.

A steam purge line admits a small quantity of open steam against the rotary valve at the outlet of tray 5. Its purpose is to purge the valve pockets of the hot drying air picked up from tray

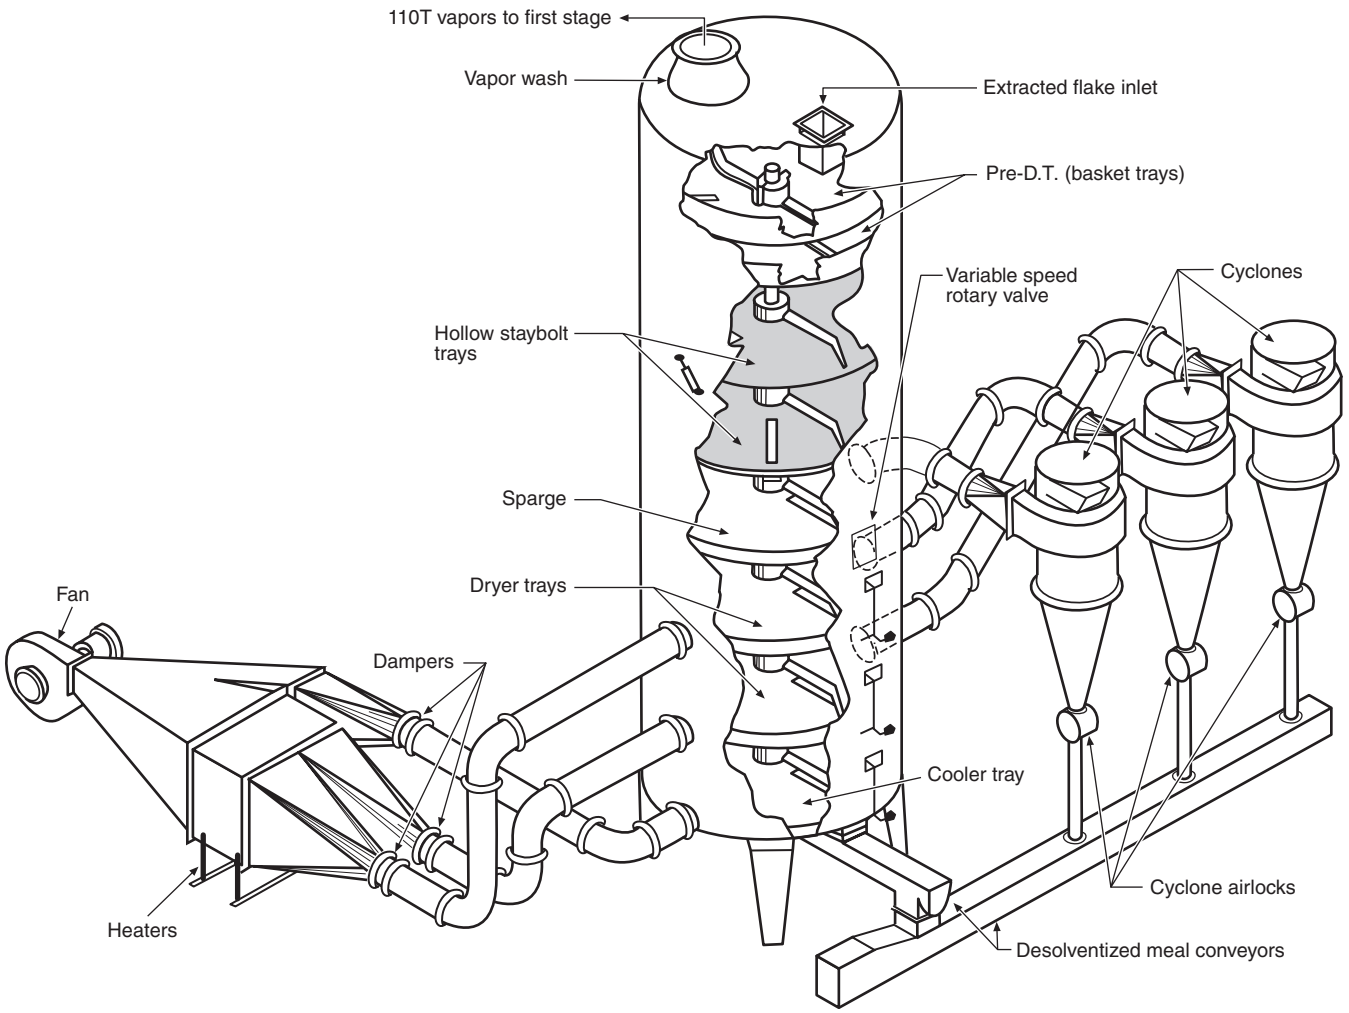

FIGURE 9.10.3 Counterflow D-T-D-C

6 as it turns in its cycle at the top of drying tray 6. The valve pockets, now filled with steam, prevent dryer air from entering the desolventizing zones of the unit and forming explosive mixtures there.

Dried meal from tray 7 drops into tray 8 where it is contacted by a stream of cool, ambient air, in similar countercurrent flow as tray 7 and through holes in the top of the tray deck. The same fan that introduces air into the drying trays sends air to the cooling tray. The meal, dried to a moisture content of 12 percent by weight and cooled to between 115 and 120°F (46 and 49°C), is conveyed to the meal finishing system for sizing by the desolventized meal conveyors. Three cyclones, each with a rotary air lock, remove meal fines from the D-T-D-C drying and cooling air streams.

A low temperature alarm sounds when the meal temperature leaving tray 5 drops to 205°F (96°C). It warns of possible carryover of hexane solvent in the meal leaving the desolventizing-toasting section of the D-T-D-C. If the warning alarm is not heeded and the meal temperature continues to fall, a low temperature shutdown switch automatically stops the inlet feed to the D-T-D-C when this temperature reaches 195°F (90°C). NFPA 36, *Standard for Solvent Extraction Plants,* requires both safety devices.

Oil is removed from the solvent in three stages by two long tube rising film evaporators and a stripping column. The first-stage evaporator operates at a vacuum of about 15 in. (51 kPa) of mercury on the tube side and uses vapors from the desolventizer-toaster to provide heat. Miscella from the first stage evaporator has an oil concentration of about 50 to 60 percent. The second-stage evaporator normally operates at atmospheric pressure, using low-pressure steam in the shell side. Final removal of solvent from the 92 percent miscella out of the second stage evaporator is carried out in a stripping column operating under vacuum ranging from 22 to 27 in. (74 to 91 kPa) of mercury at a temperature of 210 to 240°F (99 to 115°C) and using open or sparge steam at the bottom of the column. The vacuum dries or removes water from the oil, and the sparge steam strips the final traces of hexane solvent.

All solvent is condensed and returned to the solvent separator, along with solvent from the flake-desolventizing step. The solvent separator's 15 minute holding interval allows water condensed in the process to separate from the solvent. The water

flows from the separator to a wastewater evaporator, where it is heated to at least 200°F (93°C) with open steam to remove any entrained solvent, before leaving the plant for a wastewater trap and finally to a sewer. The separated solvent returns to the extractor for reuse.

A low-temperature alarm sounds when the temperature of water leaving the wastewater evaporator drops to 185°F (85°C). It warns that carryover of hexane solvent may enter public sewer systems. If the warning alarm is not heeded, and the wastewater temperature continues to fall, a low temperature shutdown switch automatically stops the extractor drive motor when the temperature reaches 175°F (80°C). NFPA 36 requires both safety devices. There was no such alarm and shutdown device at a soybean plant in Louisville, Kentucky, when a massive quantity of hexane entered the sewers in 1981 and blew up 6 miles (10 km) of the sewer system.[1]

The extractor and all other tanks and condensers in the process are vented to a separate header and into a vent recovery system. This system, which uses an edible mineral oil to absorb vent gases, consists of two columns filled with ceramic or metallic packing. One column absorbs hexane solvent vapors with a flow of cool mineral oil counter to the flow of the vapors. The other column strips the absorbed hexane solvent vapors from the mineral oil with open steam. A condensing system condenses these vapors. The mineral oil recirculates continuously for reuse. A blower on top of the mineral oil absorber removes unabsorbed water and air vapors that discharge into the atmosphere through a flame arrestor. The blower also provides a slight vacuum for all equipment in the extraction system. Maintaining the process at a low vacuum prevents solvent vapors from escaping from the system and entering the extraction building. To prevent similar incidents, extraction plants are now equipped with high-pressure alarms and high-pressure shutdown switches. High pressures in the extractor and the top of the D-T-D-C activate these devices. NFPA 36 also requires extraction plants to install relief valves on vessels such as the extractor, solvent work tank, miscella tank, and solvent-water separator. The relief valve provides emergency venting to relieve excessive internal pressures in case of a fire; it also protects the vessels from being ruptured by high internal pressures. The discharge line from the relief valves to the atmosphere must not be provided with a flame arrestor.

Efficiency of the Process

Most designers of solvent extraction facilities make efficiency guarantees for the process. The guarantees are important not only for the profitability of the process but also for safe plant operation. Exceeding these guarantees indicates potential safety problems, and steps must be taken to correct them. The guarantees given here are typical for the soybean processing industry but do vary considerably when other oilseeds are processed. In a process having a capacity that can be measured in U.S. tons/24 hour day, the following conditions can be expected:

1. Solvent loss of 0.055 percent by weight of beans processed or 0.20 U.S. gal/U.S. ton of beans (0.83 L/metric tonne)
2. Residual oil content of flakes from extractor of 0.5 percent by weight, corrected to 12 percent water by weight on a solvent-free basis
3. Crude oil 0.10 percent of total moisture and volatiles by weight that will not flash at 300°F (150°C) in a closed-cup flash tester
4. Soybean flakes from a meal cooler will not exceed a 0.15 pH rise in urease enzyme activity, measured by the Caskey-Knapp method[2]

HAZARDS OF SOLVENT EXTRACTION

The principal hazards specific to solvent extraction operations are the highly flammable solvents used and combustible dusts associated with storing and handling oilseeds. Ignition sources include arcing electrical equipment, static electricity, and open flame. Ignition can occur during regular operations, maintenance operations, or an emergency. Attempts to operate a facility beyond its design capacity can introduce hazards of abnormal operation.

Normal Operations

Solvent Loss. To prevent fires, it is necessary to keep solvent liquid or vapor from leaving the extraction plant and controlled areas. Hexane solvent vapor is about three times heavier than air and, if not dispersed, could possibly enter areas where an ignition source is present. To be ignitable, the vapor concentration in air must be within its flammable limits—1.2 to 6.9 percent by volume. (Consult Table 9.10.1 for details on the physical properties of typical commercial hexane and isohexane.)

The U.S. Environmental Protection Agency (EPA) has published its national emission standard of hazardous air pollutants (HAP) for vegetable oil production from solvent extraction plants. The standards were issued in 2000 in the U.S. Federal Register. EPA considers solvent extraction plants for vegetable oil production as a major source of *n*-hexane emissions and has classified *n*-hexane as a hazardous air pollutant. Therefore, all existing and new solvent extraction processes that are sources (defined as those facilities with the potential to emit 10 tons (9.1 tonees [2004 lb/tonne] per year or more of *n*-hexane) must meet HAP emission standards. The industry will have three years to comply. The emission loss factors values are 12 operating months rolling averages but permit deductions of losses in accordance with the plant startup, shutdown malfunction (SSM) plan.

The EPA has prepared a list of maximum permissible commercial hexane solvent losses for the different oilseeds processed. These hexane loss factors are stated as U.S. gallons/U.S. ton. The loss quantities range from 0.2 gal/U.S. ton (0.86 L/tonne [2204 lb/tonne]) for conventional soybean processing to 0.7 gal/ton (2.6 L/tonne) for peanut extraction. The new EPA requirements have caused U.S. extraction plants to greatly improve their processing efficiencies and solvent recovery systems. All solvent losses must be calculated to include the plant startups, plant shutdowns, plant spills, and plant breakdowns.

Although a solvent loss of about 0.35 gal/ton (1.5 L/tonne [2204 lb/tonne]) had been considered acceptable for soybean plant operations, a maximum loss of 0.20 gal/ton (0.8 L/tonne) must now be achieved in the United States. Since this low solvent loss is now required in the United States, it is only a matter

TABLE 9.10.1 Physical Properties of Typical Commercial Hexane and Isohexane

Property	*Hexane*	*Isohexane, Mixed Isomers*
Flammable limits (percent by vol.)	1.2–7.7	1.0–7.0

Source: NFPA 36, *Standard for Solvent Extraction Plants,* Table B.2(a), 2004, p. 36-17.

of time before these new emission regulations will become enforced in other countries. Solvent extraction plants that operate with low solvent losses are inherently safer than those with higher losses.

Conventional Soybean Extraction Plants. Conventional soybean extraction plants range in capacity from about 1000 to over 5000 U.S. tons (409 to 4545 tonnes [2204 lb/tonne]) per day. Based on a solvent loss of 0.2 gal/ton (0.8 L/tonne) and operating 330 days a year, a plant with a capacity of 1000 tons (909 tonnes) per day would emit about 180 U.S. tons (162 tonnes) of hexane solvent per year. Although a soybean plant with a capacity of 1000 tons (909 tonnes) per day was once considered a large facility, new plants now constructed can have a capacity of over 5000 tons (4545 tonnes) per day. The new 0.2 gal/ton (0.8 L/tonne) EPA regulation for solvent loss is a very strict one, and plant operators will have to be very diligent to meet this low solvent loss requirement.

Large-Capacity Solvent Extraction Plants. Within the past five years many large high capacity soybean extraction plants have been constructed and placed into operation. These capacities range in size from 5500 to 15,400 U.S. tons (5000 to 14,000 metric tonnes) per day. The large plants are located in Argentina, Brazil, and the United States.

When the original NFPA 36 was published in 1959, an extraction plant with a capacity of about 250 tons (225 tonnes) per day was considered a normal average size. A capacity of 1000 tons (909 tonnes) per day was deemed to be a large plant. The committee writing the NFPA 36 Standard at that time never imagined that a 14,000-tonne-per-day plant would be thought of, let alone constructed.

Some of the rules written in the 2004 edition of NFPA 36 are the same as those published in 1959. The NFPA 36 Committee must now review NFPA 36 to determine if changes must be made to specifically cover these newer installations that process such large quantities of oilseeds.

Solvent loss in a soybean extraction plant is a key indicator of possible hazards during normal operation. Solvent loss of 0.055 percent by weight of the material processed is considered within the bounds of efficient operation. If the loss exceeds 0.10 percent by weight, reasons for the increase must be found and corrective action taken. Table 9.10.2 shows the five sources of solvent loss from the conventional soybean extraction process and the percentage of loss attributed to each.

It is of primary importance to prevent flammable solvents from leaving the extraction building and entering the preparation building. This can happen if solvent remains in the flakes after they have been removed from the desolventizer-toaster and sent to the preparation building to be ground, sized, and finished. Because the equipment in this building is not explosionproof, ignition could occur with disastrous results.

TABLE 9.10.2 Sources of Solvent Loss from the Solvent Extraction Process

	Loss (gal/ton)	*Loss (lb/ton)**	*Loss (% by weight)*
Flakes from D-T unit	0.110	0.6084	0.0304
Leaks	0.056	0.3097	0.0155
Vent gas from vent system	0.020	0.1106	0.0055
Oil from oil stripper	0.014	0.0774	0.0038
Effluent from process waste water	—	0.0001	0.0001
Total	0.200	1.1062	0.0553

*Pounds of solvent per ton of material processed.

Startup, Shutdown, and Purging. The startup or shutdown of an extraction plant introduces a transient hazard. The equipment, especially the extractor, is full of air before startup. As hexane solvent is added, the concentration of solvent vapor and air mixture that is inside the extractor passes through the flammable range of 1.2 to 6.9 percent by volume. Two methods eliminate the possibility of ignition by static electricity when using hot liquid to purge the extractor of air. One method is to design the plant so hot vapors from the second stage evaporator flow into and rapidly heat the extractor to 104°F (40°C), thus replacing the air. The advantage of this procedure is to shorten extractor heat-up time, usually about 4 hours, to about ½ hour. Stage pumps do not start until the extractor is hot. The second method is to replace extractor air with carbon dioxide or nitrogen gas before adding hot liquid hexane to the extractor.

Vapor-proof slide gates located upstream and downstream of the extractor are closed during warmup to prevent hexane solvent vapors from flowing back to the preparation building.

A normal or controlled shutdown is accomplished by emptying the extraction plant of all oilseed flakes and hexane liquid and purging the empty extractor or desolventizer-toaster unit with air until the unit cools. Steam purging is used if normal maintenance is required inside the extractor.

If welding is necessary in the extraction area, personnel must take the following precautions:

- Empty all solids and liquids.
- Store hexane from the plant in solvent tanks isolated from the plant.
- Steam purge the extractor, desolventizer-toaster unit, and all equipment containing hexane or miscella.
- Fill all vessels with water.
- Use water to seal flake connections from the extractor and desolventizer-toaster unit to the preparation building.
- Use a portable gas analyzer to locate possible flammable mixtures.

Inert gas is satisfactory for purging an empty extractor before normal startup procedures. Inert gas can also be used for purging during normal shutdown, but steam purging is a surer method than inert gas purging for removing solvent vapor.

Abnormal Operations

Emergency Breakdowns. A serious hazard in the operation of a solvent extraction plant is an emergency breakdown in the extractor when it is full of solvent-laden flakes and cannot be emptied. Quite often the problem can neither be determined nor corrected without someone entering the unit.

The extractor should be cooled to about 104°F (40°C). The required time to do this depends on the extractor size and its specific method of operation. During this time, a plan for correcting the problem should be devised and approved by a supervisor. The extractor must then be purged with air, using the extractor purge blower provided with the unit. The purge blower air flow capacity should be 1 extractor volume air change every 3 minutes, based on an empty extractor. The purge blower must be of sparkproof construction. Inert gas purging of an extractor that has failed under load does not ensure a nonflammable condition will exist. If the extractor is not equipped with a purge blower, the unit should be steam purged for 24 to 48 hours or longer to be sure all hexane solvent inside the extractor has boiled off.

While air purging, air entering the purge blower must be checked with a meter to detect the explosive limits of hexane. Air purging continues until the air reaches 0.25 percent or less of the lower explosive limit (LEL) of hexane in air by volume. The extractor can be entered, but the purge blower keeps operating during the repair process. Persons entering the extractor must wear a safety harness and an air mask, and be supervised at all times. The LEL of the purged air leaving the extractor must be constantly monitored to ensure it is below 0.25 LEL of hexane. External and internal ignition sources must be eliminated because a flammable mixture of hexane and air might exist.

If a D-T-D-C fails under load, the material in the heating trays may overheat and cause a fire. It is important to immediately turn off the indirect steam to these trays when such a failure occurs. Normally, sparge or open steam is piped into the space above the flakes in the heating trays, which can be added to the unit's trays for several hours to desolventize the flakes and to smother smoldering material inside the trays. Doors on each tray are opened individually and their contents raked until the unit is empty and the problem corrected.

Failures. The supply of emergency cooling water should be sufficient to operate the condensers long enough for a safe shutdown. If cooling water fails, the process must be stopped, the steam to the process shut off, and the vapor slide gates closed. Similar steps should be taken in the event of steam or electrical failures.

System Overloads. If a solvent extraction plant capacity increases above its design rating, this creates a hazard, because normally the solvent condensing capacity is insufficient to recover the solvent. This will result in higher vent pressures and the inherent danger that solvent vapors may be forced into the atmosphere or carried out with flakes to form flammable mixtures.

NFPA 36, *Standard for Solvent Extraction Plants,* 2004 Edition

The 2004 edition of NFPA 36, *Standard for Solvent Extraction Plants,* was approved on January 16, 2004, with an effective date of February 5, 2004, and supersedes all previous editions. The following is a list of several major additions and revisions:

1. Revision of 4.5.3 for transfer of solvent, to correlate with NFPA 30, *Flammable and Combustible Liquids Code*
2. Revision of 5.3.2 to require the design and construction of solvent storage tanks to comply with NFPA 30, *Flammable and Combustible Liquids Code*
3. Revision of Section 7.4, Drainage and Spill Control, to provide more specific design requirements for the separation sump; this includes a new paragraph (2) for Section 7.4.2.3; it also includes a new Section 7.4.2.4 on preventing the outflow of oil, solvent, or miscella from the separation sump to the sewer system under emergency conditions or if the liquid seal fails

4. For Section 7.5, Conveying Systems, addition of Sections 7.5.1, 7.5.2, 7.5.2.1, 7.5.2.2 and the addition of Figure 7.5.2 to illustrate typical locations for providing vent openings in conveying systems
5. Revision of Section 7.6, Cooling Towers, allowing flexibility in locating the various types of cooling towers relative to the extraction process
6. Addition of an exception to Section 8.2.6 that permits an automatic control valve to be installed to regulate the pressure in the extractor, but only if the valve meets specified requirements
7. Addition of the physical property data for isohexane to Annex B to recognize its use as an extraction solvent; this is shown in Table B.2(a), Physical Properties of Typical Commercial Hexane and Isohexane (see Table 9.10.1)

The NFPA 36 Committee is considering the installation of a low temperature alarm and a low temperature shutdown switch if the oil temperature from the final oil stripper falls to a dangerous level and also a low vacuum alarm and shutdown switch if the vacuum in the oil stripper drops to a dangerous level. This is to warn of possible excess hexane solvent leaving with the finished oil.

FIRE PROTECTION

Fire protection for solvent extraction plants involves building construction and services, plant layout, fire protection equipment and systems, and safe operating procedures. Detailed guidance can be found in NFPA 36 and in other related standards, guides, and recommended practices listed at the end of this chapter.

Layout and Construction

Structural elements of solvent extraction plants should be laid out so that separation distances adequately isolate or dissipate flammable concentrations of solvent vapor from ignition sources. Figure 9.10.4 shows a typical layout and Figure 9.10.5 illustrates typical locations for the air brake vent opening.

The extraction and preparation buildings should be of fire-resistive or noncombustible construction and equipped with some form of explosion relief. It is important that electrical wiring and equipment be suitable for use in the presence of flammable vapors. All vessels, pipes, tubes, and hoses containing or carrying flammable solvent should be electrically bonded together and grounded to prevent the buildup of a static charge. Portable flammable gas detectors should be available for monitoring the atmosphere.

For a process involving combustible dust, electrical wiring and equipment should be suitable, a dust collecting system should be provided, and protection against static electricity discharges should be installed.

Programmable logic control (PLC) systems along with computers are now being installed to monitor and control the operations of extraction plants. Locating these systems in the extraction building control room is convenient, but since they are not of Class I, Groups C and D, Division 1, construction,

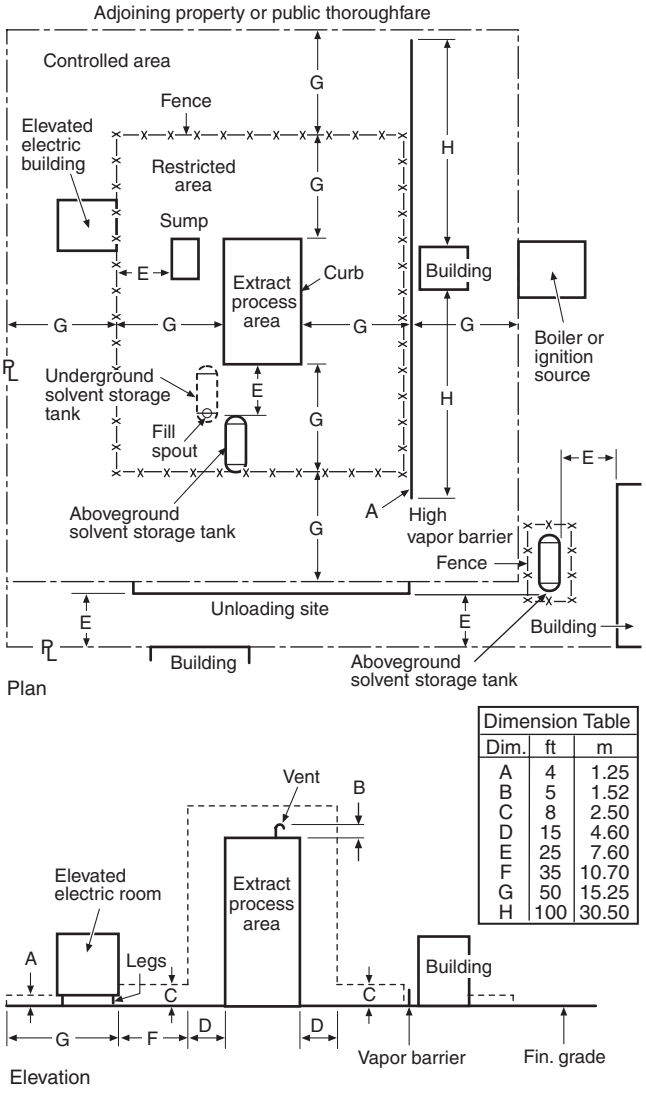

FIGURE 9.10.4 Typical Distance Diagram

special control room design must be provided. In such a design, the extraction plant control room must be designed in accordance with NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment.* Type X purging must be used; this design reduces the classification within the control room from Division 1 to nonhazardous.

Fire Protection Equipment

Water spray, deluge, or foam-water systems—singly or in combination—are suitable for use in extractor buildings. Automatic sprinkler systems are appropriate for use in preparation buildings. Portable fire extinguishers of the proper types and sizes may adequately protect the solvent unloading and storage area, if it is isolated from exposure hazards.

Portable fire extinguishers should be strategically located. The facility may also have standpipe and hose systems equipped with combination nozzles. A system of yard hydrants is an es-

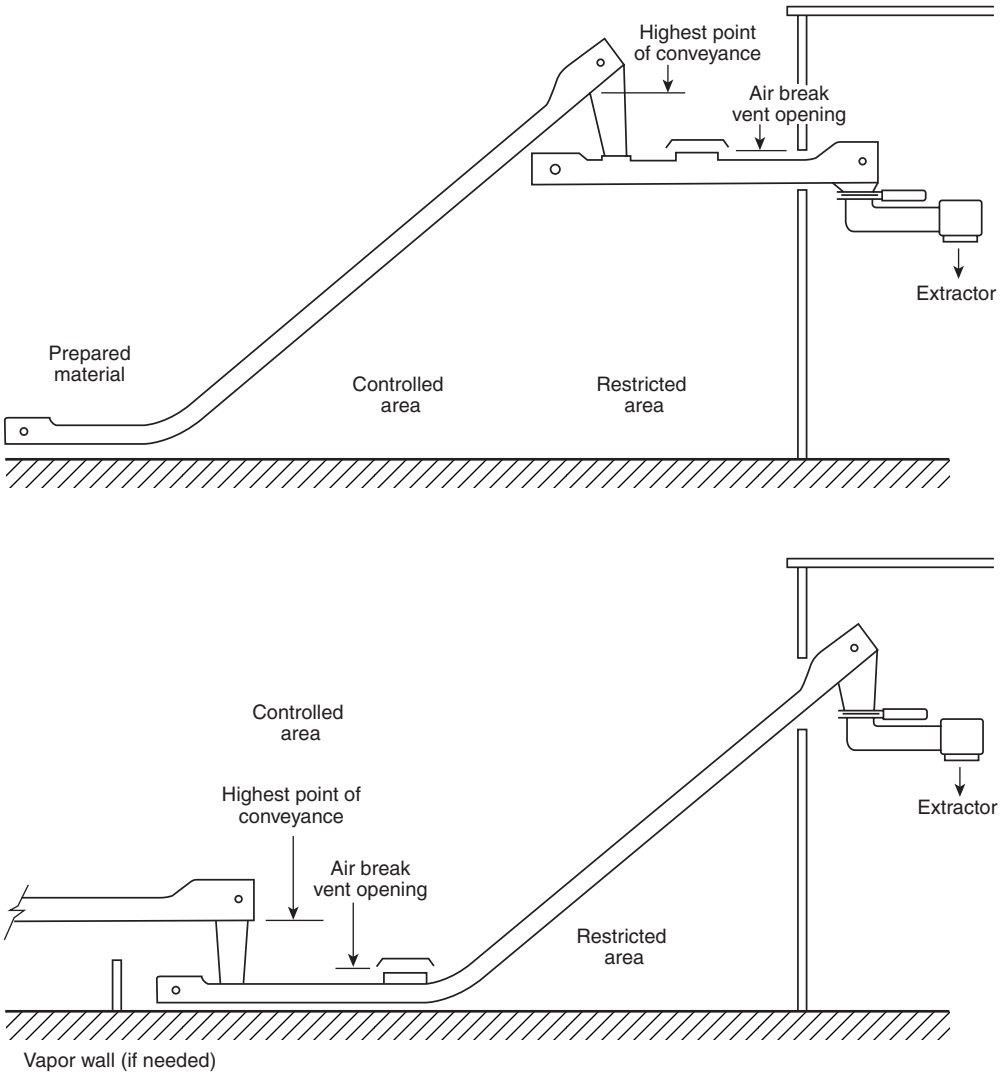

FIGURE 9.10.5 Typical Locations for Air Break Vent Opening (Source: NFPA 36, *Standard for Solvent Extraction Plants,* Figure 7.5.2, 2004, p. 36-12)

sential part of protection. Finally, the available water supply must adequately meet the needs of fixed protection and yard hydrant systems.

Policies and Procedures

It is imperative that solvent extraction equipment be operated in the manner the manufacturer prescribes and that no attempt be made to bypass or defeat safety devices and systems. Company policy should limit the output demanded of the extraction plant and not overtax its design capacity. Policy should also provide for shutdown in the event of excessive solvent loss and for regular maintenance and cleaning operations. If solvent loss increases from 0.095 to 0.135 weight percent per ton, 0.35 to 0.50 U.S. gal/ton (1.5 to 2.1 L/metric tonne) of material processed, an abnormal hazard exists and preventive action must be taken.

Fire prevention is a key factor in any fire protection program. It includes conspicuously posting safety rules and emergency procedures throughout the plant, safety education for new employees, appointment of a plant emergency organization, and a compulsory monthly safety program. A safety system audit program must be implemented to regularly check the workability of all safety devices and controls.

If a fire occurs, appropriate action is to activate fire extinguishing systems (if they are not automatically controlled), activate the plant interlock system to shut down all solids-conveying equipment in the plant, turn off the main steam valve to the extraction plant, leave the area, and notify the fire department.

SUMMARY

Oilseeds, such as cottonseed, rapeseed, flaxseed, corngerm, sunflower, safflower, peanuts, and copra, are processed in solvent extraction plants, using commercial hexane as the solvent.

Other flammable solvents, such as mixtures of aromatic hydrocarbons, are used for extracting lignite, Douglas fir bark, and other special raw materials. The principal hazards in solvent extraction operations are the highly flammable solvents used and combustible dusts associated with storing and handling oilseeds. Fire protection for solvent extraction plants involves building construction and services, plant layout, fire protection equipment and systems, safe operating procedures, and emergency planning.

Chapter 11

Protection of Wastewater Treatment Plants

James F. Wheeler

Chapter Contents

Operations and Equipment
General Hazards
Process-Related Hazards
Fire and Explosion Mitigation
Fire Protection Measures

Key Terms

collection and pumping system, denitrification, explosion, fuel gas, sewer, sewer gas, sludge gas, wastewater, wastewater liquid treatment system, wastewater solid treatment system, wastewater treatment

This chapter discusses wastewater treatment processes, process equipment, and their fire and explosion hazards. Traditionally, wastewater treatment process equipment is classified according to the various unit operations being performed. The basic unit processes fall into three categories: (1) collection and pumping, (2) liquid treatment systems, and (3) solid treatment systems. Specific unit processes to consider are pumping station wet wells that handle raw sewage or unstabilized solids, preliminary screening and grit removal processes, primary sedimentation, anaerobic digestion, scum collecting processes, and fuel and chemical handling and storage areas. A considerable variety of makes and models of equipment provide the necessary processing. Consequently, the fire and explosion hazards associated with wastewater treatment processes are much too broad a subject to examine in a single chapter. Therefore, this chapter discusses some basic principles of risk evaluation, mitigation, and fire protection that can be applied generally to individual unit processes and equipment.

The collection and transportation of liquid wastes, known as wastewater, from a community creates a disposal problem that demands a solution that protects the public's health and comfort. The series of closed conduits (pipes) conveying liquid wastes in a municipality is commonly called a sewer system. Among the first historical traces of wastewater collection is the sewer arch at Nippur, India, which was probably constructed about 3950 B.C. Although other examples of ancient sewers exist, the development of the modern wastewater collection system did not begin in the United States until 1805, with the construction of the first large sewer in New York City.[1]

With the collection of wastewater comes the requirements to provide treatment. All methods aim to produce an effluent that can be discharged without nuisance and that can protect human health and the environment. Modern cities and present-day metropolitan centers could not exist as they do without protecting the health and conveniences that comprehensive collection systems and sophisticated treatment facilities afford. As of 2004, in the United States, roughly 16,250 municipal wastewater treatment facilities served 208 million people and treated approximately 45 trillion gallons (170 trillion liters) of wastewater per day. Of the 45 trillion gallons of wastewater treated daily, 57 percent received greater than secondary treatment, 35 percent received only secondary treatment, 5 percent received less than secondary treatment, and 3 percent was not released to surface water.[2] Thousands of industries and businesses also provide their own wastewater treatment services. In addition, millions of people, most living in rural areas, are still served by individual on-site treatment units, such as septic tanks and small aerobic package plants.[3] As development expands into these rural areas, and as on-site septic systems begin to fail and pollute ground water supplies, new collector sewers must be constructed and larger, more complex treatment plants will be required.

Wastewater treatment covers any artificial processes that remove or alter wastewater's objectionable constituents to make it less offensive or dangerous. Early treatment plants included anaerobic lagoons or cesspools, which provided barely primary treatment, or provided treatment simply by dilution. Modern wastewater treatment began in the United States in 1886 with the introduction of the intermittent sand filter. The wastewater treatment industry grew rapidly during

James F. Wheeler, P.E., is an environmental engineer for the U.S. Environmental Protection Agency, Washington, DC.

the early 1900s with the development of aerobic processes, such as the trickling filter and activated sludge treatment.[1]

In addition to conventional pollutants, such as biochemical oxygen demand (BOD) and suspended solids (SS), today's wastewater industry must be prepared to treat hazardous and toxic industrial waste or explosive and flammable materials that may be illegally or accidentally discharged to the collection system. The treatment of these wastes involves highly specialized knowledge of the design, construction, maintenance, and operation of sophisticated equipment and processes. Wastewater treatment is a viable and growing industry that is continually changing as demands for better removal of toxic and hazardous materials increase and more sophisticated and complex chemical and biological processes evolve.

For related topics, see Section 6, Chapter 10, "Gases"; Section 7, Chapter 3, "Storage of Gases"; Section 11, Chapter 1, "Waste Handling and Control"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

OPERATIONS AND EQUIPMENT

In a modern wastewater treatment plant (Figure 9.11.1), treatment of wastewater can be broken into three major components: (1) collection and pumping systems, (2) liquid treatment systems, and (3) solids treatment systems. Each component utilizes different processes and equipment. Each also has specific hazards associated with its particular function.

Collection and Pumping Systems

Collection systems gather wastewater from houses, factories, or other sources and transport it to a central facility for processing. Where the terrain is flat, the collection system may consist solely of gravity piping; however, in most areas the collection system includes pumping. Among the many different kinds of collection systems, the separate sanitary sewer and the combined sewer are most common. The separate sanitary sewer carries wastewater from individual homes and excludes storm water, surface water, and groundwater. Sanitary sewers also collect wastewater from industrial and commercial businesses in the service area. Combined sewers carry both domestic wastewater and storm water, as well as industrial wastewater. Although today only separate sanitary sewers are being constructed, many older cities still have thousands of miles of large combined sewers.

Separate sanitary sewers are generally smaller than combined sewers. Sanitary sewers with diameters of 8 to 48 in. (0.2 to 1.2 m) are common. Combined sewers generally are very large, often 20 ft (6 m) in diameter or larger. These collection systems also include other appurtenances, such as manholes, valve boxes, catch basins, curb inlets, and a variety of other structures. Combined sewers may also have regulators or diversion structures that allow overflow directly into rivers or streams during major storms.

Pumping wastewater has long been a problem because of fibrous and stringy material in the wastewater. Rotary and reciprocating pumps are generally not suited for wastewater pumping, unless the wastewater has been treated to remove solids. Even many centrifugal pumps experience problems handling wastewater solids. Today, solids-handling centrifugal pumps with single-suction volutes can pump most wastewater.[4] These pumps have open impellers, thus creating large passageways, as shown in Figure 9.11.2. These centrifugal pumps can also be equipped with bladeless impellers for pumping unscreened wastewater and sludge. Pneumatic ejectors have also been used successfully for handling small volumes of unscreened wastewater.

A flat efficiency curve is desirable for sewage pumps, because the head against which the pump must work is variable.

FIGURE 9.11.1 Modern Wastewater Treatment Plant

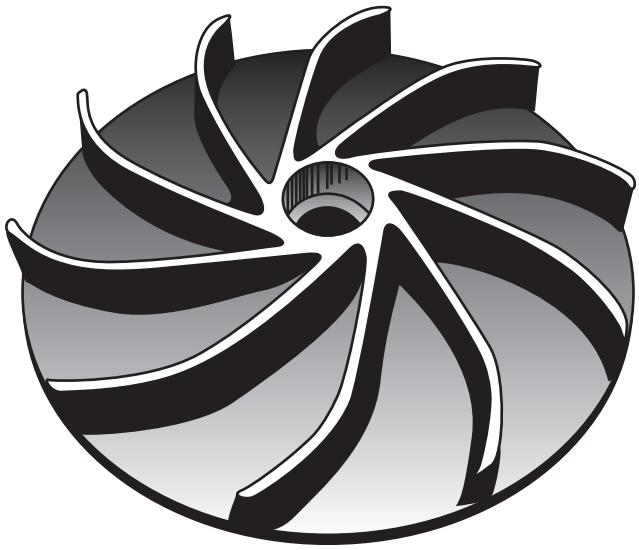

FIGURE 9.11.2 Open Nonclog Impeller for Pumping Raw Sewage

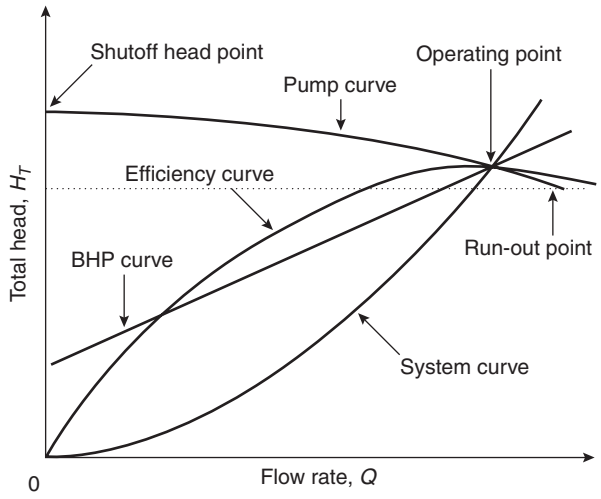

FIGURE 9.11.3 Typical System Head Curve for a Sewage Pump

Figure 9.11.3 illustrates a typical system head curve showing discharge head versus efficiency. The special nonclog impellers used in sewage pumps are generally less efficient than the enclosed impellers used to pump potable drinking water. Since dependability is more important than efficiency in most wastewater pumping applications, slow-speed operation is desirable because it reduces wear on the impeller and increases equipment life.

Most pumping stations have two parts, a dry well and a wet well. The wet well receives and temporarily stores wastewater. Wet wells often contain screens that remove large solids that could damage the pumps. Wet wells may also contain mechanical equipment, fans, lights, and so on. However, most electrical equipment, including motors, pumps, and switches, are placed in the dry well. Most pumping stations have both above and below ground structures, as shown in Figure 9.11.4, although some smaller stations are placed entirely underground, as shown in Figure 9.11.5. Figure 9.11.6 shows a suction lift pump that can be used in either station configuration.

When the required lift is too great for suction lift pumps (approximately 30 ft [10 m]), horizontal or vertical flooded end suction pumps can be mounted in the dry well side of the pumping station (Figures 9.11.7 and 9.11.8). Many large pumping stations use multiple pumps with various capacities designed to handle a wide variation in flow rates. The pumps are generally driven with electric motors that can be mounted horizontally (Figure 9.11.9) or vertically (Figure 9.11.10). The vertical arrangement has the advantage of permitting the motor to be mounted above the pump to safeguard it against flooding. Depending on the service needed, motors can be open drip proof, totally enclosed fan cooled, water resistant, or explosionproof. Pumps can also be connected to diesel or gas-driven engines, for use during emergencies or power failures.

Today many pumping stations use submersible pumps as shown in Figure 9.11.11. These pumps are located in the wet well, thus eliminating the need for a dry well. The discharge

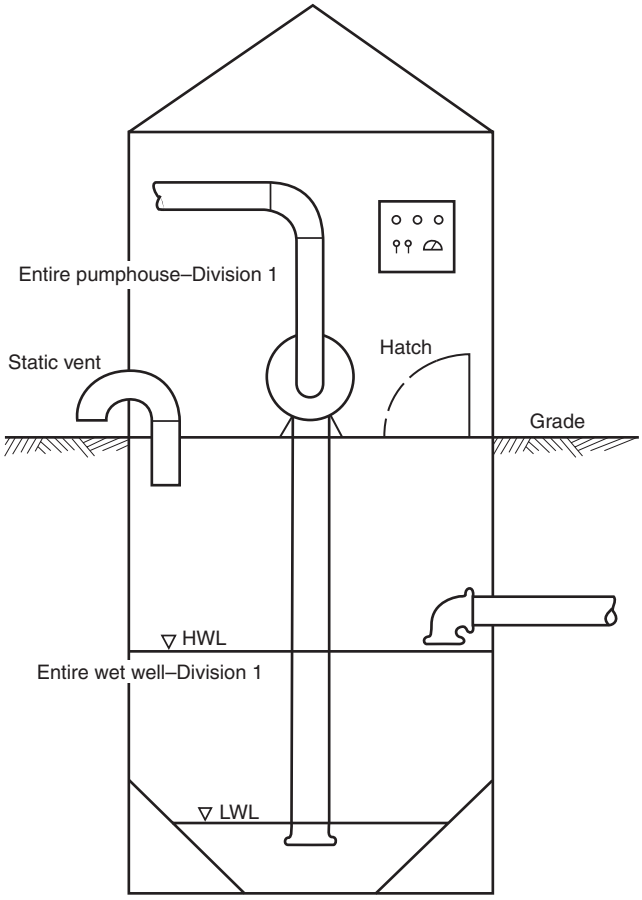

FIGURE 9.11.4 Typical Above/Below Ground Pumping Station

piping can be equipped with quick disconnects so the pumps can be removed from the wet well for servicing without entering the wet well, as shown in Figure 9.11.12. Submersible pumps can be supplied with explosionproof motors for use in hazardous environments.

Where interruption to the normal electric power source is possible, an auxiliary power source is often required. In larger stations, electric generators or gasoline or natural gas engines are provided. The engines connect directly to the pump shaft by means of a right-angled gear drive unit so that either the engine or electric motor can be used by operating a clutch. Some gas engines are dual-fuel compatible and can use either natural gas or methane gas produced at the treatment plant by anaerobic digestion of sewage sludge.

Liquid Treatment Systems

Liquid treatment processes remove objectionable constituents from the wastewater so treated water can be returned to the environment without being offensive or dangerous to public health. The principal components of liquid treatment are preliminary treatment, primary treatment, secondary treatment, tertiary treatment, and disinfection. A typical schematic flow and

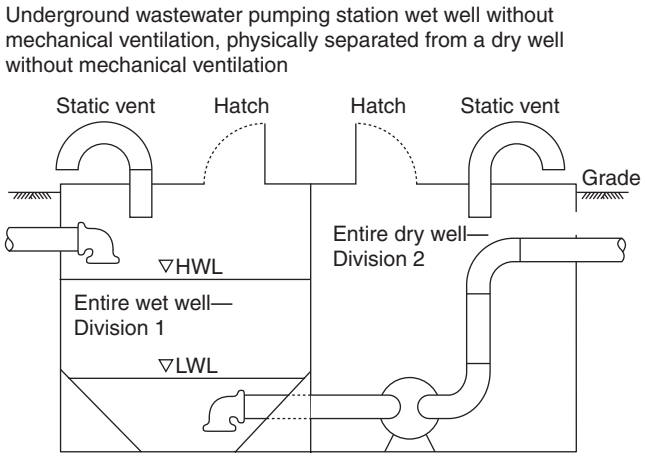

FIGURE 9.11.8 Typical Pumping Station with Horizontally Mounted Pumps (Source: NFPA 820, *Standard for Fire Protection in Wastewater Treatment and Collection Facilities,* Figure A-2.10, 1992, p. 820-50)

process diagram for wastewater treatment is shown in Figure 9.11.13.

Preliminary treatment conditions wastewater as it enters the treatment plant. Preliminary treatment removes materials that might harm or adversely affect the operation of the treatment plant or process equipment. Such material may include lumber, cardboard, rags, stones, sand, plastic, and grit. Methods and equipment used to remove these materials include comminutors, mechanically or manually cleaned bar racks, and bar

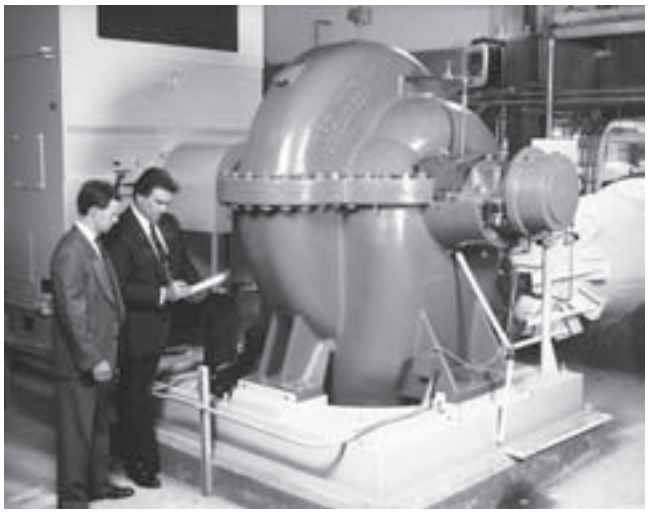

FIGURE 9.11.9 Typical Large Pumping Station with Horizontally Mounted Pumps

FIGURE 9.11.10 Typical Large Vertically Mounted Pump

screens. Particularly in combined sewers, grit and sand washed into the collection system from the street can damage mechanical equipment and adversely affect downstream units, such as sedimentation tanks and digesters. Grit is generally removed by gravity or in aerated grit chambers.

Primary treatment includes first-stage sedimentation, which removes settleable suspended solids, and floating material, such as grease and scum, from the wastewater. Figure 9.11.14 shows a typical primary clarifier. Well-operated primary treatment facilities may remove as much as 60 percent of the influent-suspended solids and 30 percent of the influent biochemical oxygen demand. However, primary treatment does not remove colloidal or dissolved solids. Some treatment plants add chemicals, such as lime, alum, or ferric chloride, to increase colloidal solids removal.

Secondary treatment is intended to reduce the concentrations of remaining suspended solids and dissolved and colloidal organic matter in wastewater. Such material is not removed to any significant degree in primary treatment. A wastewater

FIGURE 9.11.14 Typical Primary Clarifier

treatment plant having secondary treatment following primary treatment commonly can remove 85 percent of the influent-suspended solids and biochemical oxygen demand of the raw wastewater. Secondary treatment processes may be either biological or physical-chemical.

Most municipal secondary treatment processes are biological. These processes may be classified as fixed film or suspended growth. Fixed film processes include trickling filters, biotowers, and rotating biological contactors (RBC). In these processes a thin biological slime (film) grows on a fixed surface. Figure 9.11.15 shows a typical trickling filter with plastic media. Suspended growth processes include aerobic ponds, oxidation ditches, and a variety of air- and pure oxygen–activated sludge systems. Although not flammable, oxygen-rich atmospheres will greatly accelerate the rate of combustion. In these processes, the biological organisms are suspended in liquid (Figure 9.11.16). In each process, a mixed population of microorganisms establishes in the presence of oxygen. These microorganisms metabolize dissolved organic matter in wastewater and form a biological mass. The effluent from fixed film or suspended growth processes contains suspended biological solids. A portion of these solids called waste sludge is removed from the treated wastewater in a secondary sedimentation tank for further processing. A portion of these solids called return sludge may be recycled to the head of the suspended growth process for additional treatment, as shown in Figure 9.11.13.

In a small number of cases, physical-chemical treatment is used in place of, or combined with, biological unit processes. Physical-chemical processes can include chemical addition,

FIGURE 9.11.15 Typical Trickling Filter with Plastic Media

FIGURE 9.11.16 Typical Activated Sludge Aerated Tank

coagulation, precipitation, and filtration to remove suspended matter, and activated carbon absorption to remove soluble organics. In addition to lime, alum, and ferric chloride, a variety of anionic and cationic polymers also enhance settling in the physical-chemical process.

Tertiary treatment is used, as required, to reduce the concentration of inorganic and organic constituents below concentrations achievable through secondary treatment. Tertiary treatment also includes removing nitrogen and phosphorus by additional unit process operations. Tertiary treatment processes may be physical, chemical, biological, or a combination. A wide variety of chemicals are used in tertiary treatment processes. Most common are lime, alum, ferric chloride, polymers, methanol, chlorine, carbon, ozone, and oxygen.

Disinfection is required to destroy pathogenic bacteria, viruses, and amoebic cysts commonly found in wastewater. Disinfection processes may be chemical (chlorination or ozonation) or physical (ultraviolet irradiation). Chemical disinfection using chlorine is the most widely used means of wastewater disinfection. Ozone and ultraviolet irradiation are produced on site. However, chlorine is generally supplied as a gas or liquid. Smaller plants use chlorine gas in 150 lb to 1 ton (23 to 907 kg) cylinders, while larger plants may use chlorine in bulk from a tank truck or railroad tank car. Today many treatment plants also require dechlorination to protect aquatic plants and animals from the toxic effects of any chlorine remaining in the effluent. The most common chemicals used in dechlorination are sulfur dioxide or activated carbon.

Solids Treatment Systems

Solids treatment processes further treat the sludge or biosolids removed from wastewater by the liquid treatment processes. Sludges withdrawn from the treatment processes are still largely water, as much as 97 percent. The principal components of solids treatment are digestion, thickening, dewatering, and disposal. Figure 9.11.13 shows a flow schematic and process diagram for a typical solids treatment system.

Sludge handling and disposal are often the most difficult, important, and costly parts of wastewater treatment. Sludge may be stabilized either under anaerobic or aerobic conditions. Anaerobic sludge digestion occurs in the absence of free oxygen. The digested solid end product of anaerobic digestion is relatively nonputrescible and inoffensive. The off-gas produced in anaerobic sludge digestion contains about 65 percent methane and may be collected and used as fuel.

Areas around anaerobic digesters and other anaerobic treatment processes are especially dangerous, because they produce combustible gases (Figure 9.11.17). The off-gas produced by anaerobic digestion contains about 65 percent methane and 5 percent hydrogen. Figure 9.11.18 shows a typical egg-shaped anaerobic digester cluster. The off-gas from the anaerobic digester is often collected and used as fuel at the treatment plant. Digester gas handling areas can also present a fire and explosion hazard (Figure 9.11.19).

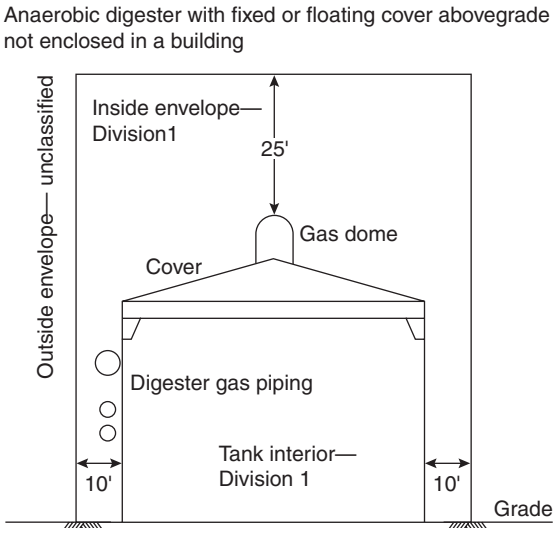

FIGURE 9.11.17 Typical Anaerobic Digester (Source: NFPA 820, *Standard for Fire Protection in Wastewater Treatment and Collection Facilities,* Figure A-4.1, 1992, p. 820-81)

FIGURE 9.11.18 Typical Egg-Shaped Anaerobic Digesters (Courtesy of Appleton Wastewater Treatment Facilities)

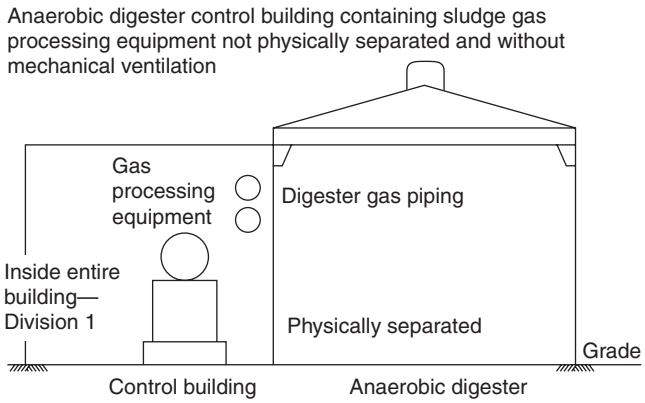

FIGURE 9.11.19 Typical Digester Gas Handling Application (Source: NFPA 820, *Standard for Fire Protection in Wastewater Treatment and Collection Facilities,* Figure A-4.5, 1992, p. 820-83)

Both anaerobic and aerobic digestion results in a reduction in the total volume and weight of excess organic matter. It is often desirable, before final disposal, to reduce further the volume and weight of sludge and to change it from a liquid that is more than 95 percent water to a semisolid form. This dewatering may be accomplished by using drying beds, vacuum filters, centrifuges, filter presses, or mechanical gravity units. The dewatering operation often is enhanced by chemically conditioning the sludge with lime or polymers before dewatering. Conditioning may include a thickening step, which could use gravity or air flotation. Thermal conditioning may also be used to prepare sludge for dewatering.

In smaller plants much of the dewatered and stabilized sludge is trucked to sanitary landfills. Municipal sludge, however, contains essential plant nutrients and useful trace elements. Some treatment plants take advantage of these nutrients and apply the sludge to the land. The sludge can be composted and used as a soil conditioner, or the sludge can be applied as a liquid fertilizer. For larger plants, or where land is not available, sludge is often incinerated. The two most common types of incineration systems are the multiple-hearth furnace and the fluid-bed incinerator. Exhaust gas from the incinerator must be treated carefully to avoid air pollution. The incinerator ash can be toxic and may require special handling and disposal methods.

GENERAL HAZARDS

Many potential hazards may be found in wastewater treatment plants and in the operations they perform. These include explosion and fire hazards, health hazards, and environmental hazards. This discussion, however, deals only with explosion and fire hazards.

Three principal sources of hazards are associated with the wastewater treatment industry. These include materials and chemicals that enter the collection system, materials and chemicals used in the treatment processes, and materials and chemicals produced as by-products of the treatment processes. Hazard sources commonly associated with the wastewater industry include fuel gases, sewer and sludge gases, specialty gases, liquids, solids, dusts, and construction materials.

Fuel Gases

Fuel gases include natural gas, manufactured gas, sludge gas, liquefied petroleum gas–air mixtures, liquefied petroleum gas in the vapor phase, and mixtures of these gases. Some of these gases have specific gravities lower than that of air, so when released they rapidly rise and diffuse above a leakage point. Flammable mixtures are produced when these gases are mixed with air within certain limits, and, since the oxygen content of each gas (when not mixed with air) is generally low, they may also be considered as suffocating gases. In addition, the wastewater treatment plant uses a variety of gaseous, solid, and liquid chemicals that by themselves or mixed with oxygen or other chemicals may be potential sources of fire and/or explosion.

Sewer and Sludge Gases

Sewer and sludge gases are flammable gases resulting from fermentation or decomposition of organic matter. Explosive conditions (especially concerning the anaerobic digestion process) may result when these gases mix with air within certain limits.

Specialty Gases

Specialty gases commonly found in the wastewater treatment plant are used in a variety of operations including (1) laboratory analysis and instrumentation calibration (e.g., hydrogen, methane, etc.); (2) wastewater treatment plant unit processes (e.g., chlorine, ozone, etc.); and (3) welding operations (e.g., acetylene, oxygen, etc.). These gases may provide flammable and/or explosive conditions when either acting alone or mixed with other chemicals.

Liquids

Liquid waste chemical products discharged into the collection system and transported to the wastewater treatment plants may be potential sources or contributing causes of fire and/or explosive conditions. Hydrocarbon liquids, such as gasoline, kerosene, oils, and other solvents, either discharged to drains or used for various applications at wastewater treatment plants, may also provide fire and/or explosion hazards at certain locations.

Combustible Solids and Dusts

Solids, such as granulated or powdered activated carbon, and other combustible dust by-products produced by various wastewater treatment processes, may be combustible and cause potential fire and/or explosive conditions.

Construction Materials

Some construction materials used in wastewater treatment plants, such as plastic, fiberglass-reinforced plastics (FRP), paints and coatings, insulating materials, and furnishings, may either be combustible or limited combustible under certain conditions. Some of these materials present a considerable fuel load, if ignited.

Ignition Sources

In addition to a combustible or flammable fuel source, there must also be an ignition source to cause a fire or explosion. Certain fundamental conditions limit the potential ignition of flammable gases, liquids, and solids (including dusts) found at a wastewater treatment plant. Gases and generated vapors must mix with sufficient air or oxygen to form a flammable mixture and be provided with heat of sufficient intensity for ignition. Ignition may result from one or more of these causes: (1) open flames and hot surfaces, (2) electrical arcs and sparks, or (3) chemical reactions.

Open Flames and Hot Surfaces. These potential means of ignition may be encountered during operations and repairs or with malfunctioning equipment and appliances. Ignition sources can include welding equipment, boilers, incinerators, kerosene-type lanterns, internal combustion engines, and smoking by humans.

Electrical Arcs and Sparks. Sustained arcing faults can extensively damage electrical switchgear and motor control centers. This can provide sufficient heat to ignite flammable gases or vapors present or generated as a result of the arc (e.g., pyrolysis of insulating material).

Sparks generated by defective/worn electrical and mechanical equipment, activities performed by personnel, and static electricity may be ignition sources for gases or flammable vapors.

Chemical Reaction. Fire and explosion may result from the chemical reaction of substances that are (1) introduced by the wastewater treatment plant influent, (2) used for laboratory analyses, (3) required in various unit processes, and (4) produced as by-products. Chemical reactions can cause hazardous conditions ranging in severity from the generation of flames (e.g., spontaneous combustion) to explosions.

PROCESS-RELATED HAZARDS

Many collection systems collect not only wastewater but various hazardous materials and chemicals. Materials and chemicals entering the collection system are the most numerous type of in-plant hazards and the least controllable, and, therefore, probably present the greatest risk of fire and explosion.

Some industries discharge combustible or explosive products, such as alcohol, industrial solvents, hexane, and other liquids and gases. Sewers also collect natural gas or gasoline from leaking pipelines or underground storage tanks. Combined sewers are particularly dangerous because they collect hazardous liquids and gases from highway spills, and fire departments sometimes inadvertently wash flammable hydrocarbons from traffic accidents into the combined sewer. In addition, illegal discharge of explosive or flammable material into the sewer system is always possible. Today utility managers must also be concerned about attempts by terrorists to introduce combustible, flammable, or explosive materials into the collection system in

an attempt to destroy the underground pipes, pumping stations, or the treatment facility.

Pumping stations that handle raw wastewater are subject to the same hazards as the collection system. When confined in a wet well, many hydrocarbons float on the surface of the wastewater. Gases that are lighter than air diffuse rapidly through the structure. Other liquid treatment processes, such as screening equipment and grit chambers that are housed in buildings or in below-grade pits, may be subject to the same fire and explosion hazards as the pumping station wet well. Unit processes, such as primary sedimentation, are generally open and allow lighter gases to escape but may collect and concentrate floating flammable liquids. Secondary and tertiary sedimentation tanks and aeration tanks not preceded by primary sedimentation may also collect and concentrate floating flammable liquids.

Liquid treatment processes are not only subject to the hazardous materials and chemicals in the incoming wastewater. They are also subject to a variety of chemicals used as additives in treating wastewater. Some of these materials are flammable or explosive, some are nonflammable but accelerate combustion, and some are not hazardous by themselves but react with other materials or chemicals. Gases commonly used in wastewater treatment and their physical properties are shown in Table 9.11.1. Their uses (from NFPA 820, *Standard for Fire Protection in Wastewater Treatment and Collection Facilities*) are described below.

Natural gas and gasoline are used as vehicle fuels, to heat buildings and unit processes, to provide hot water for personnel and cleaning operations, and for engine-driven pumps or generators. Figure 9.11.20 shows a typical vehicle fueling station.

TABLE 9.11.1 Gases Commonly Found in Wastewater Treatment Plants

Name (chemical formula)	Explosive Limits (% vol.) *LEL*	*UEL*	*Density*[a] *Heavier/Lighter Than Air*	*Sources*
Ammonia (NH_3)	16	25	L	Storage tank leaks
Chlorine[b] (Cl_2)	Nonflammable		H	Disinfection processes Storage tanks
Gasoline (C_3H_{12}—C_9H_{20})	1.3	7.1	H	Storage tanks Tank truck spills
Hydrogen chloride (HCl)	Nonflammable		H	Storage tank leaks Ceramic diffuser cleaning
Hydrogen sulfide[c] (H_2S)	4.0	44	H	Sewer gas Sludge gas
Natural gas	3.8–6.5	13–17	L	Gas piping leaks
Nitrogen (N_2)	Nonflammable		L	Storage tanks Oxygen generation processes Denitrification processes

[a]The table lists the physical properties at standard temperature and pressure. In actual field conditions, these gases might disperse and might be present throughout the structure.
[b]These gases accelerate combustion.
[c]Rarely reaches explosive concentration in wastewater treatment plants.
[d]Contains approximately 70 percent carbon dioxide, 5 percent methane, and 25 percent other gases (Source: United States Environmental Protection Agency).
[e]Contains approximately 65 percent methane, 30 percent carbon dioxide, and 5 percent other gases (Source: United States Environmental Protection Agency).

Source: Data for ammonia, gasoline, hydrogen sulfide, and natural gas from NFPA 325, *Guide to Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids.*

FIGURE 9.11.20 Typical Vehicle Fueling Station

Methanol is used as a carbon source in denitrification processes. (Dentrification is a biological process by which nitrogen is removed from the wastewater.) Oxygen is used in certain types of biological processes, such as oxygen-activated sludge. Chlorine and ozone are used for disinfection, and sulfur dioxide is used in dechlorination processes. Lime, alum, ferric chloride, and polymers are used in sedimentation processes; and granulated and powdered carbon are used in some activated sludge processes or in carbon columns to remove organic compounds.

Solids treatment processes not only use gases and chemicals, but some processes also produce explosive or flammable materials or gases. Although several anaerobic processes produce sludge gas, the principal gas-producing unit process is anaerobic digestion. When organic matter decomposes in the absence of oxygen, sludge gas is produced. This sludge gas is approximately 65 percent methane. Large plants may use this gas as a fuel source. Sludge decomposing in sewers, wet wells, pits, or other tanks can produce a form of sludge gas sometimes called sewer gas. Although never used as a fuel source, sewer gas can contain up to 5 percent methane and can reach explosive limits if confined in inadequately ventilated spaces.[4]

As with liquid treatment processes, natural gas is used to heat solid treatment unit processes, such as anaerobic digesters and other heat treatment processes. Natural gas is also used as a fuel in sludge incinerators. Ammonia is used as a nutrient in some activated sludge processes and is a by-product of air-stripping processes and some composting and sludge dewatering processes. Chlorine and ozone are used in sludge stabilization processes. Hydrogen sulfide, found in sewer gas and sludge gas, is a by-product of some sludge stabilization and dewatering processes. Nitrogen, used as a medium to transport very dry organic material in certain sludge dehydration processes, is a by-product of on-site oxygen generation processes. Some sludge stabilization processes and reaeration processes use oxygen.

Of course, many other chemicals, fuels, and materials used in or around the wastewater treatment plant might present a fire or explosion hazard, if not handled properly. These chemicals and gases include solvents, oxidizing materials, hydrogen, acetylene, kerosene, oils, and various specialty gases used in laboratory analyses and instrumentation calibration. The handling of these gases and chemicals is beyond this chapter's scope, but it is covered in other NFPA documents.

FIRE AND EXPLOSION MITIGATION

General Practice

Control procedures used to minimize potential fire and explosion incidents at wastewater treatment plants include (1) hazard evaluation, (2) risk evaluation, (3) control of fire and explosions, (4) ventilation, (5) construction materials, and (6) education. These control procedures also include proper electrical classification of hazardous locations and proper selection, installation, and operation of electrical equipment, motors, and devices that are suitable for these locations. Effective control procedures cannot be implemented and enforced without the complete cooperation of the public, private, and government sectors, and plant management and personnel, in comprehensive safety programs.

Hazard Evaluation

Hazard evaluation should be initiated early in the design process and hazard prevention and protection recommendations integrated into plant process specification or design considerations. The evaluation should be reviewed and updated periodically as conditions at the plant change. All wastewater processes should be given some kind of hazard evaluation before plants are built and whenever significant changes are made. Some evaluations can be quite informal, whereas others are highly structured with complete documentation and attempts to quantify hazards inherent in the operation.

The first and most important consideration is the identification of potential hazards. The potential hazard associated with raw wastewater entering the plant, materials used in the treatment processes, and materials produced by the treatment processes must be completely understood and evaluated. Effects of temperature and pressure outside of normal ranges must be studied. The possibility of creating a hazardous by-product and gradually increasing its concentration in a closed system must be considered. In other words, there must be complete hazard identification for all aspects of the treatment. With this information, potential severity of the process hazards can be determined. Then the means to control the anticipated hazards can be identified. Hazard analysis begins with complete, comprehensive hazard recognition.[5]

Risk Evaluation

Risk evaluation takes into account the likelihood of the hazard resulting in a fire or explosion. Numerical quantification of the risk requires estimating failure rates of equipment and people. A judgment must be made about the necessary degree of maintenance of all important equipment and instruments, as well as the degree of training and judgment required of operators.

Risk control demands that wastewater treatment processes and equipment be well designed and well maintained to minimize potential for leaking and spilling. Redundant instrumentation, emergency controls, and fail-safe design are some risk-control tools. Venting and pressure-relief systems are essential for preserving process equipment. Damage-limiting construction should be used where processes are housed in a structure. Equipment and piping should be well supported to prevent vibrations that could cause leaks.

Control of Fire and Explosions

The three basic ways to control explosions and fire are (1) remove the fuel or explosive material, (2) remove oxygen required for combustion, or (3) remove the ignition source. In most wastewater treatment plants, controlling fuel or oxygen sources is difficult; therefore, controlling the ignition source is more practical. Each part of the system—collection, liquid treatment, solids treatment, or fuel and chemical handling—has different potential sources of ignition to be considered. In general, the potential for ignition within the collection system is restricted to sites where personnel entry is possible. Therefore, manholes and pumping stations are likely to present the greatest concern. The introduction of ignition sources at these sites must be limited to those occasions following life safety procedural mandates and always with adequate ventilation. In the event that a foreign combustible material enters the sewer system, removal by vacuum or coverage with foam may be necessary.

Potential for ignition within the liquid stream of a treatment plant is restricted to flammable materials entering the early stages of treatment and to flammable gases generated as by-products of wastewater decomposition in nonflowing or septic portions of the liquid stream. Introduction of ignition sources into these areas should be limited, and adequate ventilation should always be provided.

Conditions in the solids treatment stream are often similar to liquid treatment processes. Potential for ignition within the solids treatment process is restricted to floating flammable materials skimmed from tanks and to flammable gases generated as by-products of anaerobic decomposition of sewage solids. Introduction of ignition sources into these areas should be limited, and adequate ventilation should always be provided.

Fuel and chemical handling and storage areas, including laboratories, require special consideration. In general, potential for ignition is restricted to reactive or flammable chemicals, liquid fuels, flammable natural fuel gases, and fuels generated as by-products for use in various unit processes. Introduction of ignition sources into these areas should be limited, and adequate ventilation should always be provided. Chemicals and fuels should always be stored in accordance with safety codes and the manufacturer's instructions. Reactive chemicals should always be stored separately.

Ventilation

Mitigation of explosions and fire hazards is best achieved by copious flushing with fresh air (i.e., ventilation). Ventilation rates for enclosed spaces containing wastewater exposed to the atmosphere should be based on the calculated vaporization rate of the most volatile liquid anticipated to be present in the wastewater. In considering ventilation requirements, the designer should base calculations on the surface area of channels, tanks, or other vessels containing wastewater exposed to the atmosphere; the temperature of the wastewater; the ambient air temperature; and the volatilization rate of the volatile liquid. Allowances should be made for vaporization rate of the liquid from the free water surface in connecting sewers within a reasonable distance from the structure, turbulence that may accelerate vaporization of the volatile liquid, inefficiency of the ventilation system in purging the enclosures, and any other factors that the designer could reasonably expect to affect the release rate of the flammable vapor to the structure. Table 9.11.2 presents typical ventilation rates for various areas in wastewater treatment plants. Ventilation rates should conform to Table 9.11.2 or be based on actual calculations, whichever is greater.

Construction Materials

Construction materials can be divided into three basic categories: (1) combustible, (2) noncombustible, and (3) limited combustible. NFPA 220, *Standard on Types of Building Construction,* defines these terms. Construction materials for wastewater treatment plants should be selected based on the fire hazard and fire risk evaluation. Proper application of construction materials will not prevent explosion or fire hazards. Proper application may, however, reduce or eliminate effects of fire or explosion by maintaining structural integrity, controlling flame spread and smoke generation, preventing the release of toxic products of combustion, and maintaining the facility's serviceability and operation.

Construction materials meeting the definition of noncombustible should be used in all building or unit processes considered *critical* to the integrity of the treatment plant (e.g., raw wastewater pumping station), and, if out of service for even a few hours, could permanently or unacceptably damage the environment or endanger public health by allowing the release of raw wastewater or sludge. All buildings should be constructed in accordance with national and local fire and building codes.

Construction materials meeting the definition of noncombustible or limited combustible should be used in building or unit processes that are considered *important* to the integrity of the treatment plant (e.g., biological treatment), and, if out of service for short periods of time, would not permanently or unacceptably damage the environment or endanger public health, but would become critical if out of service for several days.

Any appropriate construction materials can be used in other areas of the treatment plant, where being out of service for a week or more would not permanently or unacceptably damage the environment or endanger public health.

For separate sanitary sewers serving residential areas, where there is limited possibility that significant quantities of flammable or hazardous materials will enter the system, all appropriate material may be considered. For separate sanitary sewers that may handle flammable or hazardous materials and for all combined sewers, only materials meeting the definition of noncombustible or limited combustible should be used.

TABLE 9.11.2 Minimum Ventilation Rates

Description	Ventilation Rate, Air Changes per Hour, or Velocity as Noted		
	Class I, Div. 1	*Class I, Div. 2*	*Unclassified*
1. Wet wells, screen rooms, and other enclosed spaces with wastewater exposed to the room atmosphere	<12 air changes/hr	≥12 air changes/hr	
2. Below-grade spaces (such as dry wells, equipment rooms, tunnels, or galleries)			
(a) With equipment using or processing flammable gas	<12 air changes/hr <74 ft/min (22.2 m/min) velocity in tunnels or galleries	≥12 air changes/hr ≥74 ft/min (22.2 m/min) velocity in tunnels or galleries	
(b) With gas piping		<6 air changes/hr <37 ft/min (11 m/min) velocity in tunnels or galleries	≥6 air changes/hr ≥37 ft/min (11 m/min) velocity in tunnels or galleries
(c) Without gas piping		<6 air changes/hr for dry wells NR for tunnels and galleries	≥6 air changes/hr for dry wells
3. Above-grade spaces (such as equipment rooms and galleries)			
(a) With equipment using or processing flammable gas	<12 air changes/hr <74 ft/min (22.2 m/min) velocity for galleries	≥12 air changes/hr ≥74 ft/min (22.2 m/min) velocity in galleries	
(b) With gas piping		<6 air changes/hr <37 ft/min (11 m/min) velocity in galleries	≥6 air changes/hr ≥37 ft/min (11 m/min) velocity in galleries
(c) Without gas piping		NR for galleries	

Note: NR = no requirement.

Structures entered by personnel who handle raw or partially treated wastewater should be constructed only of materials meeting the definition of noncombustible or limited combustible. When combustible materials and coatings are used, consideration should be given to flame spread rates, smoke generation, and release of toxins during fires.

Noncombustible materials should be used for air-supply and exhaust systems. However, when combustible or limited combustible materials are used to control corrosion, approved smoke dampers and fire dampers should be installed. Separate smoke ventilation systems are preferred; however, smoke venting can be integrated into normal ventilation systems using automatic or manually positioned dampers and motor speed control.

Cellular or foamed plastic material should not be used as interior finish. Roof coverings should be Class A when tested in accordance with NFPA 256, *Standard Methods of Fire Tests of Roof Coverings.* Construction materials and interior finishes should provide a maximum degree of fire resistance, with a minimum flame spread rate and smoke generation for a particular application.

Plastic or fiberglass-reinforced plastic products are often used as construction materials in unit processes, such as rotating biological contactors (RBCs), biotowers, trickling filter media, inclined plate (tube) settlers, ventilation ducts, and other equipment that may be subject to corrosion. Under normal operating conditions, these plastic or fiberglass-reinforced plastic materials may be submerged; however, they may become exposed during maintenance and repair. Extreme care should be taken with open flame, such as repair cutting torches, during any maintenance or repair operation, because exposed plastic or fiberglass-reinforced plastic materials present a considerable fuel load, if ignited.

Education

Another important and often overlooked mitigation measure is education. In-house training programs, such as plant emergency organizations (PEOs), housekeeping, and maintenance, should be established so all employees understand and can identify, prevent, and handle hazardous sources or situations relating to potential fire, explosion, and toxicity. Close liaison should

be implemented between the local fire department (including other authorized emergency personnel) and wastewater treatment plant safety personnel, so that mutually approved emergency procedures (including familiarity of the plant) can be established.

FIRE PROTECTION MEASURES

Wastewater treatment plants receive flammable and combustible liquids and gases in three ways: (1) through the collection system, (2) through introduction into the treatment processes, or (3) as by-products of the processes. In spite of considerable care taken in design and operation, fires and explosions do occur, and fire protection and suppression equipment are necessary. Generally, fire protection and suppression measures used in the wastewater treatment industry include (1) automatic sprinkler systems, (2) chemical suppression systems, (3) standpipes and hydrants, (4) portable fire extinguishers, and (5) special fire protection measures.

Automatic Sprinkler Systems

Automatic sprinkler systems in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems,* should be installed where appropriate in buildings or structures located at a wastewater treatment plant. The fire hazard evaluation should include detailed hazard classifications, with system density and application rates sufficient to suppress any anticipated fire. In certain areas of the wastewater treatment plant, such as chemical storage areas, underground tunnels or structures, or areas where electrical hazard is the principal concern, the use of other appropriate fire protection measures should be carefully considered and evaluated.

Chemical Suppression Systems

Foam, halon and other clean agents, and dry chemical systems should be installed or used where appropriate in buildings or structures located at a wastewater treatment plant. Foam systems are most effective for wet wells, grit and screening processes, primary clarifiers, and pits and tanks where floating flammable liquid may collect on the surface. Halon and other clean-agent systems are generally used where computer equipment is located. Dry chemical extinguishing systems should be considered in chemical storage areas, underground tunnels or structures, or where electrical hazard is the principal concern and water damage would seriously impair the treatment plant's integrity.

Standpipes and Hydrants

Standpipes, hose streams, and hydrants should be provided where appropriate in buildings or structures located at a wastewater treatment plant. Water supplies should be capable of delivering the total demand of sprinklers, hose streams, and foam systems. In areas with no public water supply or an inadequate public water supply, treatment plant effluent can be used for fire protection if all contaminents have been eliminated. In treatment plants with both a public water supply and a plant water system, the plant water system can be used as the principal water source for the fire protection system or as a backup to the public water supply system.

When the plant water system is the principal source for fire protection, the system must be capable of providing an adequate quantity and pressure and have sufficient standby capacity to meet all fire waterflow requirements. If the plant water system is used as a backup to the public water supply, the system should provide easy access and connection for pumper equipment. Where dual-hydrant systems are used, cross connections (where allowed) between the public water supply and the plant water system must be installed in accordance with local requirements. When fire pumps are the sole source of supply used in the plant water system, multiple pumps with sufficient capacity to meet fire flow requirements with the largest pump out of service should be provided. Pumps should be automatic starting with manual shutdown and should not be subject to common failure of either electrical or mechanical equipment.

Portable Fire Extinguishers

Portable fire extinguishers should be provided in buildings where appropriate in accordance with NFPA 10, *Standard for Portable Fire Extinguishers.* In some areas of the treatment plant, such as basements, underground pipe galleries connecting buildings, and other areas not continuously occupied, existing codes and standards may be inappropriate. In these cases, the authority having jurisdiction should consider local optional requirements for portable fire extinguishers, depending on frequency of occupancy, intended use, equipment contained in the space, and hazard potential for fire and/or explosion.

Special Fire Protection Measures

Some wastewater treatment plants and processes have unique problems that require special fire protection considerations. For example, fire protection measures during construction at both new and existing wastewater facilities should consider life safety, property protection, and potential construction delays, as well as plant or unit process startup. Lightning protection should be provided for those structures with a risk index (R) of 4 or greater, according to NFPA 780, *Standard for the Installation of Lightning Protection Systems.* In addition, arrangements should be made to permit the municipal fire department, police department, or other authorized personnel rapid entry in case of fire or other emergency. The plant emergency organization (PEO), if present, should be properly instructed and trained in the use of all fire protection equipment located at the treatment plant.

Early detection and reporting of fires and explosions is also important in protecting the integrity of the buildings and unit processes. Protective measures that detect flame, heat, or smoke should be selected and installed where needed. The location of proper types of detection equipment (e.g., smoke, heat, flame, etc.) is a function of the hazard severity or electrical classification. Where appropriate, central station, auxiliary, remote station, or proprietary sprinkler waterflow alarm system

monitoring in accordance with *NFPA 72®*, *National Fire Alarm Code,®* should be provided.

SUMMARY

Wastewater treatment processes fall into three categories: collection and pumping, liquid treatment systems, and solid treatment systems. The highest risks of fire and explosion are associated with collection and pumping operations and the early stages of liquid and solids processing. Fire hazards common in the wastewater treatment industry are fuel gases, sewer and sludge gases, specialty gases, liquids, solids, dusts, and construction materials. Fire protection and suppression measures include automatic sprinkler systems, chemical suppression systems, standpipes and hydrants, portable fire extinguishers, and early detection systems.

Chapter 12

Fire Protection of Laboratories Using Chemicals

Revised by
Richard R. Anderson

Chapter Contents

Laboratory Design
Protection Strategies
Risk Reduction
Ventilation and Laboratory Hoods
Prevention and Emergency Planning

Key Terms

combustible liquid, compressed gas, cryogenic fluid, duct, evacuation, exhaust system, flammable liquid, hazard identification, hazardous chemical, hood, laboratory, liquefied gas, risk reduction, ventilation system

The fire protection considerations discussed herein focus on the design and operation of laboratories using chemicals to ensure the personal safety of laboratory workers, other building occupants, and emergency response personnel. Laboratories are defined in NFPA 45*, Standard on Fire Protection for Laboratories Using Chemicals,* as facilities where the containers used for reactions, transfers, and other handling of chemicals are designed to be easily and safely manipulated by one person. Other operations that often involve larger containers or quantities involved in producing or synthesizing chemicals are considered to be manufacturing or pilot plants and not laboratories within the scope of NFPA 45.

Laboratories and their buildings can present a mix of people and materials that combine aspects of hazards and population density found in office buildings and industrial sites. To elaborate, the population density of a laboratory is similar to that of an office building, and the hazards of a laboratory can resemble those found in an industrial site that uses flammable liquids and hazardous operations. Only through an adequate understanding of both the hazards and the operations conducted in the laboratory can an effective protection strategy be developed to allow for the two to safely coexist. This chapter details the components of an effective fire protection strategy for laboratories and encompasses passive and active protection strategies. These strategies are based on conducting a risk assessment, including hazard classification; using procedures to prevent fires and other incidents that may lead to a fire; and designing a laboratory that employs fire separation, fire protection equipment and systems, ventilation, and explosion hazard protection. The strategies also include the safe storage and handling of chemicals, chemical waste, and compressed and liquefied gases to prevent or minimize the consequences of a fire event.

For related topics, see Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 8, Chapter 2, "Chemical Processing Equipment"; Section 12, Chapter 9, "Fire and Emergency Services Protective Clothing and Protective Equipment"; and Section 13, Chapter 8, "Managing the Response to Hazardous Material Incidents."

LABORATORY DESIGN

The design criteria for laboratories found in most model building codes consider many elements, including the size of the fire compartment, type of construction, occupant capacity, fire loading, and provision or lack of sprinkler or other suppression protection. The hazardous chemicals to be contained will be classified,[1] and protections specified accordingly. The codes address size and height limitations and required compartmentalization.

Richard R. Anderson, CFPS, is vice-president of Anderson Risk Consultants. He is also a member of NFPA 45, Technical Committee on Laboratories Using Chemicals; responsible for NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals;* and a member of the NFPA 1600, Disaster Management and Business Continuity Technical Committee.

The design of the laboratory and operations within the laboratory should minimize the risk to the laboratory worker. The laboratory layout is important, and designers must view the entire laboratory unit, its furniture, access to means of egress, access for deliveries and pedestrian flow, flammable storage cabinets, spill containment design, and the locations of laboratory hoods, emergency showers and eyewash stations (Figure 9.12.1). The design team should include mechanical and electrical specialists, the persons responsible for the operation and maintenance of the laboratory, and safety and fire protection specialists familiar with laboratory hazards. The design of the laboratory depends primarily on the current and future use of the laboratory.

Laboratory Classification

Laboratory units are classified as Class A (high fire hazard), Class B (moderate fire hazard), Class C (low fire hazard), or Class D (minimal fire hazard). The greatest quantity of flammable and combustible liquids and liquefied flammable gases are permitted in Class A laboratory units, and the smallest quantity in Class D laboratory units. There are requirements in place to account for increases in hazards. As the hazard increases, limitations are enacted on the maximum area of the most hazardous (Class A and B) laboratory units and greater fire separation for Class A and Class B laboratories, and size restrictions for the highest hazard laboratories (Classes A and B).

Instructional laboratory units are classified as Class C or Class D laboratory units. Educational laboratory units are classified as Class D or are limited to 50 percent of the flammable and combustible liquids quantity for Class C laboratory units.

Life Safety in Laboratories

Means of Egress. Main aisles used for emergency egress should have a clearance width of at least 36 in. (0.9144 m) to expedite egress in the event of an emergency. The clearance should always be maintained even in the presence of laboratory stools. The space between adjacent workstations and laboratory benches should be 5 ft or greater to provide ease of access. In a teaching laboratory, the desired spacing is 6 ft. Bench spacing shall be considered and included in specifications and plans. Corridors and public spaces cannot be designated or used for storage, especially of any hazardous materials.

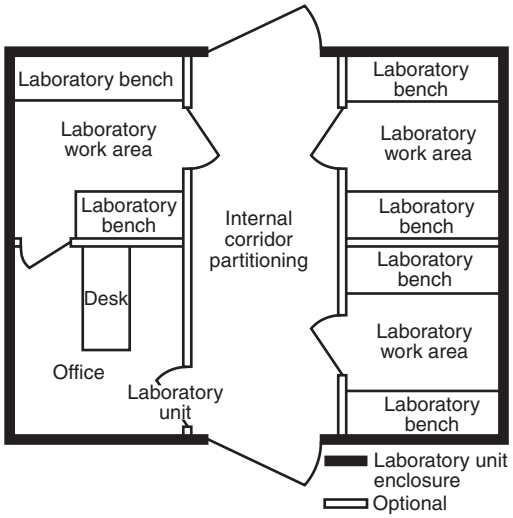

FIGURE 9.12.1 Laboratory Unit

NFPA *101*®, *Life Safety Code*®, when properly implemented, addresses all the life safety issues within a laboratory space, including egress, fire detection and alarms, and the protection of building services. These requirements for notification to the occupants and emergency forces are essential to safe evacuation of the occupants. When flammable liquids or gases are used or stored in laboratories, fires can intensify quickly, and any delay or impediment to egress cannot be tolerated. Based on the use of flammable or hazardous materials utilized in the laboratory, they are typically classified "industrial" by NFPA *101*. NFPA 45 requires laboratories to have a second means of access from the laboratory unit to a means of egress in the following six different situations:

1. An explosion hazard is located in such a manner that an incident would block access to or egress from the laboratory.
2. A laboratory work area within a Class A laboratory unit exceeds 500 ft^2 (46.5 m^2).
3. A laboratory work area within a Class B, Class C, or Class D laboratory unit exceeds 1000 ft^2 (93 m^2).
4. A laboratory hood is located adjacent to the primary means of egress.
5. A compressed gas cylinder is in use that may be larger than a standard lecture bottle and contains a gas that is either flammable or has a health hazard rating of 3 or 4 (see NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response*), or prevents the safe egress in the event of an unintentional release.
6. A cryogenic container is in use that contains a gas that is flammable or has a health hazard rating of 3 or 4 or prevents safe egress in the event of an accidental release.

Laboratory Doors. NFPA 45 also prescribes that the door swing of exit access doors from a laboratory unit be in the direction of travel with a hazard classification of Class A (High) or B (Moderate). The laboratory doors should be automatically self-closing to maintain the compartmentalization and required HVAC balance. The doors must be able to be opened with a minimum of effort to allow access and egress for physically challenged individuals.

It is important to address the situation that can occur if recirculated air to the laboratory ceases while the fume hood ventilation continues to operate, creating an extreme negative pressure in the laboratory, and thereby making it extremely hard to open the door and exit the laboratory. Furniture, casework, and equipment must also be arranged so as not to impede the path of travel to the access doors from the laboratory unit. This should include minimum aisle clearance of at least 24 in. (0.6096 m).

PROTECTION STRATEGIES

Both passive and active protection strategies are important aspects of laboratory design. Therefore, during the design phase

of a laboratory, both strategies should be considered to meet code requirements and to satisfy the designer's and owner's functional objectives.

Passive Protection Strategy

Fire Separation Requirements. NFPA 45 establishes criteria for fire separation requirements, including door and window assemblies, based on the amount of flammable and combustible liquids or flammable compressed gases, including hazardous waste, that will be in use or stored within a laboratory building or any laboratory work unit. The following approach can help determine an appropriate laboratory design and construction criteria as specified in NFPA 45:

- Determine the intended use of each laboratory.
- Determine the likely chemical inventory required for this use.
- Determine likely in-use needs and what must be on hand in storage.
- Determine waste generation and removal to quantify temporary waste storage.
- Calculate total likely in-use flammable and hazardous materials and storage, including hazardous waste.
- Determine the laboratory unit fire hazard class.
- Determine the allowable area and construction requirements specified in NFPA 45.

Laboratories built to a lower standard or classification may not be used for a higher risk operation, even on a temporary basis. Therefore, the quantity of flammable liquid to be stored in a laboratory and the location within the laboratory are important considerations.

Hazard Management. Design details contribute to safe and efficient laboratory operation when they take the following safety measures into account:

- Prevention and containment of spills
- Sufficient storage
- Access to circuit breakers
- Adequate lighting during emergency shutdowns
- Ventilation
- Countertop material
- Nonslip flooring
- Proper traps in floor drains
- Work counter heights
- Adequate workspace

Solvent storage should not be located under the laboratory fume hood, as this is a location where fires are most likely to occur in laboratories. All laboratories should be designed to conveniently and safely accommodate the temporary storage of biological, radiological, and chemical materials (nonwaste and waste) based on laboratory use projections. Laboratory benches should be constructed of noncombustible and nonporous materials. Laboratory operations can involve concurrent use of chemical solvents such as formaldehyde, phenol, and ethanol, as well as corrosives. The laboratory bench must be resistant to the chemical actions of these substances and disinfectants. Wood is porous and combustible. Fiberglass can degrade when strong disinfectants are used and can release toxic smoke when ignited.

Electrical Equipment and Appliances. All electrical installations, including wiring, apparatus, appurtenances, lighting, grounding, signal devices, and alarm systems, must comply with NFPA 70, *National Electrical Code®*. Electrical equipment and appliances used within a laboratory should display a listing of intended use that is approved by a recognized testing laboratory, unless no test standards have been established for the devices. The electrical system must be carefully designed to locate receptacles, switches, controls, and other arcing devices away from areas where spills might occur. It is equally important to provide the proper number and spacing of receptacles to eliminate the need for extension cords. Uninterrupted power supplies or emergency power may be required for some critical analytical test equipment or chemical fume hoods when ventilation is critical during hazardous operations.

In general, laboratory work areas, laboratory units, and chemical fume hood interiors should be considered as unclassified electrically, with respect to Article 500 of *NEC*. Typical laboratory operations prevent an ignitable vapor from being present in the laboratory. However, if a hazard analysis reveals the potential for a likely scenario that would produce an ignitable vapor, the laboratory work area, or a part thereof, should be classified as a hazardous location. Compliance with the requirement to mitigate a spill scenario of 5 gal (0.1892 m) or more can ensure that an ignitable vapor is unlikely to occur in the laboratory.

Electrical Classification of Hoods. Rationale and calculations are provided in the informational section of NFPA 45 to explain the electrical classification of hoods. In general, the classification of chemical fume hoods as general purpose is appropriate. This is because, in general use, the combination of the airflow rate and flammable vapor concentration will not permit a stoichiometric vapor-air mixture, which could result in an explosion, given specific quantities of flammable liquids. If quantities beyond the specific amounts are present in the hood, a scenario can exist where an ignitable vapor could become present and a fire or explosion result.

The electrical classification of the hoods depends on the ventilation rate, the quantity of flammable materials, and the type of chemical process or activity.[2] The challenge is to determine how flammable vapors or gases can be safely used in a hood with unclassified electrical equipment and heated surfaces. When the quantity of flammable vapor is minimized and ventilation rates are maximized, a determination of the volume of vapor generated by the vaporization of flammable liquid can help to approximate the maximum quantity of liquid that can be used to operate below the lower flammable limit (LFL), assuming liquid vaporization in 1 minute with perfect mixing. The exhaust air volume is a critical parameter necessary to calculate the maximum quantity that can be vaporized in 1 minute before reaching LFL. Under these ventilation rates and controlled quantities of flammable liquids, the hood is considered to be electrically unclassified, since the LFL of the specific vapor will not be reached. Ventilation is assumed to be constant, and ventilation failure that occurs simultaneously with an

unexpected development of flammable vapors above the LFL is highly unlikely.

Active Protection Strategy

As stated at the start of this section, both passive and active protection strategies are important aspects of laboratory design. During the laboratory design phase, it is essential to specify the type of suppression, detection, and alarm systems that are necessary to both meet code requirements and meet the functional objectives of the designer and owners.

Detection and Alarms. In laboratories where a risk assessment, hazard classifications, or code requirements warrant a fire alarm system, it must be installed in accordance with *NFPA 72®, National Fire Alarm Code®,* and designed to alert all those who may be affected by the emergency. This could require 100 percent testing during installation to ensure notification is achieved in all occupiable spaces in the laboratory building. Notification schemes should also be considered for storage spaces where employees may work temporarily.

Automatic Fire Protection. In the 2004 edition of NFPA 45, a requirement was added to require all new laboratories to have automatic fire-extinguishing systems. For laboratories built before 2004, where a risk assessment, hazard classification, or code requirement warrants an automatic fire-extinguishing system, it must be installed in accordance with NFPA 13*, Standard for the Installation of Sprinkler Systems.* Laboratories with a Class A or B (High-Moderate) hazard classification should be protected as ordinary hazard (Group 2); Hazard Class C and D (Low) laboratories should be protected as ordinary hazard (Group 1). A study conducted by National Institute of Standards and Technology[3] demonstrated that quick-response sprinklers controlled flammable liquid test fires that were conducted in laboratories more quickly than standard-response sprinklers. Where required or used in place of automatic sprinkler systems, special hazard extinguishing systems and nonwater automatic extinguishing systems are also acceptable.

Although new laboratories are required to have automatic fire protection systems, automatic fire protection systems are not required to be extended to chemical fume hoods or exhaust systems except in the following cases:

- Existing hoods in which flammable liquids are handled have interiors with a flame spread index greater than 25.
- A hazard assessment shows that an automatic extinguishing system is required for the chemical fume hood.

Should the decision be made to extend the protection to the hoods, consideration should be given to the fact that whereas alternative extinguishing agents can control or suppress a flammable liquid fire in a chemical fume hood, tests[4] have demonstrated that the installation of automatic sprinklers with water mist nozzles in the chemical fume hood is the most effective fire protection strategy where nonthermal damage (from the extinguishing agent) outside of the chemical fume hood is a concern. Where water-reactive materials are utilized in the hood, special precautions must be taken to avoid an inadvertent discharge, regardless of the type of extinguishing system. Although water reacts with water-reactive chemicals, when the chemical fume hood is aflame with a flammable liquid fire, the resultant reaction (even with a sodium metal) is not so significant as to eliminate water as a safe and effective fire protection strategy. Of course this assumes that the chemical fume hood is not being used for significant out-of-container storage.

The other concern typically expressed by laboratory owners is about an inadvertent discharge of an automatic sprinkler system and the resultant damage to sensitive and expensive electronic equipment that may be utilized in the laboratory. Accidental discharges from mechanical means can be eliminated by concealing sprinkler heads. Accidental discharge from other than mechanical damage or microbiologically induced corrosion issues are almost nonexistent and do not typically warrant the elimination of the significant benefits of automatic sprinkler protection or the additional cost of a preaction sprinkler system.

Fire tests[5] conducted in the UK have demonstrated that clean agents break down and evolve significant toxic by-products when they come in contact with flaming combustion. In addition, in order for clean agents to work, chemical fume hoods must be shut down. The activation of any automatic fire protection system should send an activation signal to a constantly monitored station in accordance with *NFPA 72*. Alternative systems should be installed according to the applicable standards.

Inspection, testing, and maintenance of any fire protection system should be performed in accordance with the appropriate NFPA standard. Laboratory personnel should be educated on the specific function of these suppressions systems and know who should be called to report problems. Laboratory occupants should exercise care and not block or hang anything from sprinklers or sprinkler piping. Storage and equipment must not obstruct the sprinkler discharge.

Standpipe and Hose Systems. Laboratory buildings that are two or more stories above or below ground level must have an approved standpipe system installed in accordance with NFPA 14, *Standard for the Installation of Standpipe and Hose Systems.* The standpipe system must be regularly inspected, tested, and maintained in accordance with NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems.*

Portable Fire Extinguishers. Portable fire extinguishers can be a valuable tool to control a small fire in the incipient stage. However, the extinguishment of a flammable liquid fire or fire involving other chemicals can present a significant danger to an inexperienced operator who has not had actual hands-on training with a fire extinguisher. In addition, it is essential that personnel who are designated to use a fire extinguisher receive risk management training to help them evaluate go or no-go situations. Although extinguishing a fire in the incipient stage can prevent significant damage, laboratory designers should carefully evaluate whether incipient stage extinguishment presents the potential for significant injury or death. The proper type, placement, and maintenance of extinguishers are essential. NFPA 10*, Standard for Portable Fire Extinguishers,* regulates these appliances.

Explosion Hazard Protection. If the hazard assessment determines that an explosion hazard exists, appropriate protection must be provided for the occupants. The explosion hazard could be a rupture of apparatus, an overpressurized system, or implosion due to vacuum. Explosion hazard may be mitigated by explosion venting, special protected enclosures for vacuum and distillation columns, or by isolating the high-risk operations away from the other risks in specially designed buildings. Annual inspections should be required and include all safety features that have been designed for the space. This includes system components and construction features.

RISK REDUCTION

Laboratory Hazards

Laboratory operations using chemicals can include toxins, corrosives, ionizing and nonionizing radioactive materials, flammable liquids, and gases. Laboratory operations involving these chemicals may include distillations, which involve heating flammable liquids to above their boiling point, either under pressure or under vacuum. In addition, some high-pressure reactions involve hydrogen or other flammable gas. Accidents involving these operations can include rapidly spreading flammable liquid fires, explosions, and exposure to highly toxic and hazardous materials.

Risk-Reduction Strategies

The laboratory has many inherent risks, and some represent a higher risk factor than others. A risk assessment will identify the critical areas that need special consideration. High risk operations include the use of flammable liquids and flammable gases, reactions, and distillations. It is not uncommon or unsafe to perform distillation of a flammable liquid in a 5 gal (20 L) glass vessel. Once the risk is identified, strategies can be put into place that will prevent an incident or eliminate or reduce the impact. Standard risk-reduction strategies include the following approaches: inherent, passive, active, and procedural.

Inherent Risk Reduction. The inherent safety approach is the most reliable and a true prevention strategy. The procedural risk reduction strategy discussed below can also be considered a prevention strategy. In contrast, the passive risk reduction and active risk reduction strategies (also discussed below) are risk-reduction and consequence-minimization strategies. An example of an inherent safety strategy is the substitution of a nonflammable solvent for a flammable solvent—for example, using supercritical carbon dioxide in place of hexane for extraction.

Passive Risk Reduction. The single most favorable aspect of a passive approach is its performance reliability, which is a consequence of the fact that a passive strategy requires no mechanical device or system to actively function. For example, with a reactor system, instead of relying on an active system such as a safety relief valve to protect the reactor in the event of a runaway, a passive approach would be to design the reactor to contain the maximum expected overpressure. Another example of a passive approach is a fire-rated wall that confines a fire to the room of origin. Again, the prevention element here is solely the prevention of fire spread, not the prevention of the initiating event.

Active Risk Reduction. The next preferred risk-reduction strategy is the active approach. An active approach strategy is one that requires a mechanical device or protective system to actively prevent, detect, limit, or respond to the event. An active system must be reliably designed to work when intended, installed according to strict installation rules, and maintained and tested over its entire life. An automatic suppression system, such as an automatic sprinkler system, is a good example of an active approach.

Procedural Risk Reduction. The final approach and one that can also be preventive is the procedural approach. By following proper procedures and prudent practices, spills, fires, and explosions can be prevented. Emergency response is also recognized as a procedural approach to minimizing the consequence of a spill, fire, explosion, or other incident in the laboratory. Procedures should address the handling and storage of chemicals and flammable and combustible liquids and gases, use of open flames such as Bunsen burners, and use of portable electric cords. In addition, maintenance procedures should be in place that include periodic preventive maintenance and, where appropriate, predictive testing for equipment used in hazards operations, such as reactions and distillations.

VENTILATION AND LABORATORY HOODS

Purposes of Hoods and Cabinets

Ventilation systems and laboratory hoods provide important safety features. Laboratory hoods and other local exhaust systems provide important features that are not duplicated by other types of exhausting systems designed for vastly different purposes. For example, canopy hoods, biological cabinets, and laminar flow cabinets cannot be used in lieu of laboratory hoods. The main purpose of a canopy hood is to exhaust heat, water vapor, odors, and other nonhazardous materials. The purpose of a laminar flow cabinet is to provide filtered airflow over the work surface. A biological cabinet is used for storage to protect personnel, product, and the environment during storage.

Ventilation for Safe Operations

Where toxic or flammable chemicals are handled or stored, using proper systems to ensure the effective ventilation of laboratory work areas is critical to safe operations for two important reasons.

First, to prevent personnel exposure to toxic or odiferous materials during the course of conducting normal laboratory activities, the resulting vapors or gases are usually exhausted with nonrecirculated, conditioned air through hoods and local exhaust arrangements. This is one reason why it is very important to ensure that laboratory ventilation systems operate properly while activities are being carried out in the work area. Depending on

the nature of the chemicals and the type of operations, it might be possible to reduce ventilation rates during off hours when work areas are unoccupied.

Second, when activities involve the use of toxic or flammable materials in quantities that cannot be safely handled in work areas, the activity should be carried out in a hood. Typical modern hoods operate under negative pressure compared to the work area, with hood-face velocities that range from 80 to 120 linear ft/min (0.41 to 0.61 m/sec), with 100 linear ft/min (0.5 m/sec) being the most common. These ventilation rates mix, dilute, and exhaust toxic or flammable materials to a safe location.

Ventilation System Requirements

As is the case with the other safety features designed within the laboratory, these systems must be inspected, maintained, and tested. A basic design principle is to keep the laboratory at negative pressure with respect to the other nonlaboratory areas of the building, although some exceptions apply.

Laboratories must be continuously ventilated. Supply air for laboratories must be designed to prevent toxic and flammable vapors from being recirculated back into the laboratory. This requires the fresh air intakes to be located remotely from the exhaust discharge. The disposition of room air in a laboratory is governed by NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems.*

Requirements for Hoods and Exhaust Systems

Air ducts of hoods and local exhaust systems must be constructed of noncombustible material and must be designed to maintain a negative pressure with respect to the area outside the duct. Combustible duct linings must have a flame-spread index of 25 or less when tested in accordance with NFPA 255*, Standard Method of Test of Surface Burning Characteristics of Building Materials.* When the chemical fume hood is used properly, there are no "hazardous vapors," as defined by the model building codes, and hoods are therefore exempt from the requirements of automatic fire protection systems. NFPA 45 does not require hoods to have automatic fire protection systems unless a hazard analysis deems it necessary, or if the hood interior flame-spread index is not achieved.

Air exhausted from a laboratory hood and from special systems must be discharged above the roof at a sufficient velocity and height to prevent reentry. A proper lockout procedure is also needed for laboratory hoods to properly identify if a hood is out of service. Proper signs must be located at the hood to notify the user. Fan units for laboratory hoods should be selected to meet the specific design requirements, such as corrosion resistance or nonferrous rotating elements. Individual fans should be labeled and should identify which laboratories they serve. An airflow-measuring device should be installed on each hood to indicate inadequate or unsafe airflow. Hoods must also be designed to contain minor spills.

Design of Hoods and Ducts

Automatic fire dampers should not be located in laboratory hood exhaust ducts. The building fire alarm system should not be interlocked to shut down laboratory hood exhaust systems because it could cause a dangerous build-up of flammable or toxic vapors. The design and installation of duct systems for laboratory hoods must be in accordance with NFPA 91*, Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids.*

Care must be exercised when using energy conservation devices on laboratory hoods. A user-accessible device must be available that will immediately attain maximum exhaust hood airflow. This will ensure the removal of the contaminant and potentially harmful products regardless of the sash position should an emergency occur.

Inspection of Hoods

All laboratory hoods should be inventoried and the basic operational information maintained and updated. Details should list the last inspection date, the inspection interval, average face velocity, and location of exhaust fan and its controls. This information should be available to the user and maintenance personnel. Laboratory hoods should be tested and inspected following modification, after installation, or at least annually. Laboratory staff should be trained to recognize unsafe conditions and how to arrange for correction work.

Perchloric Acid Hoods

The use of specialized local exhaust and dedicated hoods for perchloric acid are control methods that minimize the fire risk. The use of perchloric acid creates unique hazards, and care must be extended to these operations. Laboratory hoods used for perchloric operations must be designed and identified for this purpose. A water spray system must be provided for these hoods along with a method to collect the wash-down water. If a perchloric hood is to be used for any other purpose, it must be tested to ensure that it is free of residual perchlorates.

PREVENTION AND EMERGENCY PLANNING

Unusual nonfire hazards that emergency response personnel might encounter in responding to a fire in a chemical laboratory include poisons, corrosives and irritants, radioactivity, nonionizing radiation, and biological hazards. Laboratories using radioactive materials must be identified in the facility emergency plan. NFPA 801*, Standard for Fire Protection for Facilities Handling Radioactive Materials,* provides further discussion on this subject. Laboratory management should train emergency response personnel in detailed emergency response plans that address these special hazards. Preplanning for emergencies should identify significant and unique hazards in all laboratories. Emergency response personnel will need to take additional care and be familiar with the hazards and proper response and decontamination techniques. Laboratory management should also encourage the public fire department to become familiar with these hazards through in-service inspections, joint emergency plan development, and coordinated emergency response drills.

Evacuation Plans

The management of each laboratory work area should be responsible for developing and distributing an evacuation plan for the facility. The plan should contain diagrams and should be distributed to each supervisor and posted in appropriate locations for all employees to read and study. In addition to fires and explosions, the evacuation plan should also consider hazardous incidents, such as spills, leaks, or releases of flammable, toxic, or radioactive materials, and seismic events and other acts of nature, such as tornadoes, hurricanes, and floods. The evacuation plan should include, but not be limited to, the following:

- Conditions under which evacuation will be necessary
- Method of alarm transmission
- Action to be taken in addition to evacuation by personnel upon receiving an alarm (e.g., turning off flames and other ignition sources)
- Primary and secondary routes to horizontal and vertical exits leading either to the exterior of the building or to safe refuge zones within the building, as might be permitted if total evacuation is not necessary and the alarm system is appropriately zoned
- Accountability for determining if everyone has left the facility
- Methods of notifying personnel as to when it is safe to reenter the facility

Laboratory management should conduct fire exit drills at least once a year to test the evacuation procedures by familiarizing personnel with exits, especially emergency exits not normally used, and the safe and efficient use of the exits. For required frequency of fire exit drills in educational occupancies and health care occupancies, see NFPA *101*. Fire exit drills differ from fire drills in that the latter are held for purposes of fire-fighting practice by the fire brigade or other emergency organizations. No one should be excused from participating in a fire exit drill.

Hazard Identification

NFPA 45 does not exclusively endorse any particular convention for communicating unusual hazards to emergency response personnel, recognizing that professional judgments need to be made on a facility-by-facility basis. However, entrances to laboratory units, laboratory work areas, storage areas, and associated facilities should be identified by signs to warn emergency response personnel of unusual or severe hazards such as poisons and radioactivity.

Procedures and Practices

Chemical storage shelves should not be placed above laboratory sinks. All shelves must have a passive restraining system such as seismic shelf lips (¾ in. [19.05 mm] or greater). The shelves themselves must be firmly fixed so they cannot be vibrated out of place and allow shelf contents to fall.

Laboratories should have an inventory management system in place to track new and waste products entering and leaving the laboratory. Product containers should be date stamped to manage date-sensitive chemicals. Hazardous products must only be used in laboratories designed and constructed for this intended use.

Flammable and Combustible Liquids

Proper storage and handling procedures for flammable and combustible products are critical to the safe operation of a laboratory. Many restrictions are identified in NFPA 45. The maximum allowable quantities are based on laboratory class, and allotments are made for every 100 ft^2 (9.3 m^2) of laboratory area, as shown in Table 9.12.1. Quantities are increased if the liquids are in storage cabinets or safety cans. The maximum quantity for any laboratory unit (regardless of size) is also specified. In addition to maximum overall quantities in a lab, NFPA 45 sets forth maximum allowable container capacities. Educational and instructional laboratories have additional caveats on the container size for lower flashpoint liquids. The classification of flammable and combustible liquids is the same as that used in NFPA 30, *Flammable and Combustible Liquids Code,* and is essentially the same system used by OSHA. The classes are summarized in the sections that follow.

Flammable Liquids. A liquid is considered to be flammable if it has a closed-cup flashpoint below 100°F (37.8°C) and is classified as Class I. A Class I liquid is any liquid that has a closed-cup flashpoint below 100°F (37.8°C) and a Reid vapor pressure not exceeding 40 psia (2068.6 mm Hg) at 100°F (37.8°C), as determined by ASTM D 323, *Standard Method of Test for Vapor Pressure of Petroleum Products (Reid Method).* Class I liquids are further classified as follows:

- Class IA liquids—those liquids that have flashpoints below 73°F (22.8°C) and boiling points below 100°F (37.8°C)
- Class IB liquids—those liquids that have flashpoints below 73°F (22.8°C) and boiling points at or above 100°F (37.8°C)
- Class IC liquids—those liquids that have flashpoints at or above 73°F (22.8°C) but below 100°F (37.8°C)

Combustible Liquids. A liquid is considered to be combustible if it has a closed-cup flashpoint at or above 100°F (37.8°C) and is classified as Class II or Class III as follows:

- Class II Liquid—any liquid that has a flashpoint at or above 100°F (37.8°C) and below 140°F (60°C)
- Class IIIA—any liquid that has a flashpoint at or above 140°F (60°C) but below 200°F (93°C)
- Class IIIB—any liquid that has a flashpoint at or above 200°F (93°C)

Class I liquids have more restrictions than Classes II and III, including container size and total volume permitted. Container type and size should be carefully monitored for compliance, and all flammable liquids should be stored in approved containers within storage cabinets. It is not mandatory to vent these cabinets. Neither NFPA 30 nor NFPA 45 requires that the storage cabinet be vented, but both documents allow this to be done where it is deemed necessary or desirable.

Laboratory Unit Storage

Storage cabinets help to prevent a laboratory fire from spreading to those products stored within these cabinets. Products stored in cabinets must be compatible. If a product requires refrigeration,

TABLE 9.12.1 Maximum Quantities of Flammable and Combustible Liquids and Liquefied Flammable Gases in Sprinklered Laboratory Units Outside of Inside Liquid Storage Areas

		Excluding Quantities in Storage Cabinets or Safety Cans				Including Quantities in Storage Cabinets or Safety Cans			
Laboratory Unit Fire Hazard Class	*Flammable and Combustible Liquid Class*[a]	Maximum Quantity[b] per 9.3 m^2 (100 ft^2) of Laboratory Unit[c]		Maximum Quantity[b] per Laboratory Unit		Maximum Quantity[b] per 9.3 m^2 (100 ft^2) of Laboratory Unit[c]		Maximum Quantity[b] per Laboratory Unit	
		L	*gal*	*L*	*gal*	*L*	*gal*	*L*	*gal*
A (high fire hazard)	I[d]	38	10	2270	600	76	20	4540	1200
	I[d], II, and IIIA	76	20	3028	800	150	40	6060	1600
B (moderate fire hazard)	I[d]	20	5	1136	300	38	10	2270	600
	I[d], II, and IIIA	38	10	1515	400	76	20	3028	800
C (low fire hazard)	I[d]	7.5	2	570	150	15	4	1136	300
	I[d], II, and IIIA	15	4	757	200	30	8	1515	400
D (minimal fire hazard)	I[d]	4	1	284	75	7.5	2	570	150
	I[d], II, and IIIA	4	1	284	75	7.5	2	570	150

Note: For maximum container sizes, see Table 10.1.4 of NFPA 45.
[a]See 4.2.1.3 and 11.1.6.5 of NFPA 45.
[b]See 4.2.2 of NFPA 45 for additional requirements for instructional and educational laboratories.
[c]The quantities per 9.3 m^2 (100 ft^2) do not imply the quantities must be within that 9.3 m^2 (100 ft^2) area; the quantities per 9.3 m^2 (100 ft^2) are for calculation purposes to determine the total quantity allowed.
[d]This category includes Class I flammable liquids and liquefied flammable gases.
Source: NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals,* Table 10.1.1, 2004, p. 45-17.

the appliance must be approved for its intended purpose and hazard rating.

In general, any "storage" within the laboratory unit is for the chemicals in use and is subject to same requirements as the rest of the laboratory as far as quantities, construction, and so on. If additional quantities are necessary, the storage can be defined outside the laboratory unit and can be classified as a flammable or a combustible liquids storage area, subject to the requirements of NFPA 30. Rooms specifically designed to the requirements outlined in NFPA 30 should be available for the following:

- Bulk storage of product
- Containers that measure above the quantities allowed in NFPA 45
- Containers that are larger than those allowed in NFPA 45

For all storage, incompatible materials must be segregated.

Dispensing Flammable Liquids

Dispensing of Class I liquids to or from containers less than or equal to 5 gal (20 L) in capacity should be performed in one of the following locations:

- In a chemical fume hood
- In an area provided with ventilation adequate to prevent accumulations of flammable vapor/air mixtures from exceeding 25 percent of the lower flammable limit
- Inside liquid storage areas specifically designed and protected for dispensing Class I flammable liquids that meet the requirements of NFPA 30

A pressurized liquid dispensing container that meets the requirements of NFPA 45, however, does not have to be used in the three areas listed above. Class I liquids should not be transferred between conductive containers of greater than 1 gal (4 L) capacity unless the containers are electrically interconnected by direct bonding or by indirect bonding through a common grounding system. When dispensing Class I liquids involves nonconductive containers larger than 1 gal (4 L), which can be difficult to bond or ground, special dispensing procedures commensurate with the electrical characteristics of the liquid shall be developed and implemented.

Allowable Quantities of Flammable Liquids

NFPA 45 provides quantity limitations for flammable and combustible liquids based on laboratory class, class of chemical, and size of laboratory unit, as shown in Table 9.12.1. The quantities are lower for Class A laboratories when compared to Class D laboratories; the quantities of Class I flammable liquids are more restricted than the Class III liquids; and the quantities are increased incrementally for each 100 ft^2 (9.3 m^2) of laboratory unit area, with a maximum overall quantity regardless of size. There are no density requirements in the laboratory unit such

that the chemicals must be distributed evenly throughout the lab. Part of the reason for this is that in many cases the chemicals are in a storage cabinet, which is not prohibited from containing more than the quantity allowed for a 100 ft^2 (9.3 m^2) area. Additionally, the committee reasoned that if there were density requirements per every 100 ft^2 (9.3 m^2), it is likely that there would be some unusual schemes to "split" up the square footage. However, good engineering practices should also be exercised; note that NFPA standards and codes are minimum requirements and are not always considered "best practices."

Pressurized Liquid Dispensing Containers (PLDCs)

In the 2004 edition, NFPA 45 recognized and defined a container called a pressurized liquid dispensing container (PLDC). The need for a large feedstock of solvent with high purity for modern laboratory sampling and testing equipment was satisfied by the PLDC. As defined in NFPA 45, PLDCs that are used for flammable and combustible liquids should be listed or labeled for their intended use by a nationally recognized testing laboratory. These containers have undergone exposure to fire tests and have demonstrated satisfactory venting properties.

The relief devices on PLDCs should discharge to a safe location, in accordance with the manufacturer's recommendation. The piping/hose between the container and the use point should be rated for the pressure, compatible with the materials being transferred and not subject to mechanical damage. A readily accessible means to stop the flow of liquid from the container should be provided. Containers should only be pressurized with nitrogen or inert gas. These containers are also subjected to the NFPA 45 maximum spill criteria of 5 gal (20 L). It is critical to design the system to prevent the entire 60 gal (227 L) of flammable liquid in a PLDC from being leaked out of the container into the laboratory.

Hazardous Chemicals

Hazardous chemicals must not be brought into a laboratory space unless the design, construction, and fire protection systems are appropriate for the quantities and the hazard involved. These hazardous products include, but are not limited to, flammable solids, oxidizers, and organic peroxides. Quantities of hazardous chemicals should be restricted to the minimum amounts necessary to perform the work. Only trained staff should undertake these activities, and the handling and storage of these materials must conform to the manufacturer's recommendations. Special storage facilities are needed for materials having unique physical or hazardous properties, such as temperature sensitivity, water reactivity, or explosive characteristics. Disposal of these products requires special consideration, and, again, should be carried out by qualified personnel only.

Compressed and Liquefied Gas Cylinders

The use of compressed and liquefied gases within a laboratory presents another unique hazard. The volume of gas cylinders within a laboratory should be kept to a minimum. Cylinders stored outside the laboratory must conform to NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks.* Cylinders or containers with a gauge pressure over 15 psi (103 kPa) should be fabricated as specified or authorized by the U.S. Department of Transport, Transport Canada, or Section VIII of the ASME Boiler and Pressure Vessel Code. Special continuously mechanically ventilated enclosures are required for lecture bottle-size cylinders that contain pyrophoric gases, gases with health-hazard ratings of 3 or 4, and gases with health-hazard rating of 2, and having no physiological warning properties. Cylinders other than lecture bottle-size having similar hazardous properties require storage within approved continuously mechanically ventilated gas cabinets and in the case of pyrophoric gases require sprinkler protection within the cabinet. Additionally, compliance with NFPA 55 is required. Cylinders should be handled and stored in accordance with procedures developed by the Compressed Gas Association.

Cryogenic Fluids

All system components used for cryogenic fluids must be designed for such use. Systems or apparatus handling cryogenic fluids that cause freezing or liquefaction of the surrounding atmosphere must be designed to prevent contact with the condensed air and organic materials. Location spaces for cryogenic systems must be ventilated commensurate with the properties of the specific fluid.

SUMMARY

Laboratory design must take into account the laboratory's layout, including its furniture, access to means of egress, access for deliveries and pedestrian flow, and the locations of laboratory hoods, flammable storage cabinets, emergency showers, and eyewash stations, as well as spill containment design. The fire protection strategy is critical in the design and operation of laboratories using chemicals in order to safeguard laboratory workers, other building occupants, and emergency response personnel. Fire protection considerations in construction include type of building material, electrical installations, and sprinkler protection. In addition to automatic sprinklers, fire protection systems include standpipes and portable fire extinguishers. Explosion hazard protection measures, the ventilation system, and laboratory hoods are all important pieces of the overall strategy. Proper procedures must be followed in chemical storage and waste disposal, compressed or liquefied gas handling, and other hazardous operations. A comprehensive safety management system includes prevention and emergency planning, hazard assessment, procedures and protocols, and training.

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on fire protection of laboratories with chemicals discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 10, *Standard for Portable Fire Extinguishers*
NFPA 11, *Standard for Low-, Medium-, and High-Expansion Foam*
NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems*
NFPA 12A, *Standard on Halon 1301 Fire Extinguishing Systems*
NFPA 13, *Standard for the Installation of Sprinkler Systems*
NFPA 14, *Standard for the Installation of Standpipe and Hose Systems*
NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protec*tion
NFPA 17, *Standard for Dry Chemical Extinguishing Systems*
NFPA 17A, *Standard for Wet Chemical Extinguishing Systems*
NFPA 25, *Standard for the Inspection, Testing, and Maintenance of Water-Based Fire Protection Systems*
NFPA 30, *Flammable and Combustible Liquids Code*
NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals*
NFPA 55, *Standard for the Storage, Use, and Handling of Compressed Gases and Cryogenic Fluids in Portable and Stationary Containers, Cylinders, and Tanks*
NFPA 68, *Standard on Explosion Protection by Deflagration Venting*
NFPA 69, *Standard on Explosion Prevention Systems*
NFPA 70, *National Electrical Code®*
NFPA 72®, *National Fire Alarm Code®*
NFPA 77, *Recommended Practice on Static Electricity*
NFPA 86, *Standard for Ovens and Furnaces*
NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems*
NFPA 91, *Standard for Exhaust Systems for Air Conveying of Vapors, Gases, Mists, and Noncombustible Particulate Solids*
NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences*
NFPA 99, *Standard for Health Care Facilities*
NFPA *101®*, *Life Safety Code®*
NFPA 220, *Standard on Types of Building Construction*

NFPA 496, *Standard for Purged and Pressurized Enclosures for Electrical Equipment*
NFPA 704, *Standard System for the Identification of the Hazards of Materials for Emergency Response*
NFPA 750, *Standard on Water Mist Fire Protection Systems*
NFPA 801, *Standard for Fire Protection for Facilities Handling Radioactive Materials*
NFPA 2001, *Standard on Clean Agent Fire Extinguishing Systems*

Chapter 13

Fire Protection of Telecommunications Facilities

Ralph E. Transue

Chapter Contents

U.S. Telecommunications Network
Fire Record
Central Office Telecommunications Equipment
Fire Protection for the Public Network
Private Telecommunications Equipment
A Glimpse of the Future
Fire Department Concerns
Application Beyond the United States and Canada

Key Terms

central office (CO), performance-based design, private branch exchange (PBX), telecommunications, telecommunications equipment, telecommunications facility, telephone exchange

This chapter discusses protection against fire of the telecommunications network in the United States and Canada. To do so, it presents the basic layout and function of the U.S. telecommunications network, its evolution, and current trends. It describes the network's components and contains guidance for providing fire protection of the network against fire hazards to those components. It also provides recommendations for fire department response to telecommunications industry fires and for code compliance issues. It discusses both the public telecommunications network and private telecommunications equipment.

Driven by both technological advances and regulatory changes that have nothing at all to do with fire safety, dramatic changes are occurring in the North American telecommunications network. The impact of these changes on society and on fire risk is currently developing. This chapter describes many of these changes, their potential impact on fire risk, and methods to assess fire risk and determine appropriate fire protection programs.

Since Alexander Graham Bell made the first phone call on March 10, 1876, telephones have played an increasingly important role in people's lives. Once an oddity, then a convenience, the telephone is now a necessity of modern life. After some large loss fires affected the U.S. telecommunications industry in the 1960s and 1970s, the industry developed standards that include requirements to limit fire growth in equipment, wire, and cable used within central offices. This practice has been successful in limiting the size of fires that have occurred since.

Telecommunications, which touch almost every facet of daily life, include emergency 9-1-1 service, the Internet, automatic bank teller machines, point of sale transaction processing terminals, electronic funds transfer functions, fax machines, teleconferencing and videoconferencing, video services, cable TV, and standard and wireless telephone services.

Continuing evolution in the uses of telecommunications services has driven technologies that provide service to ever-increasing levels of sophistication. The following four important developments in the industry have resulted:

1. Long-distance transmission of signals between points in the network has been converted from analog signaling, which transmits a continually variable electrical signal, to digital signaling, which transmits on-and-off pulses of electricity or light.

2. Transmission routes have been extensively converted to fiber optics. This technology has found its way into local service, data and video services, and other wide bandwidth transmission facilities in many communities. Broadband connections to homes and to businesses are growing dramatically. Indeed, data communications volume is expected to exceed voice communications in the years ahead.

3. The development of wireless telephones has advanced throughout North America, and other major markets, permitting pocket-sized telephones and wireless data technologies to supplement or replace traditional land-based telecommunications facilities.

Ralph E. Transue, P.E., is senior vice-president of The RJA Group, Inc., and Rolf Jensen & Associates, Inc., in Chicago, Illinois.

4. Unrestrained competition has radically changed the telecommunications industry. Artificial barriers between long-distance service providers and local service providers have been removed. Services are now provided by traditional telecommunications service providers and new entrants, such as voice over the Internet, cable television companies, and others. However, concern is raised over the service levels provided by new entrants in this highly competitive business.

NFPA 76, *Standard for the Fire Protection of Telecommunications Facilities,* captures the best practices of the U.S. and Canadian telecommunications network providers to set a performance level for fire protection of the public network. It contains performance-based and prescriptive alternative approaches to achieve the level of network reliability against the threat of fire that the user public expects and that has been provided by the traditional telecommunication services. The performance-based method can be used for all future technology developments as the network equipment and facilities continue to evolve.

For related topics, see Section 8, Chapter 6, "Protection of Electronic Equipment"; and Section 9, Chapter 8, "Protection of Records."

U.S. TELECOMMUNICATIONS NETWORK

Many service companies provide telecommunication services in the United States and Canada. These companies operate networks ranging in size from small rural communities to large worldwide networks serving millions. Many types of facilities have emerged to provide the breadth and flexibility required in differing segments of the network. Buildings called central offices (COs) or telephone exchanges house primary control functions for the traditional network. Nearly 25,000 other smaller structures are required to operate the U.S. telecommunications network. Some of the larger buildings also include administrative office areas.

Between 1984 and the signing of the 1996 Telecommunications Reform Act passed by the U.S. Congress, the U.S. telecommunications network had two segments: (1) the portion local exchange carriers (LECs) or local phone companies provided, and (2) the portion interexchange carriers (IECs) or long-distance phone companies provided. The concept of the local access and transport area (LATA), established at the court-ordered divestiture of the Bell System in 1984, distinguished these two types of phone companies. The enactment of the 1996 Telecommunications Reform Act blurred the distinction between them, as has the entry of other communications media, such as cable TV and the Internet, into telecommunications service.

Figure 9.13.1 is a simplified schematic of a local network provided by an LEC. Each customer telephone connects to one, and only one, central office or exchange. Failure in any CO or the cables linking COs isolates all customers or services on one side of the failure from those on the other.

Although lacking redundancy at the local subscriber level, this design is made in compliance with the overall network design criteria in the United States as directed by the Federal Communications Commission (FCC). The criteria are intended to provide universal service at a low price, not uninterrupted service. However, well-established telecommunications companies do provide redundancies in certain high-traffic routes, such as links between hub COs. Many customers also have the option of purchasing redundant local services.

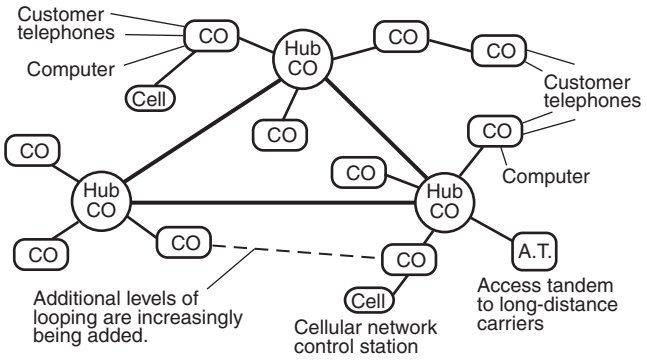

FIGURE 9.13.1 Typical Configuration of a Local Telecommunications Network

Paths between the end user, or customer, and the CO are generally composed of twisted-pair copper wires bundled into cables or from a cellular wireless network. In some cases, radio, coaxial copper, or fiber optic cable may be provided for groups of customers or certain large customers. Paths connecting various COs to one another may be composed of copper or fiber optic cables, or of microwave radio, depending on local conditions and terrain.

Figure 9.13.2 is a simplified diagram of a typical IEC network configuration. Some important differences exist between this diagram and Figure 9.13.1. Multiple paths between switching centers provide for redundant paths between points in the network in the event of a failure. The number and diversity of these paths are two key factors that predict reliability of a carrier's service. (Note that this discussion does not directly apply to "resellers" of either long-distance or local telecommunications

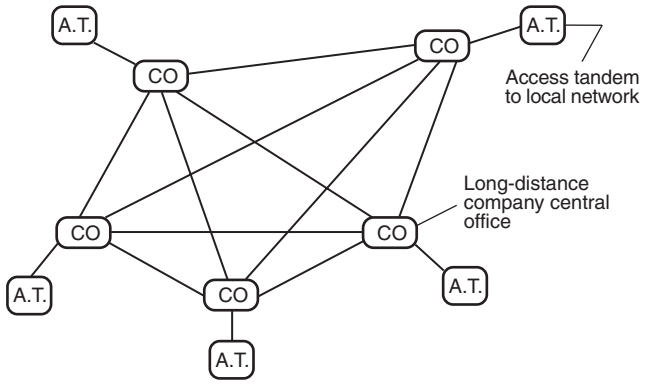

FIGURE 9.13.2 Architecture of a Typical Long-Distance Telephone Network

TABLE 9.13.1 U.S. Structure Fires in Telephone Exchanges or Central Offices

Year	*Total Fires*	*Fires with Telephone or Other Electronic Equipment as Equipment Involved in Ignition*	*Total Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
1980	132	5	0	0.40
1981	138	0	0	0.73
1982	117	4	8	0.75
1983	138	11	0	0.58
1984	79	5	10	0.07
1985	88	0	4	0.12
1986	86	3	0	0.19
1987	41	2	15	0.03
1988	73	7	2	0.78
1989	50	0	0	0.65
1990	58	5	2	0.37
1991	56	2	0	1.34
1992	75	9	0	0.32
1993	55	4	2	0.30
1994	44	0	0	0.35
1995	52	6	3	0.72
1996	37	4	0	0.40
1997	58	6	0	2.55
1998	37	0	0	0.05

Note: These are fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. Fires and civilian injuries are rounded to the nearest one, and direct property damage is rounded to the nearest ten thousand dollars. Damage has not been adjusted for inflation.

service. These companies purchase large blocks of time on the networks of telecommunications companies that own physical networks.)

Paths connecting the COs in Figure 9.13.2 are composed of various transmission technologies, depending on traffic loads, topography, prevailing weather, and redundancy requirements. They may include one or more of the following:

- Copper cable
- Fiber optic cable
- Microwave radio
- Satellite radio

Along each path, as well as those in the LEC networks, a number of repeater or regeneration stations amplify and retransmit signals. These stations compensate for signals' deterioration over distance.

FIRE RECORD

Structure fires reported to U.S. local fire departments in telephone exchanges and central offices have declined over the past several decades. In the mid- to late-1990s, the latest available study, about 40 to 50 incidents per year were reported (Table 9.13.1). Only a small fraction of these fires originate within the specialized telecommunication equipment. Most reported fires are very small in physical size and typically develop very slowly. The average direct property loss per fire tends to be lower than for most other industrial and business occupancies. This is due to the industry's practice of using fire-resistive equipment, wire, and cable that meet standards of the telecommunications industry. Table 9.13.2 summarizes the notable telecommunications fires from 1975 to 2006 and illustrates that they are few in number, considering the size and scope of the industry, and no loss of life has occurred in any

TABLE 9.13.2 Notable Central Office Fires in North America, 1975 to 2006

Incident	*Extent of Service Interruption*	*Area of Fire Origin*	*Occupant or Fire Fighter Loss of Life*
New York City, 1975	170,000 customers, several weeks	Cable vault	None
Brooklyn, NY, 1987	41,000 customers, service was restored to more than half within 10 days and the remainder within 16 days	Main distribution frame on first floor, smoke spread to fourth floor.	None
Hinsdale, IL, 1988	38,000 customers, about one third restored in 3 days, most service restored in 12 days	Cable tray containing ac and dc cables	None
Los Angeles, CA, 1994	9-1-1 service for 12 hours, normal service for 16 hours	Battery plant undergoing reconfiguration	None
Orangeburg, NY, 1994	14,000 customers, partial service restored in 26 hours	Obsolete transmission equipment	None
Idabel, OK, 1995	5000 lines, restored in 13 hours	dc power cable	None
Portland, OR, 1996	88,900 lines, 9-1-1 rerouted quickly, critical service restored in 9 hours, all service restored in 15 hours	Cables fire, loss of power to transmission equipment	None
Toronto, Ontario, 1999	113,000 lines for less than one day, reduction in available 9-1-1 lines	ac electrical switch gear undergoing reconfiguration	None

of them. The telecommunications industry in the United States has never recorded a loss of life due to fire. However, because the density of valuable, vulnerable property and the services provided are unusually high in such facilities, many of the facilities are considered to be critical by the service providers on the basis of customers served or the commercial value of the services provided.

A special study on the fire history of the telecommunications industry was done for the FCC in 1992 and 1993.[1] This study surveyed local exchange and interexchange service providers in the United States, major telecommunications equipment manufacturers, and many other sources, representing more than 93 percent of the telephone lines in the nation. The study covered the fire record for the years 1988 to 1992.

During the study period, a total of 189 fire events were reported by responders to telecommunications facilities. On average, there were 38 incidents per year; only 8 affected service. Effects on service ranged from several minutes to one instance of several weeks of service outage. The study included an exhaustive root cause analysis and made recommendations to prevent recurrence.

Considering the millions of square feet of space included in telecommunications facilities, the cited studies demonstrate an exceptionally good fire record due, in large part, to exhaustive fire prevention efforts by the industry. The studies do not show one significant fact: even "large" telecommunications fires are rather small in comparison to large fires in most other industries. Quantities of materials burned, area of burn damage, and so on have been very small. Even the most significant telecommunications fire in recent history, the Hinsdale, Illinois, fire of May 1988, which burned for over 3 hours, was confined to cable trays in a 30 ft by 40 ft (9 m by 12 m) area.[2] Although small by most measures, the impact of these fires on the community can be quite large.

CENTRAL OFFICE

The nodes in each of the networks illustrated in Figures 9.13.1 and 9.13.2 are telephone exchanges located in buildings called central offices (COs) or smaller enclosures not classified as buildings. Designed and sized to meet customers' service needs, COs range in size from small, single-story buildings to large multistory buildings in large cities. Despite size differences, the equipment layout and function are similar. Figure 9.13.3 shows typical components of a CO. In smaller buildings, all these components may be in a single room. In large COs, each component may use one or more floors of a building.

Most major metropolitan central office buildings are constructed of reinforced concrete with rather massive structural elements. Older (pre-1980) suburban and rural central offices are generally of fire-resistive construction. In addition to loss prevention incentives for this type of construction, the buildings need to be strong enough to support the large masses of heavy copper cable the network requires. Although changes in equipment technology somewhat diminish cabling needs, the massive structural elements remain in older buildings. Central offices and other telecommunications facilities constructed since the advent of competition in the telecommunications industry have generally been constructed in accordance with applicable building codes, and may not be in excess of those codes, as had been prior industry practice.

Ceilings in traditional COs are generally much higher than those in commercial buildings. Typical slab-to-slab heights in

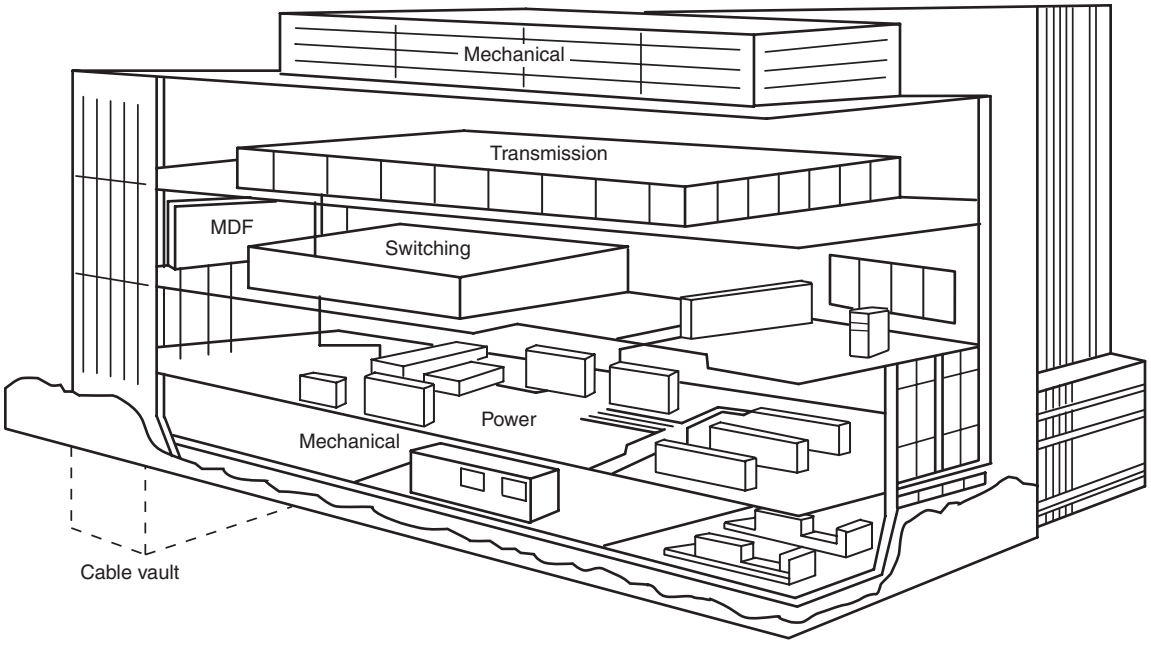

FIGURE 9.13.3 Typical Central Office Components

central offices are 14 to 16 ft (4.3 to 4.9 m). Few ceilings are dropped or suspended in the equipment areas so vertical space remains unobstructed. Clear space was necessary to accommodate 11 ft (3.5 m) equipment frames commonly used when the buildings were constructed, together with required cable racks, air-conditioning ducts, and other service equipment located above them.

CO buildings and other enclosures built more recently may have lower ceiling heights because more recently designed telecommunications equipment requires less vertical space. Newer facilities, or updated equipment areas of older facilities, may also use raised floors for cable connections between equipment cabinets. In general, telecommunications switch areas with raised floors contain less cable than do traditional switch areas due to the uses of fiber optics and newer data compression transmission techniques.

Cables enter and leave most COs through the cable vault, where they split into smaller, more fire-resistant cables for distribution in the building. Cables then rise through the building to the main distributing frame (MDF) where they break into individual pairs of wire for each circuit and cross connect to cables leading to the switching systems. After switching, signals pass to the transmission systems, which multiplex and boost the signals. After this is accomplished, the signal travels back out of the building through the cable vault on other cables. In some network switching facilities, the incoming and outgoing paths are solely fiber optic cables or wireless links, but the switching function is performed as for the copper cable COs.

In addition to standby generators, battery systems, and associated power control and distribution equipment, a variety of standard mechanical and building service systems support the telecommunications equipment (Figure 9.13.4).

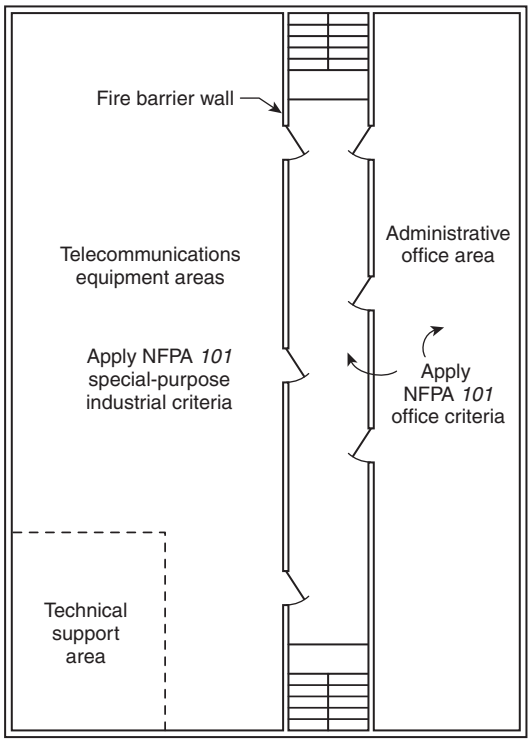

FIGURE 9.13.4 Example of the Application of NFPA *101*® to Telecommunications Equipment Areas and an Administrative Office Area (Source: NFPA 76, *Standard for the Fire Protection of Telecommunications Facilities,* Figure A.5.3.1, 2005, p. 76-28)

TELECOMMUNICATIONS EQUIPMENT

Description

Telecommunications equipment is fairly standardized in both function and appearance. It is arranged in parallel rows, or "lineups," 19 to 26 in. (48 to 66 cm) wide. The latest generations of digital electronic equipment generally range from 6 to 7 ft (1.83 to 2.14 m) in height.

Earlier generations of equipment were mounted in open frames without enclosures. This setup allowed easy access for maintenance and permitted heat dissipation by natural convection. Modern equipment is often enclosed in metal cabinets and looks much like ordinary computers. This arrangement, combined with miniaturization of equipment and attendant higher energy densities, requires forced ventilation (internal fans and extensive room air-conditioning systems) to dissipate heat generated during operation.

Providing for heat dissipation is important because the equipment is sensitive to temperature and humidity changes in the operating environment. Although absolute operating limits are rather wide, rapid changes of either a few degrees of temperature or a few percentage points of humidity can cause serious problems. Consequently, extensive environmental controls are used to ensure that ambient conditions remain within required limits.

Differences from Standard Computers

On first examination, modern digital telecommunications equipment resembles modern computers or data processing equipment. Although there are similarities, a number of important differences exist. Some were deliberately created to reduce the incidence, or effect, of potential loss-causing events. Other differences, necessitated by various technical requirements, have the opposite effect. Some of these differences present challenges that most traditional commercial loss prevention measures cannot adequately mitigate. As a result, telecommunications facilities must be analyzed on their own merits and characteristics.

One of the most significant differences is the type of information processing performed. Telecommunications systems are on-line information exchange systems. The telecommunications system does not store or process customer data; it merely transfers data from point A to point B. In a disruption, all information in transit is lost, and the ability to transmit information ceases. Data cannot be reloaded as long as the disruption continues, and missed opportunities cannot be made up. It is this ability to transmit information in real time that makes telecommunications so important. Many transactions routinely conducted over the network simply cannot wait until later.

In contrast, data processing systems generally process information stored in the system's memory subsystems. In a disruption, current memory may be lost, along with any calculation

results that have not been placed in permanent memory. However, all stored information remains in storage media. Interrupted, lost, or incomplete calculations can usually be reproduced after correcting the cause of disruption.

Another important difference between telecommunications equipment and data processing equipment is their power supplies. Data processing equipment is supplied with ac power to the cabinet. The ac to dc conversion takes place within the equipment, which generally operates at 5 to 10 V dc. On the other hand, dc power supplies telecommunications equipment. Conversion from commercial ac power to dc power takes place outside the equipment, often in a different building compartment. The power plant supplies the equipment with 12, 24, 48, or 130 V dc, depending on system requirements. Whereas emergency power off (EPO) switches may be appropriate for certain configurations of electronic data processing systems, such readily available means to kill power to telecommunications equipment would cause an abrupt end to 9-1-1 and other critical community-oriented emergency services. Therefore, the telecommunications industry avoids the use of EPO switches and NFPA 76, *Standard for the Fire Protection of Telecommunications Facilities,* provides an alternative condition-decision-based approach to use normal electrical disconnect means (Figure 9.13.5).

Another important difference lies in the redundancies usually provided for telecommunications equipment. In most networks, for instance, equipment operating in a duplex configuration performs all switching and call routing functions. This means that two separate processors simultaneously handle each call. In the unlikely event that one processor fails, the other continues to process the call, without interrupting the customer. In fact, the customer is unaware that the event occurred.

The final difference, which significantly impacts loss prevention, is the control programs' size. Programs that control various networks are among the largest and most complex. Programs involving millions of lines of program code are not uncommon. Their size naturally requires much more time to reload and initialize in the event of a disruption than common data processing programs. This requirement is one reason why it can take many hours to restart an electronic switching system in the event of a power loss. The thermal shock created by suddenly restoring power to the entire system is another.

Telecommunications equipment provided for use on a customer's premises, known as private branch exchange (PBX) equipment, differs in many respects from equipment used in COs. Major differences that impact a loss prevention program are discussed later in this chapter.

FIRE PROTECTION FOR THE PUBLIC NETWORK

Performance-Based and Prescriptive Solutions

NFPA 76 contains both a performance-based facility design method and a prescriptive method for protection of the network and life safety. NFPA 76 provides reasonable levels of fire protection for safety to life and to protect telecommunications equipment and service continuity. (See the Purpose section in NFPA 76.)

The Society of Fire Protection Engineers (SFPE) has developed *Engineering Guide to Performance-Based Fire Protection Analysis and Design.* NFPA 76 follows the SFPE format in its performance-based method.

The reasons for choosing a performance-based document type included the following:

- Many telecommunications service providers had previously existing company standards for fire safety, and the performance-based approach permits facility operators and designers to reconcile previously existing standards to the objectives and requirements of NFPA 76.
- Potentially more important, the performance-based approach can respond to the dynamic state of change currently occurring in the design of telecommunications switching and transport equipment and media, and the buildings and other structures that shelter and support that equipment.

On one hand, the prescriptive requirements found in NFPA 76 are a compilation of best practices of the industry for traditional telecommunications facilities and are directly applicable to many configurations of new telecommunications facilities. On the other hand, the performance-based objectives and guidance apply to all currently conceived telecommunications media and facilities. With new facility configurations and equipment types evolving rapidly, the performance-based approach may be more applicable to the new facility types that continue to emerge.

Traditional telecommunications industry practices for fire safety have been largely based on a chain of necessary actions and elements. Any missing action or element breaks the chain and increases the fire risk. The successful chain includes the following:

- Excellent fire prevention practices
- Noncombustible construction
- Compartmentalization
- Fire resistance–rated equipment
- Fire resistance–rated cable
- Very early warning fire detection
- Rigorous alarm processing and notification
- Rapid response by knowledgeable personnel
- Fire suppression, when needed
- Power interruption, when needed
- Smoke ventilation, when needed

The prescriptive solutions found in NFPA 76 are based on maintaining this chain unbroken for the life of a telecommunications facility. The prescriptive solutions are based on the widespread use of fire resistance–rated telecommunications equipment and cables.

For electronic equipment areas in which the predominant equipment and cable is not fire resistance rated, the chain is broken. An alternative strategy is required, generally including automatic suppression systems. Much of the industry relies on automatic suppression systems as part of its network fire protection practices.

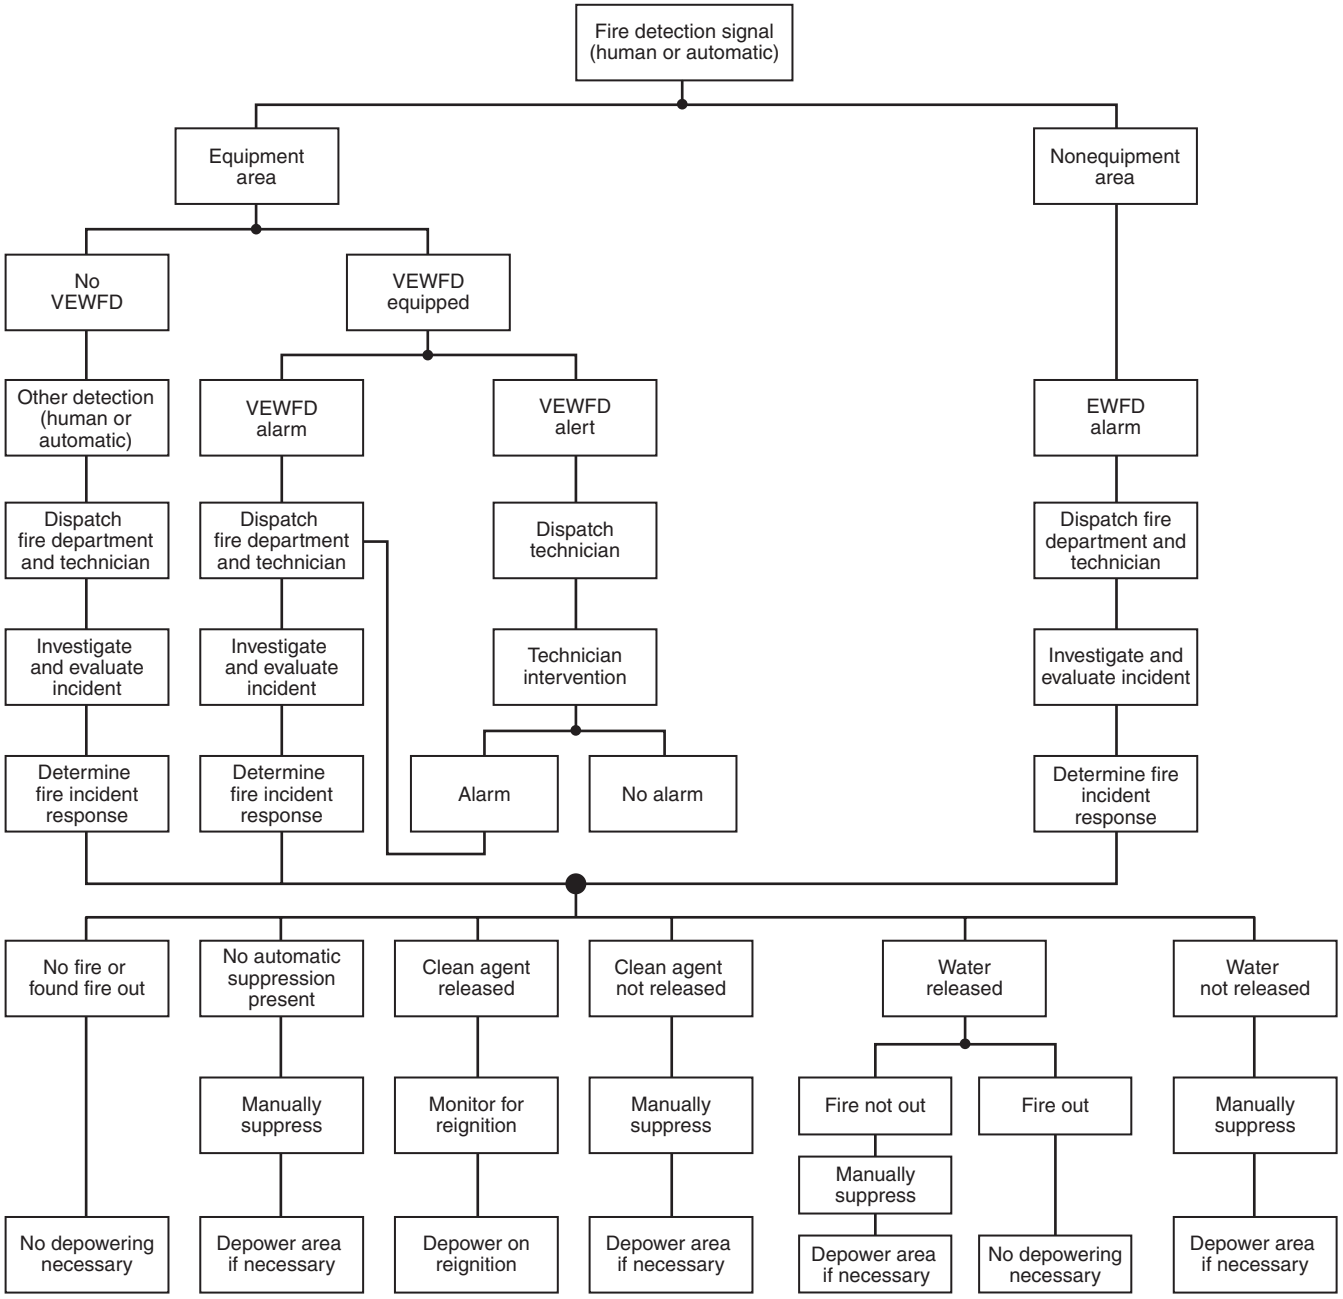

FIGURE 9.13.5 Depowering Decision Tree (Source: NFPA 76, *Standard for the Fire Protection of Telecommunications Facilities,* Figure A.6.5.1, 2005, p. 76-34)

Fire Risk Factors

Risk refers to the *probability* and *severity* of harmful events. Risk factors to consider when developing a fire safety program for telecommunications facilities include the following:

- Community served
- Public safety services
- Life safety of occupants and fire fighters
- Continuity of service
- Types of services provided
- Redundancy of facilities or services
- Property protection

Service providers make decisions on protection levels of facilities based on these risk factors, which are motivated by societal and commercial assessments of the criticality of various facilities. For instance, a switching facility that serves a major medical complex may be considered to be more critical than one that serves a small town. Although decisions of criticality are commercial and societal in nature, those decisions of criticality result in subsequent decisions on the extent to

which network redundancies and protective measures may be applied.

The goal of minimizing service interruption in emergency communications, national security information, commercial data, and voice telecommunications is the same regardless of the approach or solution chosen. Criticality is the only valid modifier.

For its prescriptive solutions, NFPA 76 approximates criticality by facility size—an imperfect approximation. The presumption is that the telecommunications flow rate is greater in larger facilities and, therefore, is more likely to contain critical data or voice communications. So the recommended fire protection measures are greater for large facilities than for small facilities.

Large facilities are defined as those having greater than 2500 ft^2 (232 m^2) of enclosed network equipment area. Small facilities are defined as those having less than 2500 ft^2 (232 m^2) of enclosed network equipment area.

When taking the performance-based approach to protecting the telecommunications network from fire, measures of criticality other than size of equipment area are more appropriate. For any given facility, or portion of a larger facility, these measures include knowledge of the community served, services provided, network redundancy, likely recovery time in the event of fire, available methods of recovery, business interruption costs, and any other factors that may determine the criticality of the facility.

The miniaturization that is occurring in telecommunications switching equipment and the differing network configurations that are emerging dictate that performance-based solutions consider all risk factors. Size of facility is not important in a performance-based analysis. It is the characteristics of the network and services provided that matter.

When the performance-based approach is applied rigorously to network facilities, one may expect a superior result compared to a prescriptive solution that is determined by facility size.

Hazard Areas

Telecommunications facilities, within buildings or other enclosures, can be categorized into one or more of eight types of areas, each with its own fire hazard characteristics (Table 9.13.3). The hazard types are the same whether a performance-based or prescriptive solution is chosen to determine a fire safety program.

Where an area combines more than one hazard area type in a single compartment or enclosure, the entire combined area should be treated as the most demanding of its subareas for protection of the network, occupants, and fire fighters.

PRIVATE TELECOMMUNICATIONS EQUIPMENT

Equipment provided by public telecommunications companies terminates at a network interface on the customer's property. The customer is responsible for providing all on-site telephone equipment and wiring. Customers accomplish this in a variety of ways. Commonly, they purchase and maintain their own telecommunications system, lease the equipment from either a telephone company or a third-party vendor, or contract with the local telephone company for a central office based service. Numerous other possibilities exist.

Large commercial or business occupancies typically have large telecommunications systems; some are more complex than those provided for whole towns. These systems can provide a wide array of voice, data, and video information to their users. Usually, they are controlled by private branch exchange (PBX) equipment located in the building or complex.

At first glance, modern PBX equipment appears to be very similar in design to modern central office equipment. PBX equipment performs many functions that CO equipment does but only for the building or complex it serves.

From a fire protection viewpoint, three significant differences exist between CO and PBX equipment:

1. The most important difference is that PBX equipment does not have to conform to the very rigorous fire resistance rating standards that apply to CO equipment. Listed by independent agencies, PBX equipment does meet a variety of other tests, including flammability tests, required to achieve that listing. The implications of this are discussed below.
2. Replacement PBX equipment is more readily available than replacement CO equipment. This allows more flexibility in making risk management decision in some instances.
3. PBX systems are usually easier to turn off than CO equipment. PBX power supplies often have redundancies similar to those of the CO, but the systems are smaller and less complex. In some cases, a switch or circuit breaker can be used to power down the equipment in the event of an emergency.

Protection Fundamentals for PBX Equipment

Most protection measures indicated for central offices are appropriate for PBX equipment as well. In general, the PBX should be protected in the same fashion as an important computer room. Several elements, as follow, are worthy of special note:

1. The equipment should be located in a room separated from the rest of the building by at least a 1 hour rated fire barrier.
2. Access to the room should be limited to authorized persons.
3. Good fire prevention and housekeeping measures should be in place at all times. Storage of combustible materials in the room should be strictly prohibited.
4. The room should be equipped with a smoke detection system that alarms at a constantly attended location.
5. Power shutdown procedures should be developed and made available for responding fire fighters to use.

Automatic Suppression

Exceptions found in most building codes that allow a central office to omit automatic suppression systems in equipment areas do not apply to PBX equipment or to telephone closets in commercial buildings. Those exemptions are based in part on fire

TABLE 9.13.3 Range of Hazard Areas in Telecommunications Facilities

Area	*Contents*	*Fire Scenarios*	*Assumptions*
Signal processing equipment area	Electronic equipment in racks or cabinets with cables in racks or under a raised floor	Slowly developing smoky fire producing corrosive vapors with heat release rates of typically 5 to 15 kW that do not exceed 150 kW for a fully involved cabinet or rack	Electronic equipment and cable meet U.S. or Canadian standards of the industry for fire resistance rating.
Cable entrance facility—separated by construction from other areas	Cables having no fire resistance rating entering the building from outside; spliced to rated cables	High or low heat release rate fires. Corrosivity of the products of combustion can affect electronic equipment if the products spread to those areas.	Cables that extend to other parts of the building are fire resistance–rated cables.
Power areas	Batteries on racks, rectifiers, switchgear, buss bars, and cables	Low heat release rate fire. Some may produce corrosive vapors. Some may result in acid spill.	Thermal effects of fire are limited to the items involved.
Main distribution frame area	Large amounts of low voltage communications wire	Low to medium heat release rate smoky fires. Corrosivity of the products of combustion can affect electronic equipment if the products spread to those areas.	The frame contains no inherent ignition sources. Other ignition sources are strictly controlled.
Standby engine area—separated by construction from other areas	Generator powered by an internal combustion engine with fuel day tank and starting batteries	Fire history of these areas indicates more electrical fires than fuel fires, but either is possible.	Major fuel storage is not in the same enclosed space. Means of fuel shutoff is available.
Technical support areas—contained within the tele-communications equipment areas	Metal desks, cabinets, tools, and equipment used by technicians in direct support of technical operations	Combustibles are present in small quantities and are stored in metal containers. Fires are typical of the telecommunications equipment areas. Exceptions may be when staging new equipment installations increases risk.	Technical support areas do not contain the quantity of combustible material typical of an administrative office area.
Administrative area	Normal commercial office furniture and equipment	Fires typical of commercial offices	Meets building code requirements for a business occupancy
Building services and support areas	Mechanical and maintenance equipment and storage as required for building operations	Fires typical of well-maintained commercial office building support areas	Combustibles are stored and handled subject to accepted fire prevention practices. Meets building code

prevention practices described earlier in this chapter and are not fully used in PBX equipment.

If code requires a building to be equipped with an automatic suppression system, the system should be provided in the PBX room. An appropriate system should be selected with a clear understanding of risks involved and advantages that each candidate system offers. The system may be omitted if the local authority having jurisdiction (AHJ) grants a variance or exemption. The system's owners may decide to install additional fire protection features to enhance the reliability of their system, because building code requirements do not address business interruption concerns. Such additional features might include very early fire warning detection systems or gaseous agent suppression systems.

A GLIMPSE OF THE FUTURE

A summary of current technology cannot be complete without drawing the separation of quite different segments of the emerging successors to the more traditional telecommunications network.

Consider three separate uses of computer-based equipment used to support today's electronic information systems. For simplicity, they can be described as the following:

- Telecommunications switching and transport equipment
- Internet server and router equipment
- Data processing computers

This chapter does not cover data processing computers.

We cannot predict the future, but we can observe current developments and trends. In electronic information distribution, the traditional telecommunications methods of switching and transport are being supplemented by new server and router configurations that may not be equivalent in equipment fire resistance or network redundancy and may be housed in buildings of less traditional design.

Trends are apparent that may change the fire risk and, therefore, the fire protection methods needed for telecommunications facilities that are affected by these changes.

Internet service providers rely on the telecommunications network for data transport. In addition, Internet switching and transport services are also provided by new types of facilities that may be small, large, or very large and may be very different from traditional telecommunications facilities. The operating equipment and cable that support these services may not have the fire resistance ratings of equipment used in traditional telecommunications services, and installation and maintenance standards may not be equivalent. Although the data communications services provided may also be quite different, mergers of these two forms of electronic data communications are taking place. Fire protection decisions for newer facility types should be based on assessments of criticality, similar to more traditional telecommunications facilities, and also on an assessment of the hazards present, construction of the facility, configuration of the building contents, and differences from the types of facilities that have proven successful in the past.

It may be anticipated that some buyers of Internet servers and routers will require that the equipment be designed and manufactured in accordance with the same fire-resistive rating standards as telephone switching equipment and they may install fire resistance–rated cables. This reinforces the need to become familiar with the contents of equipment areas as a necessary part of assessing the fire risk and determining fire protection methods for the hazard areas.

It is advantageous to locate Internet and private intranet servers and routers in close proximity to standard telecommunications switching equipment for direct access to the telecommunications network. The result is that Internet and private intranet equipment may be collocated in the same buildings as telecommunications network equipment. Where this occurs, the fire risk assessment should consider both types of equipment, separations between them, and fire resistance ratings of the equipment types.

Two current examples that can be cited of such combinations of equipment arranged to meet the requirements of NFPA 76. In one, the Internet server and router equipment and cables are required to meet the same fire resistance ratings as the telecommunications equipment and cables. In the other example, nonfire resistance–rated equipment is located in separate fire-resistive compartments within the building and those compartments are protected by automatic suppression systems.

FIRE DEPARTMENT CONCERNS

Despite the prevention measures many telecommunications companies take, fires still occur. Although these fires have historically been small in relation to fires in other industries, fire fighters face some clear differences when responding to such a fire.

Smoke Control

Fires in telecommunications equipment can produce very large quantities of dense, corrosive smoke. Visibility may become nearly impossible, even with handheld lamps. When combined with unfamiliar building configurations, the prospect for disorientation is clear. Appropriate precautions must be planned in advance. Fire departments should consider requesting that the owner install manual smoke exhaust systems, which differ from smoke control systems, to assist in fire control efforts. The portable smoke extractors or smoke fans that fire departments carry are inadequate to handle the large quantities of smoke the fires can generate. Even 10 to 12 smoke fans may be inadequate. Smoke exhaust systems have been proven highly effective in at least one actual telecommunications fire incident.[3–5]

Power Cables

A fire involving cables may involve power cables. It is critical that responding fire fighters be familiar with the power disconnect procedures established by the owner. If the owner does not provide such a plan, fire departments should demand one. The state of Illinois, site of the Hinsdale fire in 1988, requires a power shutdown plan for every telecommunications facility. This requirement is not something new, and there are established procedures for developing these plans. NFPA 76 recommends that a means to disconnect power from equipment be developed for every facility. The means is not intended to be automatic nor readily available. It is intended to be used by knowledgeable telecommunications provider personnel or fire service personnel and may require operation of electrical switchgear or overcurrent protective equipment.

Batteries and Electrical Power

Two physical hazards are present in telecommunications facilities that are not present in the same degree extent in other occupancies: large batteries and electrical power. Both are generally well engineered and maintained; neither presents extraordinary dangers in comparison to other dangers fire fighters commonly encounter. Responding personnel must be aware of these hazards and must be familiar with appropriate safety precautions before entering a smoke-filled telecommunications facility.

These issues are not insurmountable. Most telecommunications companies are happy to provide tours to familiarize fire departments with their facilities. It is important that these be done, if for no other reason than fire fighter safety.

APPLICATION BEYOND THE UNITED STATES AND CANADA

The information and guidance contained in this chapter is based on the fire experience and "best practices" for fire protection for the telecommunications industry in the United States and Canada. The recommendations of NFPA 76 are based on the same experience and practices.

Users who may be considering using this chapter or NFPA 76 to protect network equipment or facilities outside of the United States or Canada or for protection of equipment other than telecommunications equipment should first assess the fire-related characteristics of the equipment and facility to be protected.

Fire protection for equipment and facilities that do not include the equipment and cable fire resistance, the facility fire prevention practices, or fast response to fire detection signals would be more challenging. Additional measures beyond the prescriptive recommendations of NFPA 76 would be required for network protection. A performance-based analysis would be required.

SUMMARY

Methods and precautions discussed in this chapter and NFPA 76 provide a sound, proven basis for fire risk management for telecommunications equipment and services. Like any loss prevention program, the fire risk management program for telecommunications networks and equipment must be ongoing. There will be many changes both in the technology employed in the equipment and in the uses of telecommunications services as the future unfolds.

Many changes envisioned today will serve to increase redundancy in networks, thereby decreasing overall risk to network service continuity. Other changes may increase the net level of risk and present unique new challenges for risk managers. Risks must be evaluated systematically, so that effective risk reduction measures that truly reduce overall fire and network failure risk levels can be implemented.

Key Terms

boiler, coal fuel, conveyor, electric generating plant, electrical cable, flue, Powder River Basin (PRB) coal, transformer, turbine, water supply, wind energy

The purpose of this chapter is to help the reader achieve a well-developed fire safety program tailored to the needs of an electric generating plant. This chapter offers guidance on how to develop a program that addresses life safety, continuity of operations, and property protection for individuals who are responsible for the design, construction, operation, and protection of electric generating plants that are fueled by fossil fuels, alternative fuels, and hydroelectric plants.

The process of producing and delivering electrical energy to customers includes three distinctive elements: generation, transmission, and distribution. This chapter addresses fire protection for generation of electricity from a variety of fuels. One section discusses high-voltage direct current converter stations. Section 9, Chapter 15, "Nuclear Facilities," discusses some unique fire protection challenges of nuclear fueled generation. Note that many hazards and fire protection concepts discussed in this chapter may apply to all means of electric generation, including nuclear. Other methods of generating electrical energy are described in Section 8, Chapter 10, "Stationary Combustion Engines and Fuel Cells."

For related topics see Section 7, Chapter 1, "Storage and Handling of Solid Fuels"; Section 8, Chapter 10, "Stationary Combustion Engines and Fuel Cells"; Section 9, Chapter 15, "Nuclear Facilities"; and Section 10, Chapter 6, "Boiler Furnaces."

GENERAL INDUSTRY OVERVIEW

Today's society increasingly relies on the socioeconomic benefits of electric energy for residential, commercial, and industrial applications. Over the years, in our everyday lives our dependence on electrically powered labor-saving devices has escalated. In 1999, the average annual U.S. consumption was about 13,833 kWh per person. By 2004 consumption rose to 26,068 kWh per person.[1] According to the Energy Information Administration, electricity demand is expected to increase by 2.5 percent in 2006 and 1.9 percent in 2007.[1] In the future, consumption is expected to continue to rise. Industry has turned toward electrification in new ways to increase efficiency and control costs in a highly competitive global marketplace. Electrification of developing countries is an important goal in improving the standard of living and attracting investment in these countries.

The availability and reliability of the electrical supply impacts our lives in many ways. These include safety, security, and the creation of employment opportunities. Certainly, today's information-hungry, service-oriented, and computer-oriented society could not function without an adequate and reliable electrical supply.

Over 16,000 electric generating units operate in the United States.[2] Over the years the generation industry has scaled up. In the 1920s units had a capacity of about 20 MW; plants designed in the last two decades have capacities over 1000 MW. Capacity expanded most rapidly in the 1950s and 1960s as technological advancements enabled production of larger and more efficient turbines, generators, boilers, transformers, and so on, with accompanying lower capital, operating,

Daniel J. Sheridan, P.E., is a principal member of the NFPA Technical Committee on Electric Generating Plants and a former member of the Technical Committee on Nuclear Facilities. He is the president of Sheridan Engineering, Inc., of Saugatuck, Michigan, specializing in fire protection engineering for the power industry. He is also a principal of Sheridan Fire Equipment, Inc., an authorized distributor of *Protectowire Fire Systems* and other fire protection equipment.

and maintenance costs per megawatt. An electric generating plant is capital intensive, with the cost spread over its 40 to 50 year life.

The increase in energy prices in the early 1970s changed the economic structure of the utility industry. Driven by inflation, regulation, and environmental concern, the cost of building electric generating units began to escalate rapidly. Rising costs undermined traditional economies of scale, requiring optimization of plant size and configuration to control costs. Therefore, many recently constructed electric generating plants are smaller than those constructed from the 1960s to the 1980s.

The U.S. electric utility industry is changing profoundly as it heads toward deregulation. Changes began with the passage of the Public Utility Regulatory Policies Act of 1978 (PURPA), which created a new class of preferred power producers. The act intended to encourage alternative sources of electric generation. As a result, a host of newly formed entrepreneurial enterprises erected electric generating plants to compete with traditional utilities that were required to purchase their electrical output. These new nonutility generators became known as independent power producers. In 1979 independent power producers generated 3 percent of U.S. power, increasing to 34 percent in 2005.[2] In the future, independent power producers will construct a considerable portion of the new capacity; traditional utilities will construct the balance.

Increasing competition among electric producers in future years will elevate reliability issues in the eyes of stakeholders. Avoiding forced outages will become more important in a deregulated environment. Good fire protection practice for electric generating plants will contribute to reliability, operator safety, and protection of physical assets.

In its most basic form, a fossil fuel electric generating plant converts fuel to produce steam that spins a generator to produce electrical energy. A hydroelectric plant uses kinetic energy to spin a generator for similar purposes. In 2005 the means used to produce electric energy in the United States were coal (49.7 percent), natural gas (18.7 percent), nuclear (19.3 percent), hydro (6.5 percent), and other fuels (5.8 percent) including petroleum, geothermal, wood, waste, wind, and solar.[3] This chapter addresses the fire-related hazards for each fuel, as well as hazards unique to electric generating plants.

MANAGEMENT POLICY AND DIRECTION

Best practice guidance is available in NFPA 850, *Recommended Practice for Fire Protection for Electric Generating Plants and High Voltage Direct Current Converter Stations,* and NFPA 851, *Recommended Practice for Fire Protection for Hydroelectric Generating Plants.* These documents provide information on the design, construction, operation, and protection of various types of electric generating plants. In addition, NFPA 853, *Standard for the Installation of Stationary Fuel Cell Power Systems,* first issued in 2000, covers stationary fuel cell installations of all sizes.

A key element in a well-protected plant is for management to establish a policy and follow through on a program to protect lives, conserve property, and ensure continuity of operations. For an operating electric generating plant this includes a written plant fire prevention program (i.e., control of combustibles, housekeeping, hot work controls, etc.); a fire emergency plan; testing, inspection, and maintenance programs; and related policies and procedures. When an electric generating plant is being designed or is undergoing changes, a fire risk evaluation should be initiated to ensure that all fire hazards are identified and appropriate strategies are established to cope with these hazards. The fire risk evaluation should address the fire prevention and fire protection concepts offered in NFPA 850 and NFPA 851.

Management's decision on the establishment of a plant fire brigade should be made after considering a number of variables, including requirements specified by the U.S. Occupational Safety and Health Administration (OSHA) in 29 CFR 1910.156. Some electric generating plants are located in areas remote from immediately available professional or volunteer fire departments. For these plants the establishment of a fire brigade may be necessary. The trend in the generating industry today is to reduce the size of the plant operating staff, which obviously affects the pool of qualified personnel who can perform fire brigade duties. Some smaller plants even operate unmanned or with as few as three people on a shift. (See NFPA 600, *Standard on Industrial Fire Brigades.*)

In all cases, a workable fire emergency plan needs to be developed. Fire fighters (plant fire brigade or local fire department) who are expected to respond to electric generating plant fires should be trained in the unique hazards that they could face.

GENERAL PLANT DESIGN

The "power block" typically houses the steam generator (boiler-furnace), turbine-generator, and auxiliary equipment. Electric generating plants are usually large open structures, perhaps several stories high (Figure 9.14.1). Building construction is typically of heavy structural steel frame with insulated metal panel walls in cold climates. In warm climates the structure may be open, including the turbine-generator operating floor. The power block for a combined cycle plant typically houses one

FIGURE 9.14.1 Typical Fossil-Fuel Electric Generating Units (Sherco, Courtesy of Xcel Energy)

or more combustion turbines, one or more heat recovery steam generators (HRSGs), a turbine-generator, and auxiliary equipment (Figure 9.14.2).

Some hydroelectric and pumped storage plants may be located the equivalent of several stories below grade in reinforced concrete and unprotected steel structures. Generators may be housed in a single undivided building or structure (Figure 9.14.3). As one might expect, newer technologies such as wind turbine-generators (Figure 9.14.4) and stationary fuel cell power plants have relatively smaller power blocks.

LIFE SAFETY

Life safety design is a critical component of the overall design of a new electric generating plant. In general, locally adopted codes govern life safety design for new construction; however, at a minimum the design should meet the requirements of NFPA *101*®, *Life Safety Code*®. NFPA 850 provides guidance for applying NFPA *101* requirements to specific areas of electric generating plants. Other standards impacting the design of new domestic electric generating plants are OSHA and the Americans with Disabilities Act (ADA). All design criteria should be approved by the authority having jurisdiction (AHJ), including identification of ADA "accessible" areas. These areas typically include administration and office areas not associated with plant operations.

Electric generating plants are unique structures due to the equipment arrangement required for their operation and maintenance. These equipment requirements often present challenges in designing for life safety and egress. Large enclosed boiler buildings can be up to 250 ft (76 m) high and typically consist of multiple grating levels providing access to equipment for maintenance, inspection, testing, and repairs. This arrangement requires a continuous vertical opening up the boiler and, in the event of fire, presents a potential smoke hazard to any personnel performing these operations.

In emergency situations, performance of emergency shutdown procedures often delays egress of control room personnel. Therefore, control facilities should have a means of egress separate from other plant areas. At many existing plants the control

FIGURE 9.14.2 Greater Des Moines Energy Center (Courtesy Bibb & Associates, Inc.)

FIGURE 9.14.3 Typical Generator Floor at a Hydroelectric Plant (Courtesy Sheridan Engineering, Inc.)

FIGURE 9.14.4 Wind Power Units (Courtesy Mike McPheeters Photography)

room's location is such that there is a heightened risk of exposure to smoke, heat, and fire, because it is too close to likely areas of fire origin, such as the turbine-generator. Adequate fire barriers and egress facilities are required. Fire can trap control room personnel, with lethal consequences, or block them so that escape is achieved only with difficulty.

NFPA 850 recommends special hazards protection in turbine-generator buildings and boiler buildings in lieu of a more restrictive philosophy of complete automatic sprinkler protection. In general, this philosophy is accepted as an equivalent to complete sprinkler protection, allowing extended travel distance, common path of travel, and dead-end limits in accordance with NFPA *101*. The AHJ should review and approve this interpretation before designing for life safety and egress.

Water Supplies

An adequate and reliable water supply should be provided. For many electric generating plants this is typically two independent supplies, each sized to meet the simultaneous demands of the hydraulically most demanding sprinkler system and 500 gal/min (1900 L/min) for hose streams for 2 hours. Older plants have combination service water-fire protection systems, while newer plants have dedicated fire protection water supplies and underground fire water delivery systems.

Site conditions dictate the supply source. Rivers, lakes, cooling tower basins, cooling lakes and ponds, suction tanks, and municipal water supplies have all been used successfully to meet fire protection needs. Open reservoir fresh (raw) water bodies may permit biological infestation and contribute to microbiological corrosion.

Fuel Hazards

Fuels used at an electric generating plant have unique hazards that the fire risk evaluation should address.

Coal. Today's coal-fired plants in the United States typically consume bituminous coal, sometimes called Eastern coal, and subbituminous coal, sometimes called Western coal or Powder River Basin (PRB) coal. Lignite is another type of coal available in certain geographic areas. For environmental reasons many electric generating plants burn lower sulfur coals. The need for compliance with more stringent emissions standards, the rising cost of natural gas, and enhanced rail system routes have made low sulfur PRB coal a viable alternative for more and more Eastern plants. Coal's principal hazards are combustibility, spontaneous ignition, and propensity to create fugitive dust. These hazards are more prevalent in the low-sulfur, low-rack coals such as PRB and lignite. All should be carefully considered at the outset of any new project or coal conversion project.

Coal is transported by a variety of means and stored or "stacked out" in open coal yards. For economic reasons the trend is to limit storage to a 30 to 45 day supply, whereas in the past storage of over a 90 day or greater supply was common. Coal stored in open piles should be compacted to prevent spontaneous heating (Figure 9.14.5). Additional information on coal can be found in Section 7, Chapter 1, "Storage and Handling of Solid Fuels."

FIGURE 9.14.5 Spontaneous Heating in a PRB Coal Pile (Courtesy Sheridan Engineering, Inc.)

A coal-handling system moves the coal from the storage pile to the boiler-furnace where it is consumed to produce steam (Figure 9.14.6). The typical coal conveyor belt is combustible and can ignite from friction between the conveyor belt and the roller, belt slippage, or static electricity. Uncontrolled hot work can also cause fires in coal handling areas. Housekeeping and dust control are vitally important, especially with PRB coal where spontaneous heating of spillage and dust is more common. An automatic sprinkler system or water spray system is needed to protect areas above and below the conveyor belt (Figure 9.14.7). Fire-retardant conveyor belts are recommended, but they burn under certain circumstances and therefore cannot substitute for automatic sprinkler or water spray protection.

Electrical equipment in coal handling areas should meet NFPA 70, *National Electrical Code*®, criteria for Class II, Division 1 or 2, Group F occupancies. A postevent investigation attributed a severe explosion and fire to an improperly closed electrical panel at an electric generating plant in 1998. The re-

FIGURE 9.14.6 Coal-Handling System

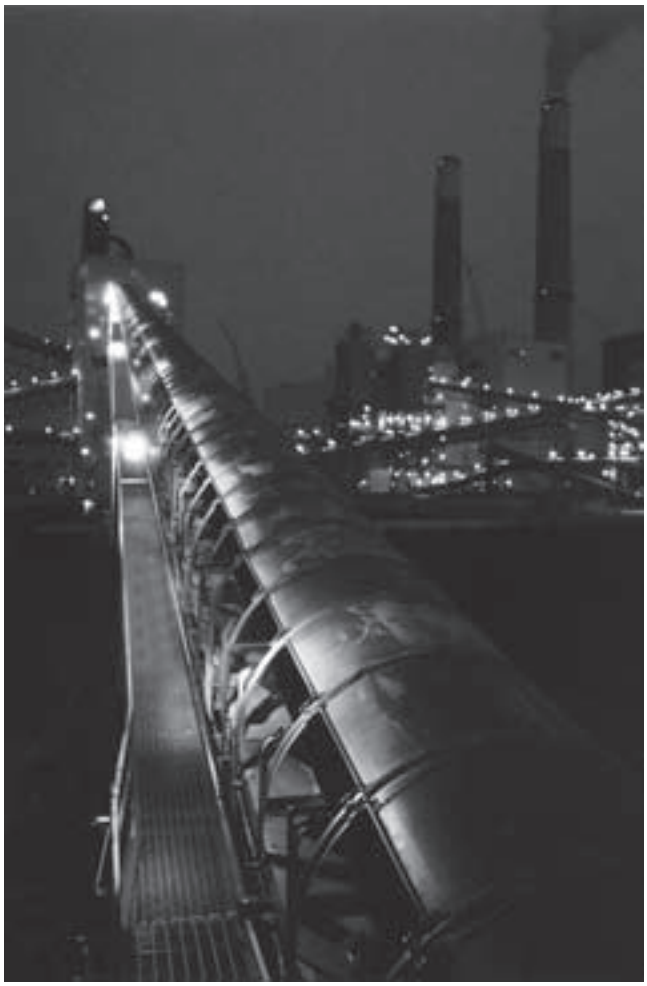

FIGURE 9.14.7 Coal Conveyor Protected with a Deluge Water Spray System (Courtesy F. E. Moran, Inc. Special Hazard Systems)

sult was 16 injuries, a 6 month plant outage, and $64.85 million in property damage (amount adjusted to 2007 U.S. dollars).[4] Crusher buildings, transfer buildings, and tripper areas (galleries) are all considered parts of the coal-handling system that require automatic sprinkler or water spray protection.

One of the largest coal-handling fires in the United States, identified in a 30 year study of large-loss fires, occurred in a crusher building because of a serious dust condition. An unknown ignition source caused an explosion that engulfed the unoccupied crusher house. The ensuing fire burned several thousand feet of conveyor belt, causing widespread damage. The result was several injuries, $35.42 million in property damage (amount adjusted to 2007 U.S. dollars), and a 4 month outage. There were no fixed automatic fire suppression systems.[4]

In-plant coal storage may be in silos (600 to 1000 tons [544.3 to 907.1 metric tonnes]) or bunkers (up to 5000 tons [4535.9 tonnes]). During plant outages the coal should be emptied to preclude spontaneous ignition. Coal fires can lead to explosions and injuries and are difficult to extinguish. These fires can last for several days or even weeks. NFPA 850 discusses various strategies to deal with these fires.

It is important to note that safe application of micelle encapsulating agents or other fire-fighting additives to burning coal requires proper planning, emergency procedures, and training. Baseline guides and procedures for preplanning and applying such agents to these fires are available from industry groups such as the PRB Coal Users' Group (http://www.prbcoals.com). These guides and procedures can be used as a *starting point* by the owner's structural fire brigade and local fire department to customize the approach for the specific facility. These fire-fighting activities are inherently dangerous and should not be performed by incipient fire brigades or other personnel. One newer strategy for extinguishment of PRB coal fires in silos and bunkers involves the use of thermal imaging cameras to locate the fire or hot spot and application of micelle encapsulator solutions via a piercing rod (Figures 9.14.8).

A pulverized coal system has significant explosion potential. See Electric Power Research Institute Project 1883-1, February 1987, *Prevention, Detection, and Control of Coal Pulverizer Fires and Explosions.* The fire protection features of these systems should be reviewed in detail if a plant desires to convert to a different type of coal. Pulverizers originally designed for eastern coal may not have OEM fire protection systems. The need for retrofit fire protection systems should be carefully considered in such cases. In an effort to lower emissions from levels associated with standard pulverized coal plants, the industry is exploring integrated gasification combined cycle (IGCC) plant designs. These plants use a gasifier to convert coal or other solid fuel to a cleaner-burning gaseous fuel. The main hazards are similar to those found in the fuel-handling areas of standard pulverized coal plants. The next edition of NFPA 850 will include recommendations for this emerging technology.

Natural Gas. Beginning in the 1980s and continuing through the early years of the new millennium, natural gas has become

FIGURE 9.14.8 Piercing Rod Components (Courtesy Hazard Control Technologies, Inc.)

the fuel of choice for much of the electric generating capacity that has or will come online. This is particularly true for combustion turbines operating in either simple-cycle or combined-cycle configurations. The gas supply piping system should be designed, installed, and maintained in accordance with NFPA 54, *National Fuel Gas Code,* and NFPA 58, *Liquefied Petroleum Gas Code.*

Oil. Very little oil-fired capacity is being added to the U.S. generation mix for economic reasons. A number of areas in the United States continue to depend on oil-fired capacity—particularly on the West and East coasts. Also note that many coal-fired plants use oil for ignition. NFPA 30, *Flammable and Combustible Liquids Code,* and NFPA 31, *Standard for the Installation of Oil-Burning Equipment,* should be followed.

Fuel oil is often heated before it is pumped to the boiler burner tip. Heating equipment may be installed inside the power block. Pipe failure and human error can result in fires involving pumping and heating equipment that expose vital equipment. NFPA 850 calls for automatic fire suppression systems to protect the hazard and a minimum 2 hour fire barrier to isolate it.

Alternative Fuels. NFPA 850 defines alternative fuels as refuse-derived fuel, municipal solid waste, and biomass. The latter includes wood chips, wood waste, rice hulls, and sugar cane stalks, among others. Each fuel presents a unique hazard and needs to be addressed as part of the fire risk evaluation. For additional information refer to Section 7, Chapter 1, "Storage and Handling of Solid Fuels."

Stationary Fuel Cell Plants. NFPA 853 addresses the unique hazards associated with fuel cells. Gas, oil, or other fuels can be used depending on the design (Figure 9.14.9).

Boiler-Furnaces

The steam generator or boiler-furnace presents a major exposure due to the potential for a firebox explosion. At the burner, an uneven or low fuel flow can result in loss of flame in a portion of the boiler. Continued introduction of fuel can result in accumulated raw fuel that another burner or hot surface can ignite. A database assembled by Marsh Risk Consulting indicates that these rare events can be very destructive. Between 1977 and 1996, eight explosions alone resulted in an average of $53.75 million in property damage per fire (amount adjusted to 2007 U.S. dollars), with forced outages at a rate of about one per year.[4] More recent explosions in the late 1990s may significantly increase the average property damage amount once cause and origin details are made available. Undoubtedly, there have been numerous "puffs" or explosions with relatively minor damage. The NFPA Technical Committee on Boiler Combustion System Hazards develops guidance on preventing explosions and implosions through properly controlling boiler operations. See NFPA 85, *Boiler and Combustion Systems Hazard Code.*

Burner front fires are a significant fire hazard associated with boiler-furnaces. These occur when oil inadvertently released from the fuel system or ignition system ignites on the hot surface of the boiler's exterior face. The oil pumping system feeds the fire, which may extend several stories on the boiler's entire vertical face. NFPA 850 recommends fire suppression systems to protect the fuel and ignition piping, and igniter and burner areas within a 20 ft (6.1 m) horizontal distance from the boiler face on all firing levels.

Flue Gas Treatment

Environmental requirements have become more stringent in an effort to control the release of sulfur dioxide, nitrogen oxide,

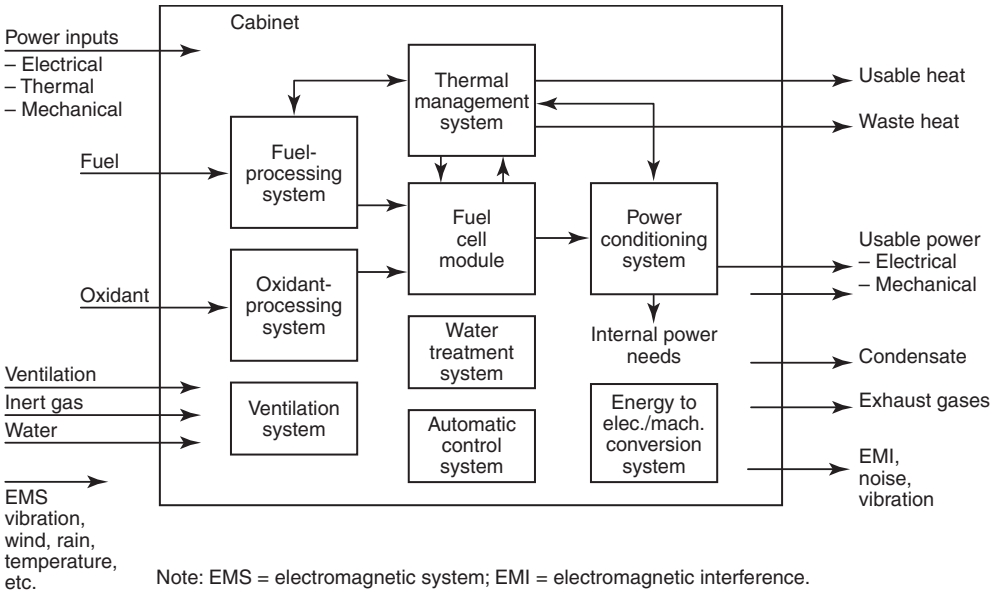

FIGURE 9.14.9 Typical Fuel Cell Power System (Source: NFPA 853, *Standard for the Installation of Stationary Fuel Cell Power Systems,* Figure B.1, 2007, p. 853-12)

and particulate matter—particularly from coal-fired plants. To deal with this challenge, the flue gas stream is erected with equipment that meets environmental requirements. This equipment includes flue gas desulfurization (FGD) systems (scrubbers), electrostatic precipitators, fabric filters (baghouses), and chimneys to release the off-gases. All have unique fire hazards that are addressed in NFPA 850.

Of particular concern is the flue gas desulfurization system, which may contain large quantities of plastics and other combustibles, particularly duct linings for corrosion control purposes. Some chimneys erected with combustible materials have presented challenging fire situations. The FGD scrubber absorbers require an emergency water quench system to cool hot flue gases which may be elevated during an abnormal event such as an air heater fire. These quench systems require large waterflow rates, which need to be available during a station blackout. They should have dedicated water supplies such that the quench water demand does not impair the fire protection system.

Steam Turbine-Generators

A study of 20 significant turbine-generator fires that occurred worldwide over 10 years at both fossil and nuclear power plants found four fatalities, several injuries, and an average of $47 million in property damage per fire with an average forced outage of 200 days. Two fires led to the permanent decommissioning of plants. Extensive vibration, overspeed, instrumentation failure, human error, blade failure, and filtration failure caused these fires.[5]

The heart of the fire challenge is the pressurized lubrication oil system (in the range of a gauge pressure of 150 to 250 psi [1035 to 1725 kPa]) that uses a Class III B combustible liquid with a flashpoint ranging from 400 to 500°F (204 to 260°C) and an autoignition temperature of 700°F (371°C). Lubrication oil is released if the lubrication oil piping system is breached. Ignition may occur due to a hot surface, which can cause a spray fire, three-dimensional fire, pool fire, or a combination of all three, producing large quantities of smoke and heat. Turbine-generators can take from 20 to 40 minutes to coast down. Turbine shaft-driven pumps shut down at 90 to 95 percent of rated speed. However, motor-driven backup pumps are designed to continue to supply lubricating oil while the shaft rotates and therefore they could feed oil to a fire.

Strategies to deal with a turbine-generator fire are outlined in NFPA 850 and Electric Power Research Institute Project 1843-2, July 1985, *Turbine-Generator Fire Protection by Sprinkler System.* Automatic sprinklers and heat detectors should be provided over all bearings. All lubrication oil piping, including instrumentation lines above the turbine operating floor and its lagging or skirt area, should be protected by automatic sprinklers. Protecting areas where oil can spread beneath the turbine-generator with automatic sprinklers is vitally important. The extent of coverage is critical and should include areas beneath the mezzanine and in condenser pit areas.

Fire suppression is also recommended for the oil storage reservoir and filtration equipment. Ideally, this equipment should be installed in a room with a minimum fire barrier rating of 2 hours.

Turbine-generator fires can also expose the turbine hall roof to excessive heat exposure and possible structural failure. There is no requirement for automatic sprinklers throughout the roof area of a large turbine hall, but roof level automatic sprinklers may be critical for newer, more compact plants without solid turbine operating floors. Smoke and heat venting is important in preventing structural roof failures.

Another potential hazard is the hydraulic control system if it is common with the lubrication oil discussed above. These systems operate at high pressures (up to 1600 psi [11,032 kPa]) and, therefore, can result in spray oil fires. Newer units, particularly those built after the early 1970s, use a separate electro-hydraulic control system that has nearly eliminated this hazard by using a less flammable synthetic fluid such as a phosphate ester.

Concentric or guarded piping for lubrication oil systems is recognized as good design practice. It does not, however, completely replace the automatic sprinkler systems discussed earlier. Fire experience shows that smaller lines that cannot be practically placed in concentric piping have been known to fail. In one case, an instrumentation line failure caused $24.43 million in damage (amount adjusted to 2007 U.S. dollars). In another case, oil escaped from a concentric pipe, resulting in a $19.54 million fire, and in yet another case, human error caused oil to be released from a filter system, resulting in a $65.96 million fire (both amounts adjusted to 2007 U.S. dollars).[4]

The vast majority of generators are hydrogen cooled. In North America, hydrogen is received in bulk and may be located on tube trailers or in high-pressure cylinders. Some foreign plants produce hydrogen on site. Hydrogen can contribute to turbine-generator fires and cause explosion damage, expected to be minor in comparison to the more severe fire damage associated with turbine lubrication oil. Hydrogen explosions inside the generator are considered unlikely as hydrogen is typically 100 percent pure and therefore there is insufficient oxygen to support combustion. Rugged generator casings have minimized the amount of damage.

Historically, one reason for not providing fire protection for turbine-generators was the belief that water released from the fire protection system would cause thermal shock to turbine components and auxiliary equipment. The previously mentioned Electric Power Research Institute (EPRI) report studied this subject.[6] The study focused on utility experience with respect to the application of water around hot turbine parts, including both intended and inadvertent fire protection system activation. Of the 24 events studied, the application of water caused no significant damage. No cases of thermal shock have been reported since the EPRI report's release. A dissertation also examined this issue; it corroborated the EPRI report and found that fire risk far exceeds any damage that a fire protection system causes.[7]

Combustion Turbines

Traditionally, combustion turbines or gas turbines were used in peaking applications during high demand periods, usually in the summer. The bulk of the peaking capacity was installed during the decade following the 1965 Northeast blackout. These machines are typically in the 10 to 40 MW range. Today, in

areas with low electric reserve margins it is not uncommon to operate these peaking units around the clock. The availability of natural gas, advances in gas turbine technology, and the advent of nonutility generators has resulted in a significant increase in the number of gas turbines in the United States and in the world. In 1999 in the United States there were 2366 units in operation, which is a 17 percent increase over 1998.[8] Since the late 1990s, natural gas has been the fuel of choice for the majority of new generating units, resulting in a nearly 81 percent increase in gas-fired capacity since 1999. The construction of natural gas plants began increasing in 1999, peaked during 2002 and 2003, and since then has declined considerably.[2]

Combustion turbines are typically purchased as a package, and the seller, not the buyer, usually determines the type of fire suppression system. Initially, the overwhelming majority has been protected with carbon dioxide or halon systems. More recently, FM-200 has been used to protect new installations. Fear of thermal shock is the chief reason for avoiding water-based systems. Currently, there is interest in protecting these machines with water mist technology and systems specifically approved for large combustion turbines.

Gas turbines are frequently installed in combined-cycle facilities utilizing heat recovery steam generators (HRSG). Steam produced by an HRSG drives a steam turbine with the same fire hazards as described earlier. The NFPA Technical Committee on Boiler Combustion System Hazards has produced NFPA 85, which addresses these hazards.

Hydroelectric Plants

Unique Fire Protection Challenges. Hydroelectric plants (Figure 9.14.10) are addressed in NFPA 851. Hydroelectric plants lack many fire hazards addressed above with respect to combustible fuels and large pressurized lubrication oil systems that operate under high pressure. Nevertheless, hydroelectric plants present unique fire protection challenges. Among them are life safety (particularly when facilities are several hundred feet below grade), use of oil-filled cable and grouped electrical cable, minimal staffing or unattended operations (even in plants as large as 1300 MW), transformer exposure, use of hydraulic control and lubrication oil systems for penstock or wicket gates, and use of generator windings.[9]

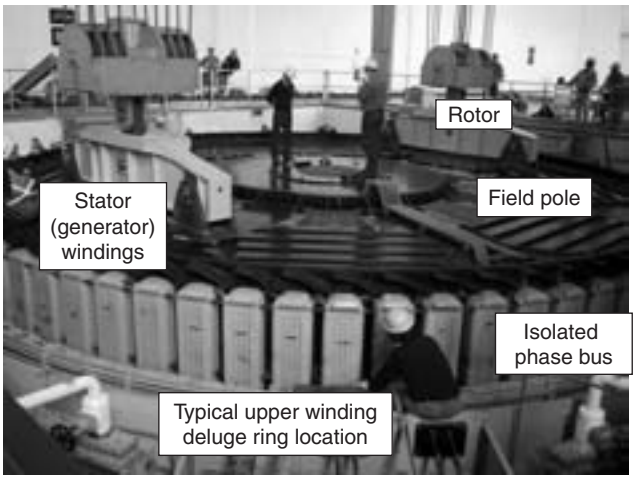

FIGURE 9.14.10 Rotor Lift at Large Hydro Unit (Courtesy Manitoba Hydro)

Generator Windings. If the phases of the generator (A, B, C, Neutral) are not totally balanced, these components can overheat or short. Such electrical faults represent a very high energy ignition source and can easily develop into a large fire considering the quantity of combustible components in the generators. The magnitude of the generator fire hazard depends on the materials used. Thermoplastic materials such as asphalt are more common on older units. Thermoplastic materials such as asphalt are highly combustible and tend to break down over time, presenting a higher risk of electrical fault. Thermoset materials such as fiberglass epoxy resins are more common on new units. Thermoset materials tend to be self-extinguishing when de-energized.

Rewinding the generator with thermoset insulation does not entirely eliminate the hazard. Other combustible components typically remain, such as current transformers, potential transformers, grounding transformers, grounding resistors, thermoplastic end-turn windings and isophase bus ducts. Protection should be provided. Fire stops should be considered for isophase ducts.

One of the largest hydroelectric plant fires occurred in 1981. A fault in an oil-filled cable led to a hot smoky fire, complicated by difficult access into the cable tunnel. An inadequate water supply hampered fire fighters. Property damage was $39.09 million (amount adjusted to 2007 U.S. dollars), and the 700 MW unit was out of service for one year.[4]

Use of Carbon Dioxide Systems. Historically, carbon dioxide fire protection systems have been commonly used to protect hydroelectric generators. NFPA 12, *Standard on Carbon Dioxide Extinguishing Systems,* specifically addresses the design of carbon dioxide systems for protection of rotating electrical equipment. However, there are widespread efforts in the international hydroelectric industry to replace these systems. In the United States, the trend is to replace aging high-pressure carbon dioxide systems with new bulk storage low-pressure carbon dioxide systems. This addresses the need to lower maintenance costs associated with the cylinders and addresses difficulties obtaining spare parts for the old systems, some of which are over 50 years old. The low-pressure systems are also designed in accordance with NFPA 12.

In Canada, the trend is to replace carbon dioxide systems with deluge water spray. This addresses a grass-roots life safety concern with the use of carbon dioxide in below-grade areas and addresses a nationwide effort to reduce greenhouse gas emissions in accordance with the Kyoto Protocol. The water spray system designs vary. Generally a "water ring" header is installed above and below the rotor, with nozzles or orifices directing water towards the stator windings. Flow rates depend on the diameter. Sophisticated interlocks and protective relays ensure that all fields in the generator are de-energized prior to waterflow. Windage inside the rotating generator helps convert the

spray to a fine mist to penetrate deep-seated insulation fires. On extinguishment, the wicket gates are immediately opened to rotate the de-energized machine until completely dry.[10]

In New Zealand and Australia, the trend is to eliminate thermoplastic windings whenever possible. Otherwise, the trend is to replace carbon dioxide with FM-200 or Inergen. This addresses a life safety concern with the use of carbon dioxide which could migrate to potentially occupied spaces. There is also an interest in water mist technologies; however implementation in the future depends on the availability of funding for fire tests to determine a viable design basis.[11,12]

WIND ENERGY

Wind turbine generator technology is evolving rapidly and individual units are now available in the 2 to 3 MW range for use onshore. Offshore units can be as large as 6 MW. Europe has led the way with over 40,000 MW of wind energy capacity as of 2005. An additional 8000 MW were expected by the end of 2006.[13] Total capacity in the United States from wind began with 10 MW in 1981 and has risen to over 9000 MW in 2005. Preliminary data indicates that another 2500 MW were added in 2006.[14] The next edition of NFPA 850 will provide fire protection recommendations for this new technology.

Electrical Cable

Electric generating plants use insulated, jacketed cable for power, instrumentation, and control. Cables are typically routed in open cable trays throughout the power block. Plants built in the 1960s through the 1990s used significant quantities of cable. Future electric generating plants may use less cable due to computer advances and changes in technology, including the use of fiber optic cable.

Many electric generating plants are traditionally arranged to concentrate cable in areas immediately below the control room. The arrangement may typically include a control room at the top level with a cable spreading room below and a burner management room below that, with motor control centers and relay rooms on lower elevations. All these areas should be erected within walls and floor/ceiling assemblies of 2 hour fire resistance and with suitably protected openings.

Grouped electrical cables constructed of organic materials present fire hazards of various magnitudes. A few very severe fires involved PVC jacketed cable, including the 1975 fire in the cable spreading room at the Browns Ferry nuclear power plant. Electricians used an open candle flame to check a cable penetration seal made of polyurethane. The flame accidentally ignited the sealant material in the wall between the cable spreading room and reactor building. Fire then spread to the grouped electrical cable system. No serious injuries resulted, but the fire caused $302.93 million in property damage (amount adjusted to 2007 U.S. dollars), a 1½ year outage for the two 1065 MW units, and worldwide reappraisal of fire protection for nuclear power plants.[4]

At a foreign fossil-fuel plant, an electrical fault ignited the cables, consuming 5 tons of PVC in 10 hours and causing $45.19 million in property damage (amount adjusted to 2007 U.S. dollars). The plant was out of service for nearly one year.[4]

NFPA 850 recommends installation of cable that passes the flame propagation test of IEEE 383. The insulation and/or jacketing of many newer cables are of materials that are difficult to ignite. However, under certain circumstances even this cable burns. A fire risk evaluation should be performed to determine the need for automatic fire sprinkler systems in areas with significant amounts of grouped electrical cable.

Transformers

Electric generating plants use both indoor and outdoor transformers. Usually indoor transformers are relatively small, air insulated, and used for individual plant service. Larger, oil-cooled transformers used for main generator voltage step up and for station service are located outdoors. These transformers are usually grouped in an area close to the generator to minimize the length of the isolated-phase bus duct from the generator leads to the main power transformer. The amount of cooling oil can range from 20,000 to 25,000 gal (75,000 to 94,750 L). Internal high energy faults can be violent, expending tremendous power, rupturing the transformer casing, releasing oil (and possibly missiles), and subsequently igniting.[15] There have been cases of a transformer fire propagating to the generator, or from the generator to the transformer, resulting in the challenge of combating two fires simultaneously.

NFPA 850 provides guidance on transformer, spatial separation, and fire walls. For example, transformers with an oil capacity of 500 to 5000 gal (1,895 to 18,950 L) should be separated from adjacent transformers and from buildings by a minimum distance of 25 ft (7.6 m) or by a fire wall. NFPA 850 also provides criteria for the fire resistance and height of fire walls. For best practice, installation should include lightning protection, a drainage system, fire barriers, and automatic water spray systems (Figure 9.14.11). The latter should be designed according to NFPA 15, *Standard for Water Spray Fixed Systems for Fire Protection.*

FIGURE 9.14.11 Water Spray System Protecting a Transformer (Courtesy McDaniel Fire Systems, Inc.)

The purpose of an automatic water spray system is exposure protection. The benefit of such systems under catastrophic conditions has been debated. Some contend that the violent nature of a transformer failure renders automatic water spray systems useless. Although this may have occurred, in many cases the automatic water spray systems did survive explosions and were credited with controlling fire, limiting damage, and minimizing plant downtime.

Alternative fire suppression technologies are being developed. One such system being considered for acceptance testing relieves pressure buildup from a transformer excursion and conducts the escaping transformer oil to a holding tank. The transformer shell is protected against overpressurization and the oil does not come in contact with oxygen, so there is no spill or fire to extinguish. Nitrogen is bubbled up through the core of the transformer to aid in cooling.

High-Voltage Direct Current Converter Stations

A high-voltage direct current converter station with transmission line effectively controls electrical power systems that may not be synchronized, such as those between the United States and Canada. High-voltage direct current transmission links also transmit large blocks of power more efficiently over long distances. At one end of the line, the converter station converts alternating current, and at the other end, the converter station functions as an inverter, changing power back to alternating current for consumption by the local grid.

A 30 year study of the approximately 75 converter stations in the world identified about 30 minor fires and 3 major fires between 1989 and 1993.[4] The major fires caused property damage of $31.76 million, $34.20 million, and $41.53 million, respectively (amounts adjusted to 2007 U.S. dollars). First utilized in these facilities, mercury arc technology has now been replaced by thyristor technology. All three major fires have been in thyristor valves. The valves are stacked in an array of energized electrical components with combustible dielectric fluids and plastics. The stacks can be suspended from the ceiling or mounted on the floor.

This technology presents a unique fire problem. Under normal shutdown conditions, isolating and properly grounding the equipment may take up to an hour. Under emergency conditions this can be done more rapidly, but a delay can be expected in manual fire-fighting operations. High temperatures at the ceiling or thermal shock from fire water may cause the valve stack supports to fail. Major damage can then be expected from smoke and contamination of sensitive electronic equipment.

Air sampling smoke detection systems should be considered as a means to detect smoke in a fire's incipient stage. The use of automatic sprinklers is expected to be limited. There is a need for early warning fire detection and a preplanned fire fighting strategy.

SUMMARY

This chapter addresses conventional means of producing electrical energy from fossil fuels, biomass, and hydro sources. Other technologies, such as geothermal, solar, wind, and fuel cells, also exist. A variety of economic and technological reasons limit their contribution to the total electric production mix. It is highly likely that technological advances will bring forth new and unknown electric production technologies.

As the demand for electricity increases, there will be a need to build new electric generating plants, to renovate older plants, and to retire and replace plants that have outlived their usefulness. The trend is to deregulate the electric utility industry in the United States and to privatize in many foreign countries. All these issues increase the importance of fire protection for electric generation plants globally.

Chapter Contents

Nuclear Reactors
Radiation Machines
Facilities Handling Radioactive Materials
Radiation Exposure
Fire Protection

Key Terms

glove box, hot cell, nuclear reactor, nuclear safety, particle accelerator, performance-based approach, radiation exposure, radioactive material

Since the 1950s, the use of nuclear materials has continued to increase worldwide. In addition to nuclear fuels used for the production of electric power, nuclear materials are widely used for medical purposes, industrial controls, household uses (e.g., ionization smoke detectors), basic research, and weapons operations. Global use of nuclear materials continues to expand.

The use and storage of nuclear materials present special fire protection concerns. Although the general fire hazard in facilities that use or store nuclear materials are the same as those of similar facilities that do not include nuclear materials, fires in nuclear facilities may have more significant consequences. Employees and emergency response personnel must be protected against direct exposure to nuclear radiation and contamination. The environment and general public should not be unnecessarily exposed to radiation hazards. Unintentional nuclear criticality (self-sustaining nuclear fission reactions) must be avoided. In addition, fires and explosions may compromise circuits, mechanical systems, and equipment necessary to safely contain and confine nuclear materials and radiation.

This chapter discusses some special practices and hazards associated with facilities handling and using nuclear materials. Among the special occupancies this chapter addresses are nuclear reactors, radiation machines, and other facilities handling nuclear materials. This chapter also discusses hazards associated with radiation exposure and special fire protection procedures for nuclear facilities. Other chapters of this handbook discuss general fire hazards, construction practices, and fire control practices not unique to nuclear facilities, but common to all facilities.

For related topics, see Section 1, Chapter 6, "Premises Security"; Section 1, Chapter 7, "Protecting Against Extreme Events"; Section 5, Chapter 3, "Disaster Preparedness Education"; Section 7, Chapter 5, "Hazardous Waste Control"; Section 9, Chapter 14, "Electric Generating Plants"; and Section 12, Chapter 12, "Disaster Planning and Response Services."

NUCLEAR REACTORS

Whereas nuclear power accounts for less than 20 percent of electric power production in the United States, nuclear power is more prominent in the fuel mix for electric power in other countries. For example, in 2005 nuclear power accounted for over half of the electric power produced in France (78 percent), Lithuania (72 percent), Belgium (55 percent), Slovakia (55 percent), Sweden (52 percent), and the Ukraine (51 percent).[1]

Of 443 nuclear power reactors operating in 31 countries in 2005, 339 are located outside the United States. Another 23 nuclear power reactors are under construction, and an additional 48 reactors are on order or planned outside the United States. Nuclear power will continue to be an important source of energy worldwide.

An international collaboration known as the Generation IV International Forum (GIF) is working on the development of the next-generation nuclear energy systems known as "Generation IV." Argentina, Brazil, Canada, France, Japan, the Republic of Korea, the Republic of South Africa, Switzerland, the United Kingdom, and the United States, along with the European Agency Euratom, are working to develop and demonstrate advanced nuclear energy systems. These systems will meet future needs for safe, sustainable, environmentally responsible, economical, proliferation-resistant,

Wayne D. Holmes, P.E., FSFPE, is vice-president of HSB Professional Loss Control and chair of the NFPA Technical Committee on Fire Protection for Nuclear Facilities.

and physically secure energy. Generation IV reactors, which might include Very High Temperature Reactors, Supercritical Water Cooled Reactors, Molten Salt Reactors, Gas-Cooled Fast Reactors, Sodium-Cooled Fast Reactors, or Lead-Cooled Fast Reactors, are expected to be available for global construction by about 2030.

In the meantime, there are indications of a future revival of nuclear power in the United States. Three utilities have filed early site permit applications for nuclear power plants. Three advanced reactor designs have been certified. Several construction and operating license applications are expected to be submitted in 2008. The nuclear energy industry's Vision *2020* is that an additional 50,000 megawatts of nuclear electric power will be available in the United States by the year 2020.

By any available measure of frequency of acute incidents, the nuclear power industry has had a good safety record. However, the costliest U.S. fire ever involving the electric power industry occurred at an Alabama nuclear power facility, and the global effects of the Chernobyl station incident have shaped perceptions of safety in many people's minds. Because of the high consequence potential, the industry has reason to seek out and adopt improvements in safety, notwithstanding the low incident frequency.

A nuclear reactor is a device or assembly for initiating and maintaining a controlled nuclear chain reaction in a fissionable fuel (uranium or plutonium). Nuclear reactors are used to produce energy, to study the fission process, or to produce radioactive materials within the reactor or in a material exposed by the reactor's radiation or radioactive particles. Basically, nuclear reactors may be divided into two categories: (1) large nuclear power reactors, up to 3500 MW (megawatts thermal) or 1100 MW(e) (megawatts electrical), and (2) research reactors that operate at power levels from a few watts to many megawatts.

Nuclear reactors that include a containment vessel, generating equipment, and heat-removal equipment can be as large as the largest fossil-fueled electrical generating plants. Most research reactors, however, are so small that they may occupy only one small corner of a room in a typical laboratory building at a research facility or college campus. Therefore, the magnitude of hazard each kind of reactor presents varies considerably.

Various national and international groups have addressed the need for fire protection requirements for nuclear power reactors and research reactors. These groups include the National Fire Protection Association (NFPA), the American Nuclear Society, the United States Nuclear Regulatory Commission (NRC), the American Nuclear Insurers, Nuclear Energy Institute (NEI), Nuclear Electric Insurance Limited, and the International Atomic Energy Agency (IAEA). (See Bibliography at the end of this chapter.)

Objectives for achieving and maintaining adequate nuclear reactor safety include the following:

- Provide means to safely shutdown the reactor and maintain it in safe shutdown condition during and after accident conditions.
- Provide means to remove residual heat from the reactor core after reactor shutdown, including during and after accident conditions.
- Provide means to reduce the potential for radioactive releases within acceptable limits.

To meet these safety objectives, different reactor designs provide redundant safety systems so that initiating events, such as fires, do not prevent safety systems from performing their required functions. Advanced reactor designs include a high degree of safety system redundancy. Earlier designs of reactors include less redundancy. As redundancy decreases, the need to protect each system from the effects of fire and explosion increases. Improved passive fire protection, increased physical separation, and greater use of fire detection and suppression systems often provide this protection.

A high degree of fire protection is necessary to ensure that fires will not significantly degrade the level of nuclear safety. The "defense-in-depth" concept can achieve this safety. It includes three principle objectives:

1. Preventing fires from occurring
2. Detecting and quickly extinguishing those fires that do start, thus limiting fire damage
3. Preventing the spread of those fires that have not been extinguished, thus minimizing their effect on essential plant functions

The first objective requires that plant design and operation be such that the probability of a fire is minimized. The second objective concerns early detection and extinguishing of fires by a combination of automatic and/or manual fire-fighting techniques and relies on active fire protection measures. The third objective places particular emphasis on passive fire barriers and physical separation. This is the last line of defense if the first two objectives are not met. For the defense-in-depth concept to be effective, fire safety design and procedures must include all three objectives and implement them simultaneously.

Heat Removal

All nuclear reactors, even very low power training or research reactors, produce heat while operating. This heat either must be dissipated or used, depending on the amount produced and the reactor's intended purpose.

Reactor Control

Reactor control systems and safety systems are of utmost importance. The control system design is fitted to the technical characteristics of the reactor and is capable of producing power changes at acceptable rates. The control system design also makes it possible to produce and maintain the desired power level within the reactor so that excessive temperatures are avoided. The safety system, an addition to the control system, is adapted to the characteristics of the reactor in the instrument and control system. The safety system automatically operates in response to signals from the instruments to prevent operational variables from exceeding safe limits. On appropriate signals, the safety system warns of incipient performance changes and, if necessary, shuts down the reactor.

A reactor becomes "critical" when the total rate of production of neutrons, under control conditions, is such that self-sustaining reactions occur. Control methods must be rapid, sensitive, and protected from fire. Since the control system is vital to the reactor's adequate functioning and safe operation, protection of the control room, cableways, emergency power supply, and electrically or hydraulically operated equipment is of prime importance. Protection for these areas should be fully consistent with that used in computer rooms containing vital records.

Power Reactors

Nuclear power reactors have many of the common and special fire protection hazards that are frequently encountered at large industrial facilities. Other chapters in this handbook and numerous NFPA standards can be consulted for recommendations on appropriate means of managing such hazards. Unique to nuclear power plants are fire consequences that could result in loss of ability to adequately cool the nuclear reactor or that could result in release of radioactive materials. Special attention must be paid to controlling fire hazards in nuclear power plants so that the nuclear safety risks are successfully managed.

History of Relevant NFPA Standards. NFPA has provided fire safety standards for nuclear facilities for over 50 years with the publication in 1955 of NFPA 801, *Standard for Fire Protection for Facilities Handling Radioactive Materials,* as the first NFPA nuclear fire protection standard. The first NFPA recommended practice for nuclear reactors, NFPA 802, *Fire Protection for Nuclear Research and Production Reactors,* was initially published in 1958. This was followed by NFPA 803, *Standard for Fire Protection for Light Water Nuclear Power Plants,* adopted by NFPA in 1978. However, NFPA 802 and 803 are no longer current. NFPA 803 was replaced by a performance-based standard as described in the following section. The NFPA documents on nuclear fire protection address the unique exposures of nuclear materials and operations as well as common fire protection hazards in nuclear facilities.

Performance-Based Standards. In the mid-1990s, NFPA recognized the need to develop performance-based standards for general fire safety. A white paper, *NFPA's Future in Performance-Based Codes and Standards,* was published in July 1995. This was followed by five NFPA primers on performance-based methods developed by the NFPA staff performance-based support team. In the late 1990s, the NFPA Technical Committee on Fire Protection for Nuclear Facilities was the first NFPA technical committee to begin work on a proposed performance-based standard. This standard, NFPA 805, *Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants,* was proposed to replace the existing prescriptive standard, NFPA 803. To meet the requirements of Public Law 104-113 to support consensus standards rather than develop federal standards, the U.S. Nuclear Regulatory Commission (USNRC) encouraged, supported, and participated in the development of NFPA 805.

As described by NFPA, performance-based codes and standards specifically state their safety goals and reference approved methods that can be used to demonstrate compliance with their requirements. A performance-based code or standard may be phrased as a method for quantifying equivalencies to an existing prescriptive-based code or standard, or it may identify one or more prescriptive codes or standards as approved solutions. Either way, the document allows the use of any solution that demonstrates compliance.

Nuclear Safety. NFPA 805 was created on the foundation of NFPA 803 and accepted fire protection practices but added numerous new features in an NFPA standard. For the first time, nuclear safety was addressed in an NFPA standard. Previously, NFPA 803 and other NFPA nuclear standards addressed property protection, business interruption, and life safety but not nuclear safety. Fire protection approaches to nuclear power safety are discussed in the paragraphs that follow.

Safety performance goals, objectives, and criteria can be used to implement an effective fire protection program for nuclear power plants. These performance elements are important in establishing benchmarks to measure safety performance. Performance-based or deterministic approaches for nuclear safety can be used to meet performance criteria. The performance elements are summarized in Tables 9.15.1 through 9.15.4.

Certain minimum and fundamental fire protection requirements are specified prescriptively in NFPA 805. Common fire

TABLE 9.15.1 Performance-Based Approach to Maintaining Nuclear Safety

Goal	*Objectives*	*Criteria*
Maintain fuel in safe and stable condition	• Achieve and maintain subcritical conditions • Achieve and maintain decay heat removal and inventory control functions • Prevent fuel clad damage	• Prompt negative reactivity insertion to subcritical condition • Maintain coolant level to prevent fuel clad damage • Maintain sufficient decay heat removal to keep fuel safe and stable • Maintain vital auxiliary support for nuclear safety criteria functions • Maintain process monitoring for nuclear safety criteria functions

TABLE 9.15.2 Performance-Based Approach to Preventing Radioactive Release

Goal	*Objectives*	*Criteria*
Reasonably prevent radiological release that adversely affects the public, plant personnel, or the environment	• Maintain containment integrity *–OR–* • Limit source term	Radiological release as low as reasonably achievable and less than regulatory limits

TABLE 9.15.3 Performance-Based Approach to Providing Life Safety

Goal	*Objectives*	*Criteria*
Reasonably prevent loss of life of plant occupants due to fire	• Protect occupants not intimate with fire from loss of life and improve survivability of those intimate with fire *–AND–* • Provide adequate protection for essential and emergency personnel	• Provide safe egress or area of refuge for occupants other than essential personnel • Provide adequate protection and lighting for essential personnel to perform necessary functions • Provide adequate protection for essential personnel providing necessary emergency services

TABLE 9.15.4 Performance-Based Approach to Limiting Plant Damage and Business Interruption

Goal	*Objectives*	*Criteria*
Assure acceptable risk of economic consequences	• Limit property damage to levels acceptable to the owner/operator • Limit business interruption (plant downtime) to levels acceptable to the owner/operator	• Limit the probable maximum loss (PML) to levels acceptable to the owner/operator • Limit the business interruption due to probable maximum loss (PML) fire to levels acceptable to the owner/operator

protection requirements might not be subject to performance-based methods. These include the following:

- Minimum and fundamental fire protection elements, such as fire protection programs, plans, and procedures
- Minimum protection requirements for manual and automatic fire protection
- Compliance with applicable NFPA standards for equipment, systems, or features that are credited with providing protection

The flowchart in Figure 9.15.1, derived from NFPA 805, illustrates deterministic or performance-based methods which can be used to demonstrate attainment of safety goals. The standard allows for the performance-based approach to be implemented either by fire modeling or by risk evaluation methods.

A standard framework by which risk-informed, performance-based fire protection can be implemented in a nuclear power plant is further described in NFPA 805. The methods provide nuclear power plant operators with flexibility in meeting safety objectives, while maintaining existing prescribed levels of safety. The performance-based approach to nuclear power plant fire protection allows for innovative solutions that may be more risk-specific and risk-effective than solutions developed through other approaches. Implementation of the performance-based nuclear fire protection methods provides the potential to reduce regulatory burden by providing relief from prescriptive requirements. In June 2004, the USNRC revised Title 10 Code of Federal Regulations 50.48 and endorsed NFPA 805-2001 as a voluntary alternative for licensing. Several nuclear power plant operators are considering the use of NFPA 805 as a licensing alternative.

At the urging of the USNRC and with participation by the USNRC and other nuclear stakeholders, the NFPA Technical Committee is developing a proposed NFPA 806, *Performance-Based Standard for Fire Protection for Advanced Nuclear Reactor Electric Generating Plants.* NFPA 806, which will apply to future reactor designs, is proposed for adoption as a 2008 edition.

Beyond the effects that fire might have on nuclear safety functions, the fire hazards in nuclear electric-generating stations include large volumes of combustible lubricating oils, concentrations of combustible cables, oil insulated transformers, and similar hazards that are common to all types of electric generating plants. See Section 9, Chapter 14, "Electric Generating Plants," of this handbook for further information about fire protection for electric generating plants.

Research and Production Reactors

In general, research and production reactors may present particular problems due to their location in existing buildings (which are sometimes of combustible construction), and the use of much combustible loading in the form of paraffin shielding, boronated polyethylene, wall finishes, and instrumentation. Combustibles should be eliminated wherever possible. For example, water can be used in place of paraffin. Where combustibles cannot be eliminated, automatic sprinkler protection can be very effective in controlling potential fire exposure. Supervi-

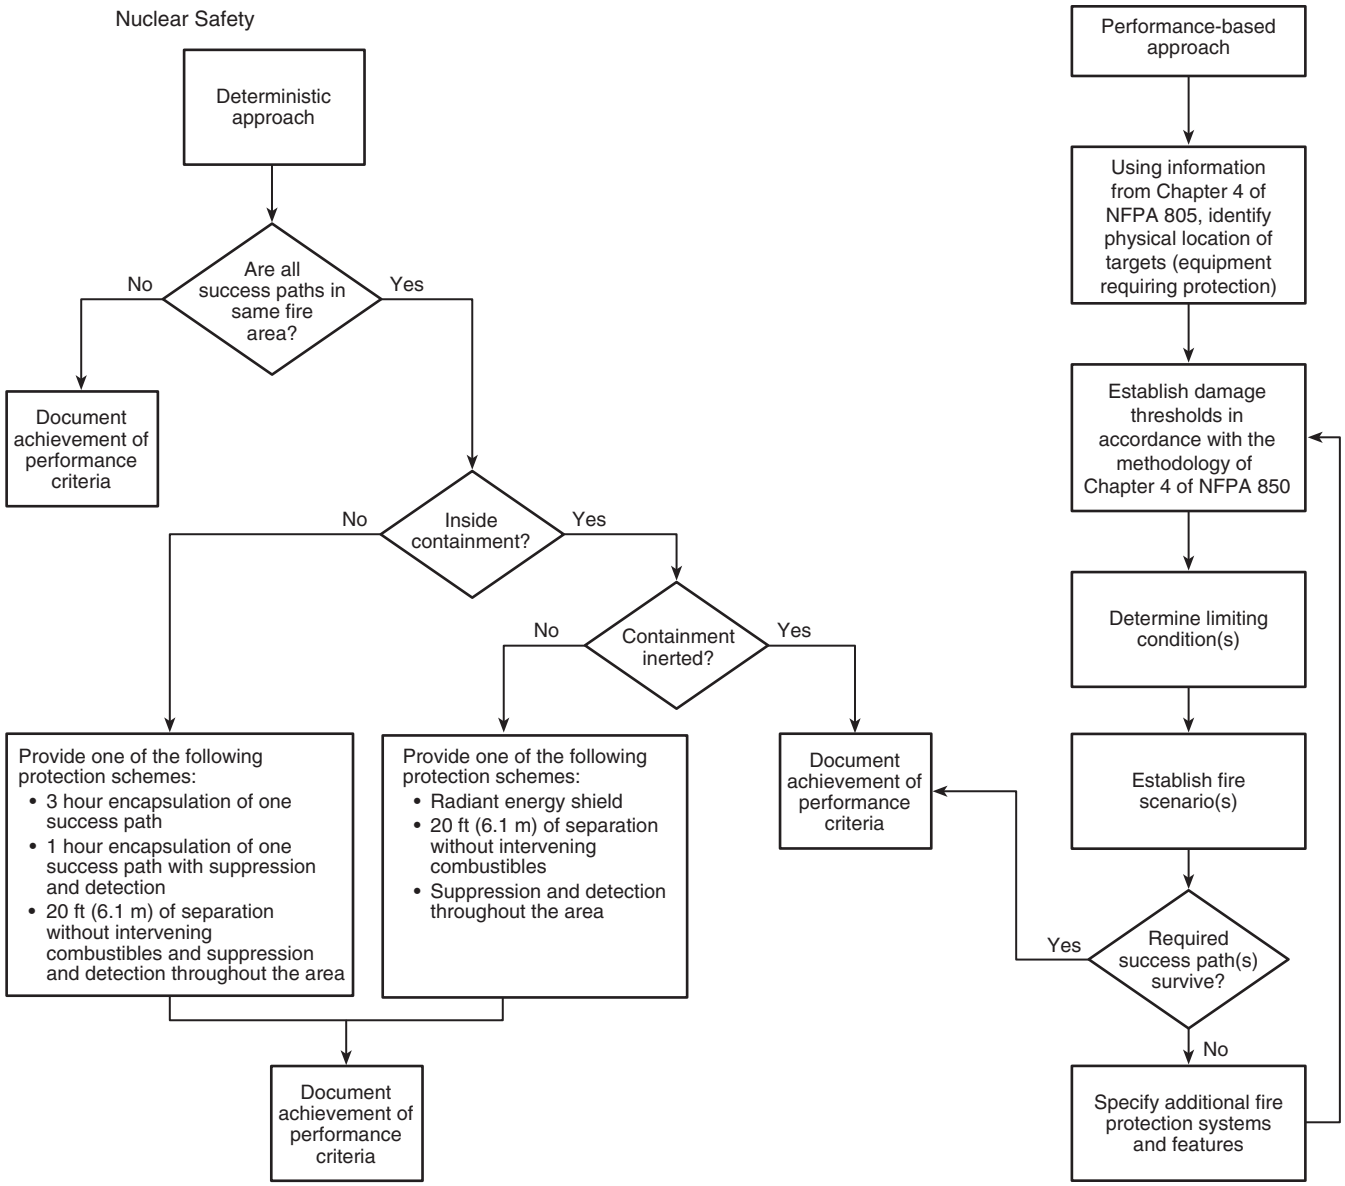

FIGURE 9.15.1 Nuclear Safety Capability Flowchart (Source: NFPA 805, *Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants,* Figure 6.2.2.1, 2006, p. 805-21)

sion of construction/operating personnel is especially important because a number of different operating groups may be involved with a single reactor.

A general lack of containment for research and production reactors further increases the need for effective fire protection design and procedures. Large power reactors often include passive containment systems and structures, typically of massive concrete and steel construction, to contain nuclear materials; research and production reactors may lack such containment structures. In these cases, confinement systems control and limit the undesirable release of nuclear contaminants. Ventilation systems become a key component in preventing nuclear releases. Special precautions must be taken to ensure that fires will not directly damage ventilation and confinement systems necessary to prevent the release of nuclear contaminants. Further, dynamic pressures created by fires and explosions must be considered and protected against to prevent air flow reversals that might significantly impact the spread of nuclear contamination.

RADIATION MACHINES

Radiation machines include mechanical and electrical devices that produce or use subatomic particles or electromagnetic radiation, or both. X-ray machines are used in radiography, therapeutic treatment, and studies of the behavior of radiation and its effect on materials. Particle accelerators, although they are radiation sources, are primarily devices for imparting extremely

high energies to subatomic particles that enter and alter atomic nuclei, thereby providing the means for developing basic information concerning the structure and behavior of matter. Gamma ray sources in the form of radioactive isotopes are employed in radiography equipment. This equipment may produce intense radiation. The use of isotopes as a source of radiation is not discussed in this chapter.

X-Ray Machines

Except for the radiation hazard while in use, X-ray machine hazards are mainly hazards of high-potential and high-energy electrical equipment. When shut down, there is seldom any appreciable residual radiation to interfere with fire-fighting or salvage operations. Although no flammable gases or hazardous amounts of flammable liquids are ordinarily needed to operate X-ray machines, they are frequently encountered in studies of the effects of radiation on a wide variety of substances.

Particle Accelerators

Particle accelerators include Van de Graaff generators, linear accelerators, cyclotrons, synchrotrons, betatrons, or bevatrons. The machines are used, as their names imply, to accelerate various charged atomic particles to tremendous speeds and, consequently, to high-energy levels. Particle accelerators furnish scientists with atomic particles, in the form of a beam, which may be used for fundamental studies of atomic structure. In addition, accelerators furnish high-energy radiation, which may be used for radiography, therapy, or chemical processing. Particle accelerators emit appreciable radiation only while operating. Attempts to extinguish a fire in the immediate vicinity of the machine should be delayed until the machine's power supply can be disconnected.

Certain "target" materials become radioactive when bombarded by atomic particles, and for this reason monitoring equipment should be used during fire-fighting operations to estimate the radiation hazard. The usual hazard presented by particle accelerators is largely that of electrical equipment. There are, however, some important exceptions. Some installations use such hazardous materials as liquid hydrogen or other flammable materials in considerable quantities. The large amounts of paraffin used in the past for neutron shielding have been replaced, in many cases, by boronated polyethylene. In fires, polyethylene materials have a very high heat release rate, which can further increase the fire hazard. In some cases, fire-retardant chemicals added to polyethylene decrease its ignition potential. Once ignited, however, even "fire-retardant" polyethylene may burn intensely when exposed by other burning materials. Limited, small-scale fire testing of combustible moderator and shielding materials does not ensure that these materials will not burn in the configurations in which they are used. Another factor is the possible presence of combustible oils used for insulating and cooling.

Industrial applications for particle accelerators include chemical activation, acceleration of polymerization in plastics production, and the sterilization and preservation of packaged drugs and sutures. The general fire protection and prevention measures for these machines should include the use of noncombustible or limited combustible (Type I or Type II) construction housing, noncombustible or slow-burning wiring and interior finishing, and the elimination of as much other combustible material as possible. (See NFPA 220, *Standard on Types of Building Construction.*) Automatic sprinkler protection should be provided in areas containing hazardous amounts of combustible material or equipment. Special fire protection should be provided for high-voltage electrical equipment.

FACILITIES HANDLING RADIOACTIVE MATERIALS

The type of equipment used to process radioactive materials depends not only on the work to be performed but also on the degree of hazard associated with the material and the process it is to undergo. Materials with low levels of radioactivity and with little or no inherent fire or explosion hazards require less protective equipment than others. To protect personnel, the amount and kind of shielding required will depend on the types of radiation emitted, as well as the activity involved. In addition, the chemical and physical nature of the radioactive materials will dictate the degree of containment necessary, as well as the construction materials necessary in the containment system. All equipment used for handling and processing radioactive materials should be designed to minimize fire and explosion potentials, as well as to protect personnel against harmful radiation exposure and prevent damage to property by contamination.

NFPA 801 provides requirements for personnel responsible for the design or operation of facilities that involve the storage, handling, or use of radioactive materials. The requirements in NFPA 801 apply to all locations, except power plants, where radioactive materials are stored, handled, or used in quantities and conditions that require government oversight license (e.g., U.S. Nuclear Regulatory Commission or U.S. Department of Energy) to possess or use these materials and to all other locations with equal quantities or conditions.

Many types of equipment and systems handle radioactive materials; most can be classified as benches, hoods, glove boxes, or hot cells.

Benches

Benches are used generally for handling relatively small amounts of alpha- or beta-emitting materials requiring little or no shielding when handled with gloved hands or tongs. No special ventilation for the bench is provided in most instances, and its use is thereby restricted to materials that will not easily become airborne.

Benches should be of noncombustible construction with a nonporous continuous working surface that can be decontaminated easily. Usually, one or two layers of blotting paper on the bench top to absorb small spills will not materially increase the fire hazard.

Hoods

Hoods, sometimes referred to as *fume hoods,* are similar to benches except for an enclosure and exhaust system added to re-

move vapors. The nature of the operations conducted within the hood may require a filter system to prevent the spread of radioactive materials. Filters with a low degree of combustibility are desirable. Fire protection and ventilation requirements for hoods are similar to those described for glove boxes. For requirements for laboratory exhaust hoods, see NFPA 45, *Standard on Fire Protection for Laboratories Using Chemicals.*

Glove Boxes

The term *glove box* refers to a system designed to contain materials, generally alpha-radiation emitters, that present little or no external radiation hazard but that can present a serious problem if they become airborne. Glove boxes may be large and are used in a wide variety of operations involving flammable liquids and gases, combustible solids, and toxic materials. The sides are fitted with long rubber-like gloves that permit manual operations to be conducted without personal contact with the hazardous materials. Figure 9.15.2 shows a typical glove box with gloves extending from the ports in the viewing window on the left. Note the portable fire extinguisher adapted for discharge into the box through a fixed piping arrangement.

Confinement of radioactive materials that may be contained in hoods and glove boxes greatly depends on the enclosure materials and the ventilation systems. Therefore, fire hazards, fire protection, construction materials, and ventilation must receive special attention to prevent a breach of the confinement system.

Burning of combustible materials that may be present in the hood or glove box could produce dynamic pressures that might overpressurize the enclosure or cause direct fire damage to the enclosure. Where combustible material must be used inside the hood or glove box, special extinguishing agents, such as dry powders, clean fire suppression agents, or automatic sprinklers, may be necessary to prevent internal fires from breaching the containment enclosure. This could lead to release of nuclear materials. Additionally, extreme care must be exercised to assure that introducing the fire suppression agent will not overpressurize the enclosure or increase the potential for accidental nuclear criticality where fissile materials may be present. The design of ventilation systems—whose purpose is to maintain a negative pressure in the hood or glove box or to maintain a specific airflow pattern—should anticipate and control pressure and airflow changes due to fires or fire suppression systems.

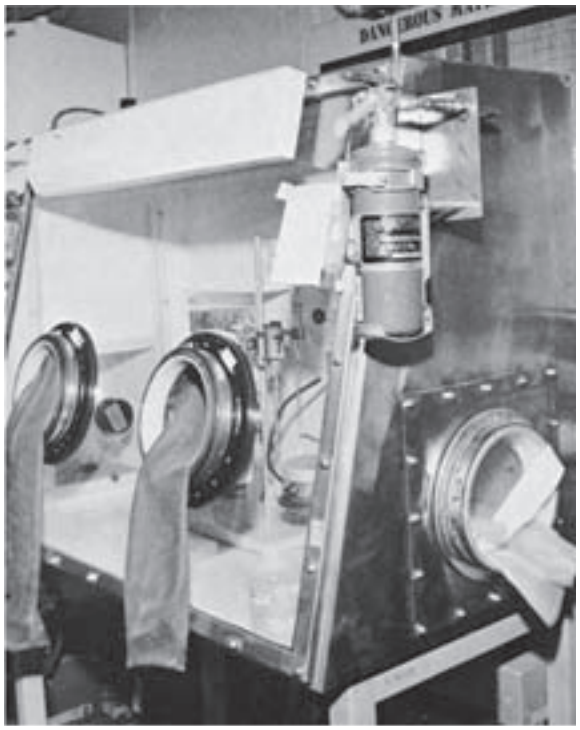

FIGURE 9.15.2 Typical Glove Box

Hot Cells

A hot cell is a heavily shielded enclosure in which gamma-emitting radioactive materials can be handled by persons using remote manipulators while viewing the operation through shielded windows or periscopes. Hot cells are preferably constructed of noncombustible materials and contain the minimum amount of combustibles consistent with operational requirements.

The high gamma radiation hazard associated with hot cells may be further complicated by the need to handle combustible materials in the hot cells, the use of combustible moderators and shielding materials, combustible oils in shielded viewing windows, and the lack of internal accessibility within the cell. Fire protection and ventilation concerns for hot cells are similar to those described for hoods and glove boxes.

In addition to all the fire and explosion hazards of glove boxes, hot cells also present increased damage potential due to the nature of the high gamma ray producing materials used. Where gamma radiation levels are very high, the possible failure of containers as a result of radiation damage must also be considered.

RADIATION EXPOSURE

Radiation Injury

The amount of injury to a person from radiation varies with the type of radiation, how much of the body has been exposed, and whether it is a one-time exposure or an accumulation of exposures to small amounts of radiation. Injuries from excessive exposures may not become apparent for days, weeks, months, or years.

Radiation experts report that, similar to many potentially hazardous materials, any exposure to radiation, either external or internal, has some element of risk, which may be too low to be measurable. Certain exposures are believed to be of reasonable risk balanced against the benefits from any activity using radiation exposure, such as medical and dental uses of radiation. Since the human race has evolved on a planet that has always been radioactive from naturally occurring radioisotopes in the air, soil, and water, it is probable that a low "background" radiation is tolerable. The controversy on radiation exposure

concerns the additional amounts that humans can tolerate. Standards have been set with the objective of lowering risks to the best practicable levels.

Occupational Exposure from Radiation in Air and Water

Radiological authorities having jurisdiction (AHJs) have set extremely low limits on concentrations of radioisotopes in air and water, based on quantities that may be inhaled or ingested. Complete treatment of the subject would require consideration of maximum permissible concentrations in both air and water. The problem of airborne concentrations is of particular concern in fires, as fire fighters and other emergency personnel may be confronted with such material in the fumes, dust, smoke, and gases liberated by a fire involving radioactive materials.

A hard-and-fast rule should be mandated that self-contained breathing apparatus (SCBA) are to be used whenever exposure to airborne radiation is a possibility. Maximum permissible concentrations (MPCs) of various radioisotopes in air and water are commonly stated as limits intended to apply to persons who are continuously exposed to the concentrations named. Consequently, the concentrations are far below the exposures that could be tolerated for infrequent exposure, as would most often be the case with fire fighters or emergency workers. Apparatus is available for sampling an atmosphere. The number of radioactive emissions in the air can be counted with an appropriate counting instrument. From these counts, the extent to which the particular atmosphere is contaminated can be determined. Figure 9.15.3 illustrates portable instruments developed at Oak Ridge National Laboratory for measuring radioactive emissions. The meters are for fast neutrons (shown bottom row at left), thermal neutrons (shown bottom row at right), beta-gamma (shown top row at left), and for alpha particles (shown top row at right), with an alpha scintillation detector at the top of the picture.

Any space normally occupied by persons not primarily engaged in radiation work should not be subjected to unreasonable radiation levels. Also, a person outside the installation should not be subjected to excessive radiation level exposure through contact with radioactive waste or by other means. Air should be monitored continuously for the presence of radiation from fixed sources or from airborne radioactive matter. In emergencies, alarms should sound and radiation levels be recorded by available commercial instruments.

Fire Department Radiation Exposures

Emergency exposures are usually allowed to exceed those tolerable to persons who work continuously with radioactive materials. In an emergency, such as a necessary rescue operation, raising the exposure, within limits, for single doses is considered acceptable. The National Council on Radiation Protection and Measurement has recommended that in a life-saving action, such as search for and removal of injured persons or for entry to prevent conditions that would injure or kill numerous persons, the planned dose to the whole body should not exceed 100 rems.[2] During less stressful circumstances, where it is still desirable to enter a hazardous area to protect facilities, eliminate further escape of effluents, or control fires, the recommended planned dose to the whole body should not exceed 25 rems.[2] These rules may be applied to the fire fighter for a single emergency; further exposure is not recommended. Internal radiation exposure may be guarded against by adequate respiratory equipment.

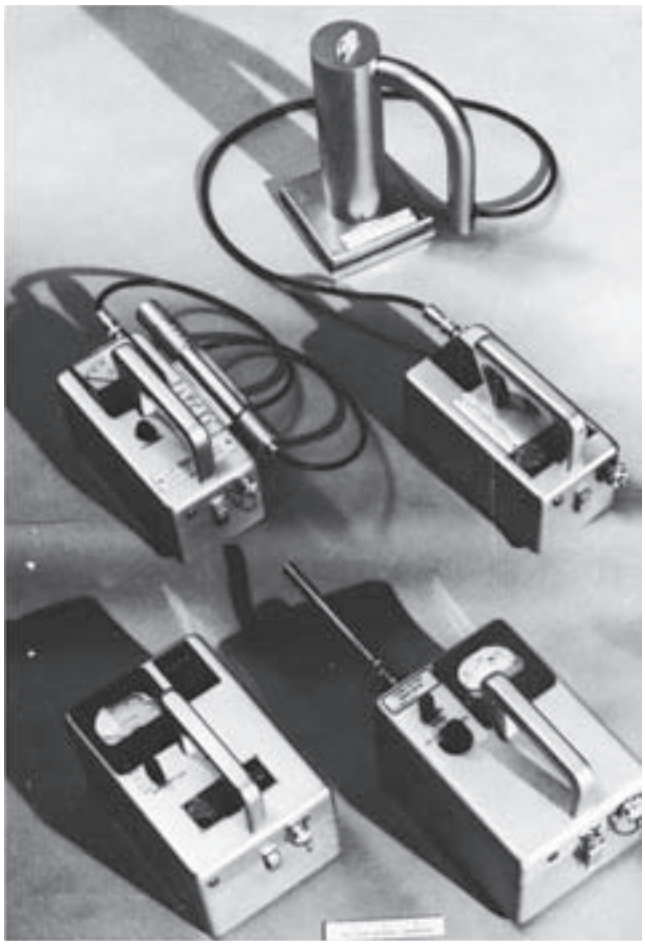

FIGURE 9.15.3 Portable Instruments for Measuring Radioactive Emissions

External exposure at the time of a single fire emergency can be judged by the use of commercial radiation survey meters, which measure radiation in roentgens or by counted disintegration rates, or by the close observation of the dosimeter indicators individuals carry. Pocket-sized dose rate alarms, which can be carried on the person, are also available. These give an audible signal dependent on radiation intensity. Film badges do not provide immediate information.

A rescue procedure that would combine external and internal radiation exposure is usually not attempted. SCBA should be used when instruments indicate the presence of airborne radiation.

Property Contamination

Entire buildings, land, and important equipment can be rendered unusable for long time periods because of severe radioac-

tive contamination from the inadvertent escape of radioactive substances. Radiological contamination may not stay in one area—it can sift through openings or ventilating systems in the form of dust or vapor and spread throughout a structure. Careless movement of persons through a contaminated area could also spread contamination to an uncontaminated area. Once a surface has become contaminated, a decision must be made as to how to remove the particular contaminating material, if this is possible. Vacuum cleaning can sometimes remove radioactive dust from building surfaces. If vacuum cleaning is used, however, highly efficient particulate filters must be used on the exhaust. Some surfaces can be hosed with water. Cleaning with soap and detergents is often a hand operation. The amount of exposure that persons doing the cleaning may tolerate must be continuously checked. Sand or vacuum blasting can be used on some surfaces, and paint may cover alpha contamination.

FIRE PROTECTION

As noted previously, substances and operations involving radioactive substances or devices presenting radiation hazards have the same fire and explosion features as those of similar materials and operations without radiation hazards. The presence of radiation or of radioactive substances affects the loss caused by fire, explosion, and accident in the following ways:

- Possible interference with manual fire fighting due to the presence of harmful radiation or possible criticality of radiation levels
- Possible increased delay in salvage and in normal resumption of operations due to the necessity of decontaminating of buildings, equipment, or materials

In properties where atomic energy is a factor, an in-plant fire protection force is recommended. In nuclear reactors, and many other such plants, 24-hour/day routines must be maintained for handling fires and emergencies. (See NFPA 600, *Standard on Industrial Fire Brigades.*)

Plan for Handling Fires

In plants involving a nuclear reactor, radiation machines, and in other facilities handling radioactive materials, the problems affecting decisions on how best to deal with a fire or other emergency are not those types of problems that can be solved by simply calling the public fire department. As many decisions as possible must be made with respect to the types of fire or emergency to be expected—and these decisions must be made well in advance. The particular fire-fighting and personnel safety measures to be taken may involve shutting down or isolating parts of the plant or individual equipment items. The areas where special procedures are necessary must be identified, and the procedures for these special areas thoroughly understood by all plant/facility personnel.

Fire emergency arrangements should include provisions for prompt notification of the plant emergency organization and public fire department, usually through a public fire alarm signal box. However, the plant fire protection department must preplan fire-fighting operations with the local fire department so that the local department will be properly coordinated with the plant's own emergency plans. Emergency planning should include measures to prevent the spread of contamination and to promptly decontaminate the area in case of accidental release of radioactive substances.

Fire fighters and other emergency personnel operating in areas where radiation exposure is a danger must be fully trained and be provided with suitable protective clothing. Respiratory protective equipment is a must, and competent radiological advisors, equipped with instruments for measuring area and local exposure, are necessary to guide emergency personnel. Dosimeters or other instruments for recording each individual's accumulated radiation exposure are helpful.

A nuclear reactor site must have a generous water supply to facilitate fire control and decontamination operations. Facilities must also be prearranged for safe disposal or storage of water that may be contaminated. The use of noncombustible materials for reactor buildings and equipment will help to avoid complications of fire hazards. For example, all finish materials used for decorative, acoustical, or insulation purposes should be both noncombustible and easy to decontaminate.

The hazard of a reactor structure exposing other buildings to radiation is prevented by appropriate distance separation or fire barriers. To prevent exposure to the reactor, it is always appropriate to separate shops and service spaces from the reactor equipment and structure itself. Wiring ducts in floors introduce an opportunity for fire or contaminated liquid or gas to spread from one space to another. Good duct seals separate one space from another. Subassembly or other operations in the preparation of fuel elements for reactors is carried on in work areas separated from the reactor so that fire cannot reach the reactor space.

Equipment for Fighting Fires

Automatic sprinkler systems or specially designed piped water spray systems are the first choice for fire protection in any location where fires may occur in nuclear reactor plants, properties housing radiation machines, and facilities handling radioactive materials. Sprinklers can operate with full effectiveness under radiation or contamination conditions that would make approach by fire fighters impossible.

In spaces where water used in fire fighting is subject to possible contamination, the collection and disposal of this water must be provided for in the local facilities; this means the facilities should have waterproofed floors and controlled floor drainage. Substantial capacity of such drainage systems would be required if hose streams and manual fire fighting were necessary. By contrast, sprinklers or a specially designed spray system would require relatively modest amounts of water for fire fighting.

If a fire occurs in a containment vessel during construction, the difficulties of access and visibility warrant the provision of temporary fixed automatic extinguishing systems when combustibles cannot be effectively controlled. Temporary interior hose stations and an ample supply of portable extinguishing equipment should be within easy reach in all portions of the vessel. Because of the smoke confinement potential, only very fast

manual response may be effective; hence, the available manual fire-fighting equipment should be in excess of normal construction practice to ensure the earliest response.

Incompatible Materials

Careful design analysis is required to reduce the fire protection problems inherent in the use of materials that are incompatible in fire situations. For example, the contemplated use of liquid metal as a reactor coolant/moderator requires special extinguishing systems not compatible with water; in fact, the possibility of a water-liquid metal reaction may justify the exclusion of water systems from the area. Such a decision, however, imposes severe limitations on the presence of flammable oils, plastics, foam insulations, and other materials that generally require copious quantities of water for fire extinguishment. Where such mixed hazards exist, careful consideration must be given to the potentials for a failure in one system to cause a failure in the incompatible system. In such cases, either protection systems must be provided that can ensure the extinguishment of fire in either system before it can rupture the other system, or a single protection system (such as inerting) must be developed that is adequate for either hazard. The difficulties inherent in such problems warrant the most thorough hazards analysis at the earliest design stages.

Water is a preferred fire suppression agent in many cases due to its high effectiveness in suppressing fires, its low cost, and its general availability. Water from sprinkler systems, water spray systems, and hose streams can be used effectively in nuclear facilities to reduce the nuclear safety impact of fires. However, the positive fire control contribution of water as a suppression agent in nuclear facilities must be balanced against the detrimental effects of water if used indiscriminately in nuclear facilities. Because of the very positive fire suppression capabilities of water and the potentially highly detrimental effects of uncontrolled fires in nuclear facilities, the use of water should not be dismissed just because its use may have some undesirable effects.

The use of water as a fire suppression agent introduces the potential for spread of water-borne contamination. Means of confining potentially contaminated fire-fighting water must be provided. In addition to providing for confinement of potentially contaminated water, radwaste processing systems should have sufficient capacity to process the amounts of water that may be discharged for fire fighting. Automatic sprinkler systems provide the advantage of discharging only limited amounts of water and only in locations where fires are actually burning, thus limiting the total amount of water that may become contaminated. Further, automatic sprinklers have high effectiveness in controlling fires and a very low frequency of inadvertent water discharge.

Where combustible and fissile materials may be present, it may be desirable to eliminate water suppression systems due to the concern for the neutron moderating and reflecting effects of the water and the potential for unintentional nuclear criticality (i.e., accidental, self-sustaining nuclear fission reactions). Some nuclear criticality specialists are reluctant to allow the use of water to control fires where fissile materials are present, even when the degree of fire hazard dictates that providing automatic sprinklers would be prudent. Such reluctance is certainly understandable, but not necessarily justifiable in all cases. In many, if not most, situations where both combustible and fissile materials are present, water spray or sprinkler protection can and should be provided. Nuclear criticality safety analyses can predict and include the neutron moderating effects of sprinklers. A safety system that simultaneously maintains fire safety and criticality safety at acceptable levels can include automatic sprinkler protection.

SUMMARY

Fires in facilities that store or use nuclear material are especially dangerous, because of the hazards of nuclear radiation and contamination. In nuclear reactors, a high degree of fire protection is necessary to ensure that fires will not significantly degrade the level of nuclear safety. The primary goals of fire protection are preventing fires from occurring; detecting and quickly extinguishing those fires that do start; and preventing the spread of those fires that have not been extinguished. These goals can be achieved by plant construction design, a combination of automatic and/or manual fire-fighting techniques, and passive fire barriers and physical separation. For radiation machines, general fire protection and prevention measures should include the use of noncombustible or limited-combustible construction housing, noncombustible or slow-burning wiring and interior finishing, and the elimination of as much other combustible material as possible. All equipment used for handling and processing radioactive materials should be designed to minimize fire and explosion potentials, as well as to protect personnel against harmful radiation exposure and prevent damage to property by contamination. In any facility handling radioactive materials, emergency planning and coordination with the local fire department are essential, including provisions for alarm systems, fire suppression systems, personal safety equipment, radiation measuring, and procedures that minimize the spread of contamination.

Chapter 16

Mining and Mineral Processing

Larry J. Moore

Chapter Contents

Surface Mining Methods
Underground Mining Methods
Mineral and Coal Processing Methods
Fire and Explosion Hazards
Fire and Explosion Safeguards

Key Terms

coal fuel, coal mining, coal preparation plant, explosion, methane, mine safety, mineral processing, mining (contour), mining (metal and nonmetal), mining (open pit), mining (strip), mining (surface), mining (underground), ore mining, smelting

This chapter describes typical mining methods, the excavation and distribution equipment used in mining, and the various and typical mineral concentration or coal preparation processes used to convert mined materials into intermediate or final consumer products. Fire and explosion hazards presented by the mining and processing of coal, metal and nonmetal ores, structural and construction materials are the focus.

Examples of coal are bituminous, anthracite, and lignite grades. Examples of metal ores are those of gold, silver, lead, copper, nickel, iron, aluminum, and zinc. Nonmetal minerals are materials such as fertilizers (e.g., potash, soda ash, and phosphate), gemstones (e.g., diamonds), salt, and sulfur. Nonmetal structural materials include limestone (used in cement), sand, gravel aggregates, and quarried materials such as marble, granite, and sandstone.

Mining is defined as the process of gaining access to and extraction of minerals, materials, or coal from the earth. The goal of mining is to economically remove desirable raw mineralized ore or materials and transport these raw materials to the next point of use or processing (Figure 9.16.1).

Mining can be done underground, on the earth's surface, or on or under bodies of water. Underground and surface mining is prevalent, with surface strip or open pit mining being the preferable and most common form of mineral or coal extraction due to economics.

Surface mining involves removing all overlying layers of dirt and rock strata—called overburden—before excavating desired materials. Underground mining is used where the overlying strata are so thick that it is uneconomical to reach the desired ore or mineral from the surface. In some cases, an open pit surface mine reaches a practical and safe limit of depth, often defined by pit wall slope stability or other geotechnical factors, and underground mining commences from the bottom of the pit. Desirable minerals located under shallow bodies of water are usually mined using a dredge, which is a floating excavation and processing plant.

Following extraction, the mined ore or coal and waste rock are removed from the mine and transported or distributed to the next point of use, a processing mill (concentrator facility) or coal preparation plant. The process of ore and mineral distribution and transportation, whether using large haul trucks, hoist systems, rubber belt conveyors, and/or large reclaim equipment, presents many fire hazards.

The goal of mineral processing or coal preparation is to convert the mined material into a more concentrated or consumer usable form. Processing of ores, coal, and nonmetal materials takes many forms and includes sizing (crushing, grinding, and milling), cleaning, separation of desirable ores or materials from undesirable waste, chemical treatment, and often electrical or heat refining. In the case of coal, preparation usually takes the form of simply sizing, cleaning, and drying the coal for shipment to a power plant. In the case of metal ores, many complex processes—such as flotation, leaching, or solvent extraction using combustible or flammable reagents—are often needed to remove the desired metal from undesired elements (such as sulfides and pyrites). Mineral processing plants (called concentrators or mills) and coal preparation facilities are usually on the mine site or nearby the mine.

Larry J. Moore, P.E., is the past chairman of the NFPA Mining Facilities Committee and has been with FM Global his entire career in a variety of engineering and management positions. He is currently the corporate principal engineer for mining and metallurgical refining and has a professional engineer's license in fire protection engineering.

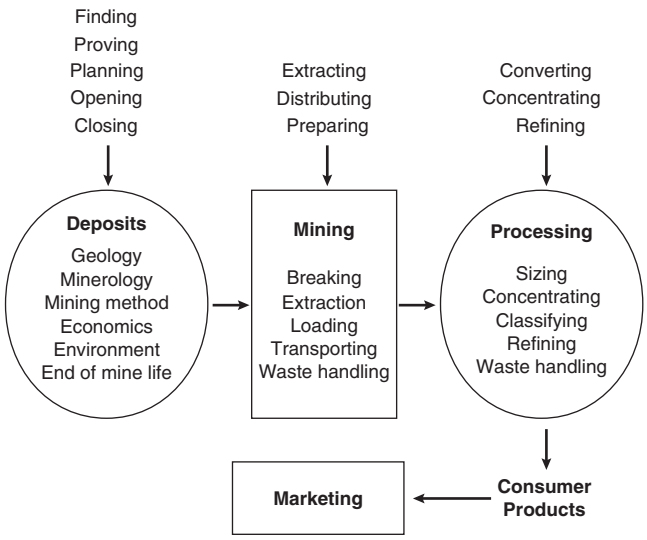

FIGURE 9.16.1 Mine Development and Life Matrix (Source: Property Loss Prevention Data Sheet 7-12, "Mining and Ore Processing Facilities"; © 2006 Factory Mutual Insurance Company. Reprinted with permission. All rights reserved.)

Large pyro- or electrometallurgical smelters and blast furnaces or hydrometallurgical chemical plants are often used to produce final metallic products such as aluminum, gold, copper, zinc, cobalt, nickel, steel, and lead from concentrated ores produced in mineral processing facilities. These facilities are usually remote from actual mining sites and are not applicable to this chapter.

The following chapters contain additional information relevant to mining and ore processing hazards: Section 2, Chapter 8, "Explosions"; Section 6, Chapter 8, "Dusts"; Section 6, Chapter 15, "Explosives and Blasting Agents"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 8, Chapter 11, "Fluid Power Systems"; and Section 14, Chapter 8, "Gas and Vapor Detection Systems and Monitors."

SURFACE MINING METHODS

Numerous surface mining methods have evolved in response to varying surface and subsurface geological conditions and to continual improvement in mining equipment technology. Methods of surface coal mining, or strip mining, include area strip mining and various forms of contour mining.[1,2]

Crushed stone and dimension stone are mined from rock quarries. Stone for crushed aggregate generally is mined by conventional open pit methods. Dimension stone is removed in large blocks using wire saws, channeling machines, or similar means.

Other than maintenance facilities, the surface mining process involves few fixed structures. Rather, surface mining is performed outdoors by specialized mobile and portable mining equipment. Major equipment types and their primary functions include blasthole drills to drill holes for explosives (used in both overburden and coal or ore); stripping machines, such as draglines, stripping shovels, and bucketwheel excavators, for overburden removal; equipment, such as shovels, wheeled loaders, and hydraulic excavators, for loading overburden, coal, or ore at the working face; and haulage trucks, trains, or conveyors to transport materials from the working face to storage or processing facilities.[3]

The mining process requires support from a wide variety of miscellaneous equipment. This equipment includes scrapers, explosives haulers, dozers, graders, water trucks, pumps, power substations, generators, crushers, cranes, backhoes, and maintenance and utility vehicles.

Area Strip Mining

Area strip mining is practiced where terrain is relatively flat, mineral seams are moderately thick (3 to 30 ft [0.9 to 9 m]) and overburden seams are relatively shallow. Strip mining is most often used for coal. Most surface coal mining in the midwestern states and the less mountainous areas in the eastern and western coal fields employs the area strip mining method. It begins with removal of overburden from above the coal seam in a roughly linear strip usually 100 to 170 ft (30 to 52 m) wide and several miles long. Overburden depths of 60 to 120 ft (18 to 37 m) are common. Uncovered coal is loaded into trucks and hauled to storage or processing facilities. When an entire strip has been mined, the process is repeated, with the overburden above the adjoining strip of coal cast onto spoil piles in the cut previously mined (Figure 9.16.2). Stripped areas are recontoured and reclaimed.

Contour Mining

Contour strip mining is most common where flat-lying coal seams occur in rolling or mountainous terrain, typical in many parts of the Appalachian coal field. In contour mining, an initial cut is established along a hillside at the point where the coal seam outcrops or is exposed. Successive cuts then are made into the hillside until an economic stripping limit is reached. Mining proceeds laterally along the hillside, following the outcrop. Contour mining follows the same overburden removal/coal loading cycle as area strip mining but generally employs much smaller equipment.

Open Pit Mining

Most surface metal and nonmetal mining is by the open pit or open cast method.[4] The overburden is first stripped to expose the top of the ore body; stripping and mining then proceed concurrently. The pit expands in depth and area until an economic pit limit is reached (Figure 9.16.3). Pit geometries vary, owing to ore bodies' irregular shape and orientation, but dimensions of 0.5 mi (0.8 km) to several miles across and 100 to over 1000 ft (30 to 305 m) deep are common.

Specialized Mining Systems

Specialized mining systems resembling metal and nonmetal open pit methods have been developed for multiple, steeply pitched, and/or thick seams. Some of the largest and most pro-

FIGURE 9.16.2 Area Strip Mining

FIGURE 9.16.3 Open Pit Mine

ductive surface coal mines in the world are located in Wyoming and Montana, where these methods are used to mine coal seams 200 ft (61 m) thick or more.

Specialized mining systems are used for certain metal and nonmetal ore deposits. Examples include dragline stripping and hydraulic removal of phosphates, placer mining, and dredging of alluvial beach sands, gold, and tin. Sand and gravel generally are mined from shallow pits and small surface excavations or with draglines and dredges from natural or artificial ponds.

UNDERGROUND MINING METHODS

Access to underground mine workings from the surface is by shaft, slope, adit, or entry. A shaft is a vertical or nearly vertical opening, usually equipped with hoisting facilities for transporting personnel, supplies, and mined products. A slope—also called an incline or decline—is an inclined opening that may be designed to accommodate a belt conveyor for materials haulage, a hoist for personnel and supplies, or diesel trackless haulage. An adit mine, or drift mine, is entered through a horizontal opening in a hillside. The term *adit* is used for metal and nonmetal mines and the term *entry* is used for coal mines. An individual mine may employ any or all of these access means, depending on the depth and orientation of its coal seam or ore body and the requirements of its production and materials-handling systems.

Where a single, uniform, relatively flat-lying coal seam or ore body is worked, the entire mine is generally confined to a single working level. Where multiple, irregularly shaped, and/or steeply inclined coal seams or ore bodies are worked, mining may be spread over many levels. Large mines may comprise miles of drifts or entries, which are horizontal openings in metal or coal mines, respectively, on many levels and interconnected with shafts, slopes, raises (vertical openings between levels), and ramps (inclined openings between levels).

The predominant constraint influencing the underground mining method selected is the amount of support required to prevent failure of the roof and/or walls. Factors related to this constraint are the physical character, size, shape, orientation, and depth of the coal seam or ore body, and the characteristics of the surrounding and overlying strata. In addition, planned production capacity and the presence of water, methane, high-rock temperatures, radon, or other environmental factors may be important considerations in selecting a mining method.

Mine designs and operating practices vary widely, since nearly infinite variability exists among these factors from deposit to deposit and even within a single mine. However, the broad spectrum of underground mining methods can be subdivided into three generic classifications:

1. Methods that produce openings that are naturally supporting or that require minimal artificial support
2. Methods that provide for substantial artificial roof support
3. Caving methods, where roof failure is integral to the mining process

With few exceptions, coal mining systems differ from non-coal mining systems, and this chapter treats them separately. Similarities that do exist are limited to softer, bedded nonmetallics, such as potash, salt, and trona, which are often amenable to coal mining systems and equipment.

Underground Coal Mining

The two basic coal mining methods are (1) room-and-pillar, which produces naturally supportive openings, and (2) longwall, which requires substantial artificial support.[1] As its name implies, room-and-pillar mining involves extracting coal in a regular pattern of rooms separated by pillars of in-place coal to support the roof (Figure 9.16.4).

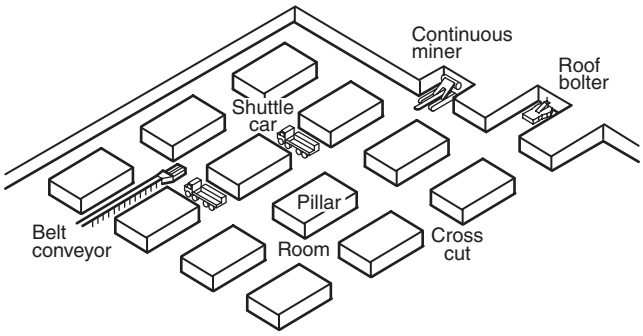

FIGURE 9.16.4 Room-and-Pillar Coal Mining

Room-and-Pillar Method. Two systems are used for room-and-pillar coal mining: (1) conventional and (2) continuous. Of the two methods, continuous mining is much more common in the United States. In conventional mining, coal is extracted in a sequence of operations, and executing each step requires specialized equipment. A cutting machine resembling a large chain saw cuts a slot into the coal face across the entire width of the room along the floor, center, or roof line. Next, a drill bores holes for explosives in the coal face. A loading machine gathers coal broken by the explosives. The machine either feeds a self-propelled shuttle car or may be loaded and hauled by a self-propelled diesel or electric scoop. In either case, coal is discharged onto a conveyor belt or into rail cars for transport to the surface or to hoisting facilities.

In continuous mining, a single machine called a "continuous miner" mechanically cuts coal from the face using a rotating drum fitted with dozens of cutting picks. The continuous miner also has a means for gathering broken coal and loading it into a shuttle car or self-propelled scoop. After each drill-blast-load cycle in conventional mining, or each machine advance in continuous mining, the mining equipment is withdrawn, and a machine called a "roof bolter" secures the roof. Holes are drilled into the roof, and long bolts are inserted and anchored to strengthen the roof span and prevent roof failure.

Longwall Mining Method. Longwall mining involves extracting coal (and occasionally soft deposits like Trona, which is the mineral form of sodium sesquicarbonate) in a nearly continuous operation using a specialized, integrated mining and roof support system (Figure 9.16.5). Using standard room-and-pillar techniques, blocks of unmined coal called longwall panels are prepared. These blocks are typically 300 to 1000 ft (90 to 305 m) by 3000 to 6000 ft (915 to 1830 m); however, "super longwalls" with lengths of 20,000 ft (6100 m) or more are possible. Each longwall panel is mined in linear slices at full seam height by a mechanical cutting machine or plow drawn back and forth across the short face. Cut coal is forced onto a chain conveyor that extends the face's entire length. Large, self-advancing hydraulic jack units called longwall shields support the roof immediately adjacent to the face. As the roof support line advances with the coal face, the roof behind it is permitted to cave. Longwall mining is more productive and generally considered safer than conventional or continuous mining.

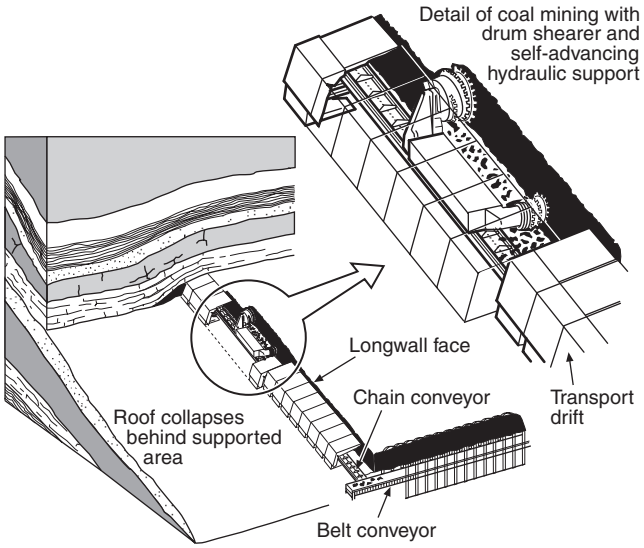

FIGURE 9.16.5 Longwall Coal Mining (Source: Courtesy of Atlas Copco)

It accounts for about 35 percent of U.S. underground coal mine production.

Coal Mining Equipment

Most coal mining equipment is electrically powered. Electrically powered mobile equipment, such as undercutting machines, drills, loading machines, continuous miners, shuttle cars, scoops, and roof bolters, generally receive power through a trailing cable. Belt conveyors, pumps, and trolley haulage systems are generally wired directly to a permanent or semi-permanent power center. Battery-powered scoops, personnel transports, and utility vehicles are also common. Some mobile haulage equipment, notably scoops, load-haul-dump (LHD) vehicles (low-profile front-end loaders, also called *scoop trams*), and rail locomotives, can also be diesel powered. Although significant and growing, diesel-powered equipment is not as extensively used as electrically powered equipment in underground coal mining.

Ancillary Operations

Numerous ancillary operations must be coordinated with the mining process. The main haulage network, whether rail or belt, must function smoothly to prevent materials-handling bottlenecks from interfering with production. The roof in active areas is constantly monitored for failures or signs of impending failure. In heavily traveled areas, such as main haulageways and important ventilation routes, heavy timbers or steel arches or beams are often installed to help support the roof. Water supply, power distribution, and ventilation systems require periodic attention; equipment and facilities inspection, maintenance, and repair are continuous. Dust control also receives high priority, both to protect miners' health and to prevent explosive conditions.

Underground Metal and Nonmetal Mining

Underground metal and nonmetal mining methods are more diverse than underground coal mining methods, because the physical character, size, shape, and orientation of these ore bodies vary more greatly than most coal seams.[5] The following paragraphs describe six standard mining methods. In actual practice, great variability, combination, and adaptation of standard methods are required to suit local conditions.[6] Room-and-pillar and sublevel stoping methods are used in extraction areas that require minimal artificial roof support. Shrinkage stoping and cut-and-fill are used in extraction areas that require substantial roof and wall support. The two most common caving methods are sublevel caving and block caving.

Room-and-Pillar Method. The room-and-pillar method (Figure 9.16.6) is used for relatively flat-lying deposits of moderate thickness with a competent roof. With the exception of the softer, bedded nonmetallics, metal and nonmetal mine openings are generally larger than those in typical room-and-pillar coal operations, permitting the use of larger, more productive mining equipment.

Sublevel Stoping Method. Sublevel stoping, used in vertical or nearly vertical ore bodies of highly competent rock, requires considerable premine development to prepare the ore body for production mining. Sublevel drifts along the longitudinal centerline of the ore body are driven in a vertical column between the mine's main levels (Figure 9.16.7). On the main haulage levels, drawpoints perpendicular to the sublevel drifts are driven into the ore body. A complete radial pattern of blastholes, or parallel rows of vertical blastholes, is then drilled at regular intervals along the entire length of each sublevel drift. Each ring or row of holes is loaded individually with explosives and blasted. Every blast vertically slices ore, which falls to the bottom of the open cavity, or stope, where it is loaded out through the drawpoints.

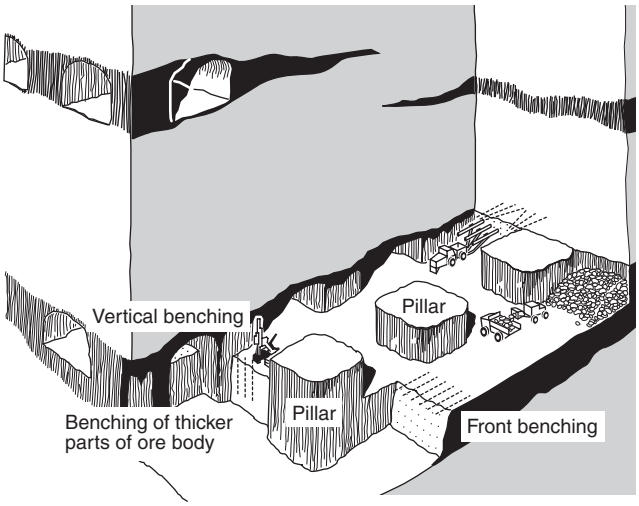

FIGURE 9.16.6 Room-and-Pillar Metal and Nonmetal Mining (Source: Courtesy of Atlas Copco)

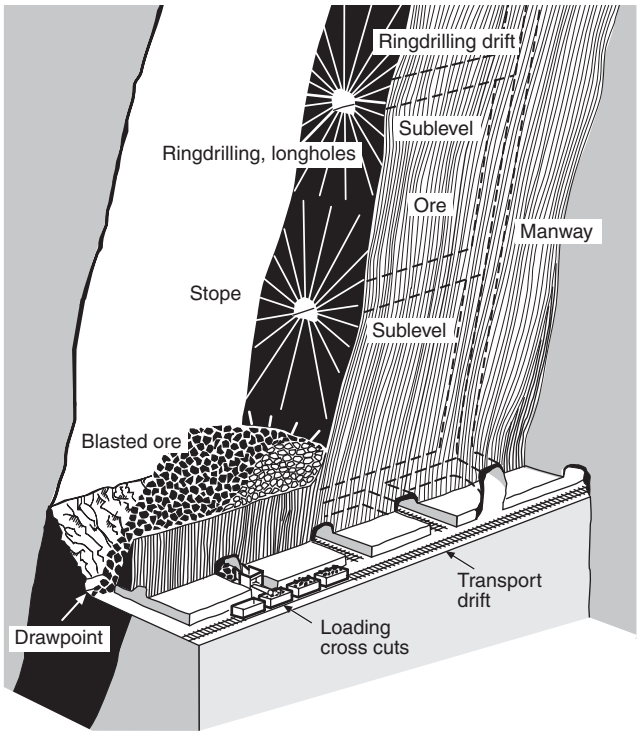

FIGURE 9.16.7 Sublevel Stoping (Source: Courtesy of Atlas Copco)

Shrinkage Stoping Method. If the ore or surrounding rock is too weak or the rock pressures too great, open stopes are not feasible. Such ore bodies require artificial support of the stopes during mining. Shrinkage stoping and cut-and-fill stoping are most commonly employed to extract such ore bodies. Shrinkage stoping requires very little preproduction development. Drawpoints are driven into the ore body at regular intervals along the main levels, and raises are driven into the ore between levels (Figure 9.16.8). The ore is extracted in horizontal slices, starting at the bottom of the stope and advancing upward by drilling and blasting the roof. Just enough broken ore is removed from the stope to provide a work platform for miners. Ore remaining in the stope supports the walls and prevents adjoining rock from breaking loose and contaminating and diluting the ore. The process of mining horizontal slices repeats until the upper limit of the stope is reached. The stope is then emptied of ore.

Cut-and-Fill Method. Preproduction development for cut-and-fill mining is similar to that for shrinkage stoping, except it requires only one or two drawpoints (Figure 9.16.9). Mining is similar as well, with the ore body mined in horizontal slices from bottom to top. However, the stope is emptied of broken ore after each slice, or cut, and the stope is filled with waste material before mining resumes. The fill provides a work platform for miners and supports the stope walls. Ore is removed from the stope through timber or steel ore chutes embedded in the fill.

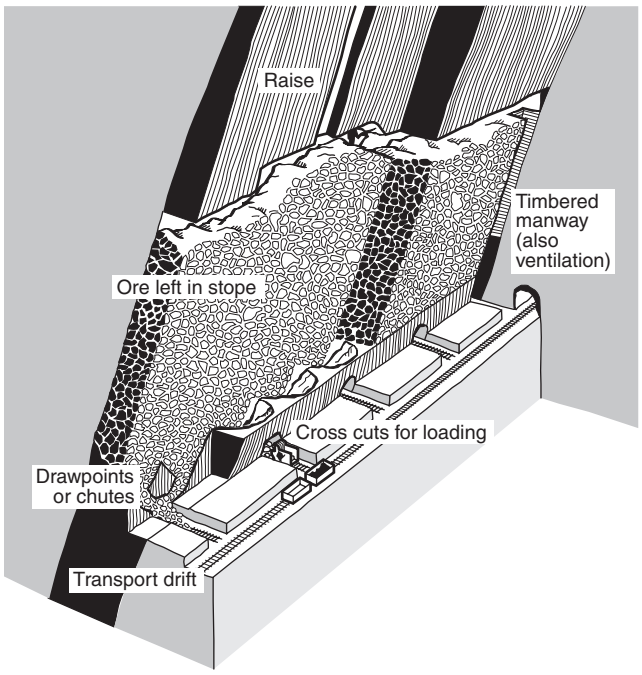

FIGURE 9.16.8 Shrinkage Stoping (Source: Courtesy of Atlas Copco)

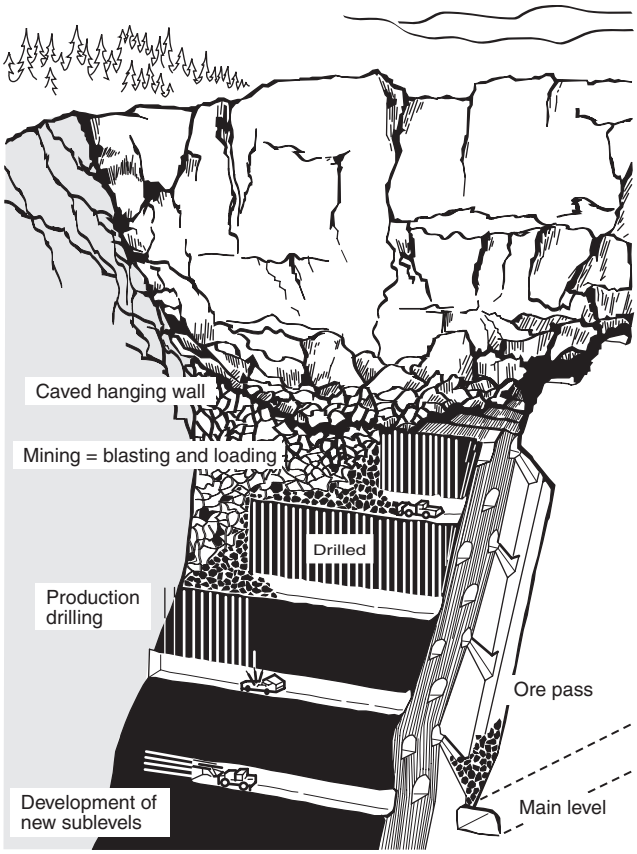

FIGURE 9.16.10 Sublevel Caving (Source: Courtesy of Atlas Copco)

Sublevel Caving Method. A high degree of mechanization, high production capacity, and low production costs characterize caving systems. In sublevel caving, preproduction development is similar to sublevel stoping, with sublevel drifts driven into the ore at 30 to 50 ft (9 to 15 m) intervals (Figure 9.16.10). Drawpoints on the main levels are not required, how-

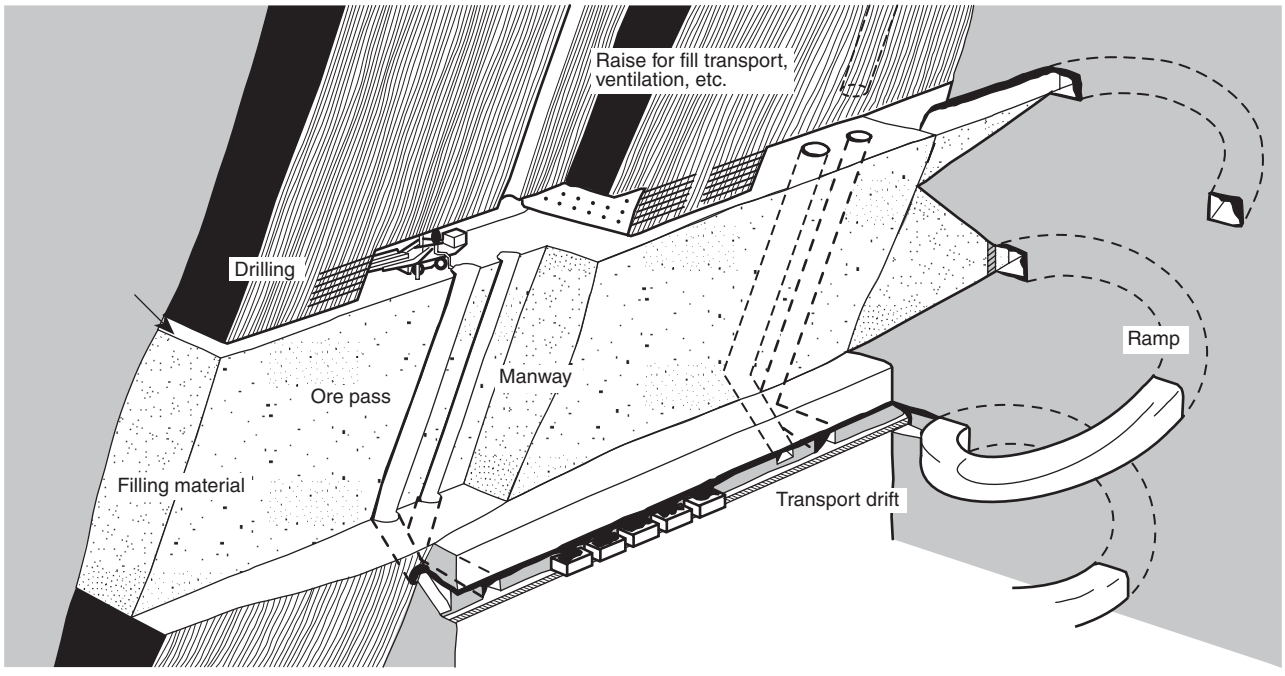

FIGURE 9.16.9 Cut-and-Fill Mining (Source: Courtesy of Atlas Copco)

ever, because the ore is retrieved through the sublevel drifts. Fan-shaped blasthole patterns are drilled upward at regular intervals along the entire length of each sublevel drift. Drill fans are blasted individually, with broken ore caving into the sublevel drifts. LHDs load the ore and transport it to an ore pass system.

Block Caving Method. The principle of block-cave mining is the natural fracturing and caving of ore that has been undercut over a large area. The ore extraction phase requires minimal drilling and blasting, because the ore fractures itself as gravity acts on the undercut rock masses.

Preproduction development is undertaken in four steps (Figure 9.16.11). First, a network of haulageways is developed beneath the ore horizon. Next, finger raises are driven up to a set of grizzly drifts. From the grizzly drifts, a second set of finger raises is driven, gradually widening to form funnels at the undercut level. Finally, the entire ore block is undercut.

The weight of overlying ore and overburden creates enormous stresses on the ore at the bottom of the block, causing it to fracture and cave into the funnels.

Equipment

A wide variety of equipment is used in underground metal and nonmetal mining. Where space permits, drilling is performed with mobile "drill jumbos" fitted with two or more rock drills. Diesel-powered LHDs are used to load and haul broken ore from the drawpoint or working face. Where space is limited, small, portable, manually operated rock drills perform drilling. Broken ore is loaded out by small pneumatic loading machines or by a scraper blade suspended on a cable between a hoist and a pulley, which gathers ore as it is dragged over a pile. Main haulage usually is accomplished with belt conveyors, rail cars, or haulage trucks.

As with underground coal mining, a vast array of ancillary operations supports the ore extraction process. Primary among these are the inspection, maintenance, and repair of mine equipment, which is performed at most mines in large underground shops. Mines relying on diesel equipment also must have facilities in which to store and/or transfer diesel fuel. In addition, power distribution, ventilation, hoisting, roof control, and dewatering are important ancillary operations.

With the dual goals of increasing productivity and removing miners from hazardous workplaces, emerging mining technologies in the coal and metal and nonmetal sectors employ modern automation and robotics technology. In the coal sector, significant research is aimed at both fully automated and teleoperated remotely controlled extraction and haulage systems. The metal and nonmetal sector has developed and deployed fully automated haulage systems based on both rail and trackless equipment.

MINERAL AND COAL PROCESSING METHODS

After extraction by one of the aforementioned mining methods, the mineral, structural material, or coal is transported to a processing facility or, in the case of coal, to a preparation plant

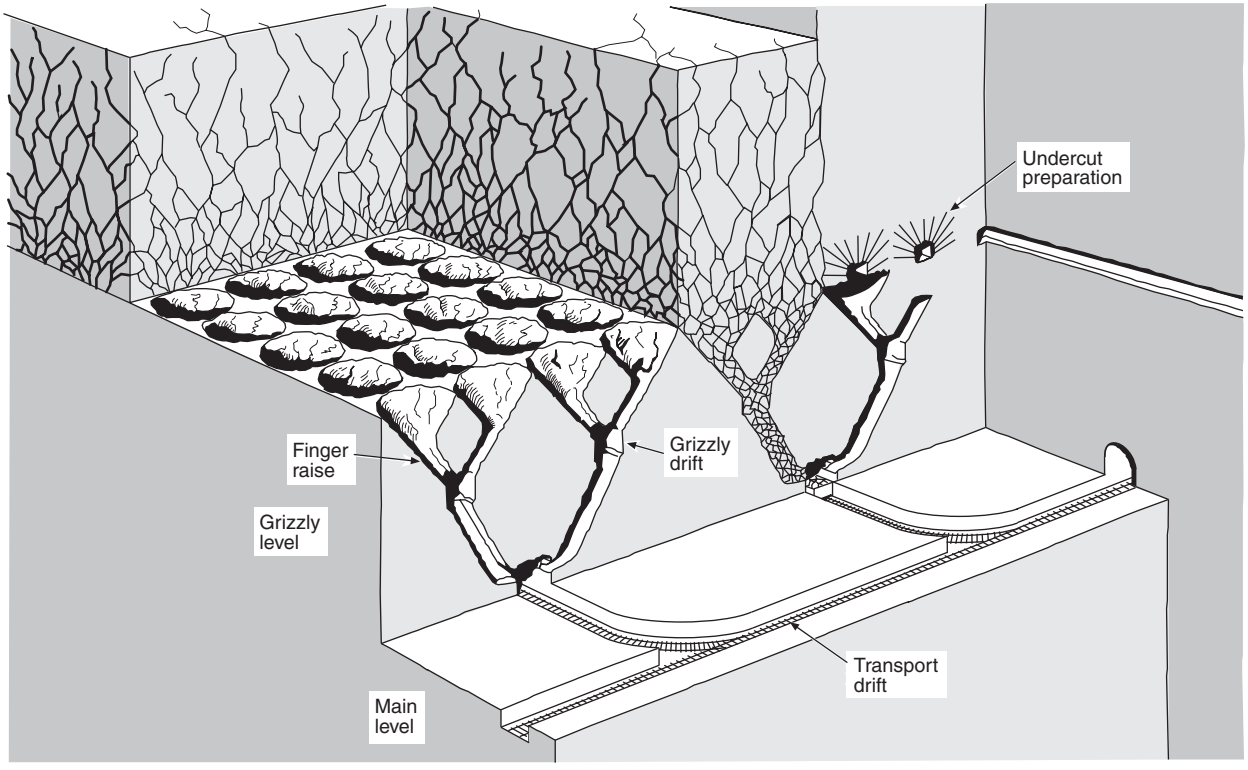

FIGURE 9.16.11 Block Caving (Source: Courtesy of Atlas Copco)

for conversion to intermediate or final consumer products. The processing facility is commonly located on or near the mining site due to the poor economics of transporting low-grade or run of mine (ROM) ores or coal over long distances. Waste rock or overburden from the mine may be used for road building or might be sent back to the mine for fill or for environmental remediation.

The purpose of the processing or preparation plant is to size, dry, clean, chemically convert, and/or concentrate the ore or coal (Figure 9.16.12). It also allows for removal and disposal of waste materials.

Prior to processing, the ore, structural material, or coal is transported from the mine by rubber belt conveyor, haul truck, tramway, sluice, pipeline, or other conveyance. The preprocessed ore or coal is usually stored in open stockpiles, silos, or inside buildings if susceptible to damage from the elements (such as water-soluble fertilizers like potash).

Structural materials such as granite and sandstone are cut to size, polished, stored, and shipped with little further processing or finishing. Aggregates such as sand and gravel are sized and washed also with little further processing. Limestone is often heat calcined in horizontal or vertical fuel-fired kilns or roasters and mixed on site with sand or gravel to produce cement or concrete.

Metal ores are subjected to many processing steps depending on the material. The most common processing facility is known as an ore concentrating or dressing mill. The first step is rough sizing whereby ore is crushed in large crushers and screened. Primary crushers may be located inside open pits or underground. Secondary crushers are usually located closer to the mill. Each crushing step further reduces the mineralized rock in size (Figure 9.16.13).

The crushed ore may be stored in intermediate stockpiles. Large semimobile or rail-mounted equipment and conveyors may be used to reclaim the ore for transport to further downstream processing.

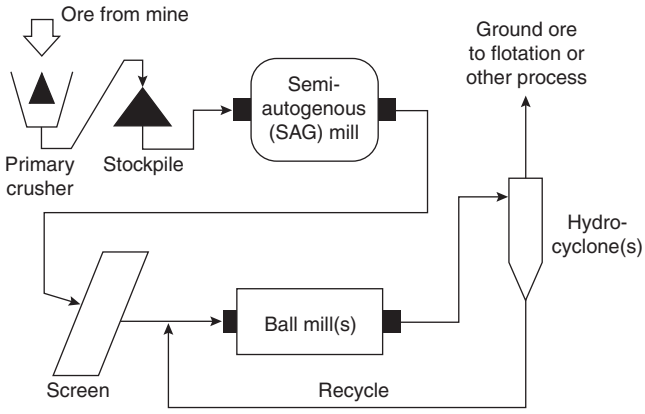

FIGURE 9.16.13 Typical Metal Ore Grinding Circuit (Source: Property Loss Prevention Data Sheet 7-12, "Mining and Ore Processing Facilities"; © 2006 Factory Mutual Insurance Company. Reprinted with permission. All rights reserved.)

After crushing, the rock is wet milled with water or low-grade acid solutions using ball or rod, semiautogenous grinding (SAG) mills, or fully autogenous grinding (FAG) mills. Wet mills reduce the rock to a fine, talc-like powder. These mills are large rotating machines that use steel balls, steel rods (less common), or ore-to-ore contact to reduce the particle size. World-class-size SAG mills are 35 ft (10.7 m) in diameter and may be driven by 10,000 hp electric motors (Figure 9.16.14).

Following fine grinding, the powdered ore is usually in a liquid slurry (or pulp) form and can be piped throughout the facility. Desired metal minerals are separated from undesired waste materials (called gangue) by separation processes such as flotation, spirals, thickening, gravity, shaker tables, or mag-

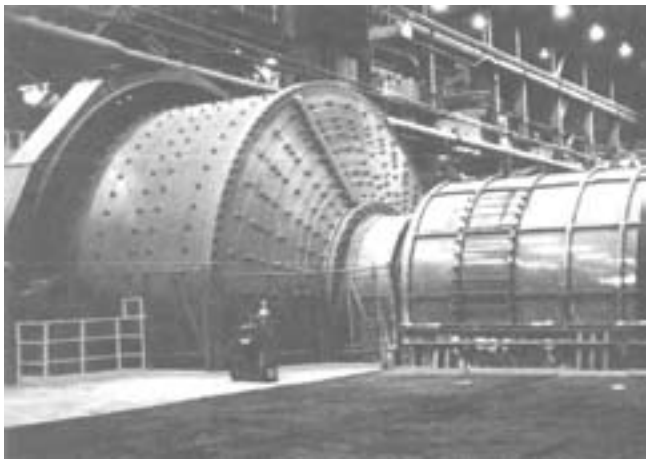

FIGURE 9.16.14 Semiautogenous Grinding (SAG) Mill (Source: Property Loss Prevention Data Sheet 7-12, "Mining and Ore Processing Facilities"; © 2006 Factory Mutual Insurance Company. Reprinted with permission. All rights reserved.)

nets. Mill circuits feature extensive rubber-lined equipment; plastic screens; rubber belt conveyors; grouped electric cables with combustible plastic insulation; large hydraulic, thermal, and lubrication oil systems; and combustible or toxic flotation reagents. In cold climates, concentration processes are located inside large industrial buildings. Plastic materials are often used in construction.

Some highly oxidized and low sulfide ores (notably copper and gold) can be directly processed by heap pad leaching. In this process, pyramidal-shaped mountains of ore are layered onto impervious layers such as clay or rubber liners by large earthmoving equipment, haul trucks, and conveyors. These man-made mountains of ore can be over 400 ft (150 m) high and thousands of feet (hundreds of meters) long and wide and can fill entire valleys. A water-based solution of weak cyanide (for gold) and/or sulfuric acid (for copper) is sprayed or irrigated onto the pile. The solution selectively dissolves the desired metals and is captured onto the impervious layer under the pile. The metal-rich pregnant solution is gravity-flowed or pumped to collection ponds from which it is sent to downstream processing. The pregnant solution, in the case of copper, is then processed by solvent extraction (SX) featuring flammable or combustible organic solutions and sent to an electrowinning plant for metal recovery. In the case of gold or other ores, there is a wide variety of alternate processes.

Waste materials from concentrating processes are pumped to a tailings disposal facility, where solids and liquids are separated and toxic or waste solids are permanently stored and environmentally monitored and controlled.

The desired product from an ore-processing mill is a moderately concentrated form of the metal ore. It is dried and filtered and then stored for further processing. Concentrates up to approximately 30 percent metal value can be obtained from this process.

Following concentration, the concentrate is further processed to remove remaining undesirable materials, notably common sulfides (pyrites) and iron-based compounds. These downstream steps are categorized as hydrometallurgical, electrometallurgical, pyrometallurgical, or chemical processes.

A typical pyrometallurgical process is one in which the concentrate is sintered, calcined, roasted, or smelted at high temperatures in the presence of oxygen or enriched air (Figure 9.16.15). This is typical for zinc, gold, copper, and lead. This process usually removes sulfides (which are often converted to sulfuric acid in emission control acid plants) and trace, undesirable iron compounds, which are disposed of as slag.

Examples of hydrometallurgical processes are pressure oxidation leaching of gold using high-pressure chemical reactors (called autoclaves in the industry), zinc lixiviation using acids, and solvent extraction of copper or uranium using flammable or combustible organic liquids.

Examples of electrometallurgical processes are electrowinning (Figure 9.16.16), often used for gold and copper, and electrorefining, often used for aluminum and zinc. Highly specialized electrical and chemical processes are used to recover titanium, zirconium, and magnesium. Chemical reduction reactions using hydrogen or hydrogen sulfide gases are used for nickel, cobalt, and direct reduction iron. All these specialized processes present unique and often challenging fire and explosion exposures.

FIGURE 9.16.15 Large Copper Smelting Facility (Source: Property Loss Prevention Data Sheet 7-12, "Mining and Ore Processing Facilities"; © 2006 Factory Mutual Insurance Company. Reprinted with permission. All rights reserved.)

FIGURE 9.16.16 Electrowinning Plant for Copper (Source: Property Loss Prevention Data Sheet 7-12, "Mining and Ore Processing Facilities"; © 2006 Factory Mutual Insurance Company. Reprinted with permission. All rights reserved.)

Diamond-bearing ores are initially processed similar to metal ores (crushing, screening, etc.) but do not use flotation with reagents. Processes such as Dense (or Heavy) Media Separation are used instead.

Coal processing—usually called preparation—is used to clean (remove impurities), wash, dry, and size the coal prior to further downstream use. Most downstream use of coal is for power plants or for producing steel. Many of the coal preparation processes and hazards are similar to those of metal ore concentrating plants, including sizing, grinding (or pulverizing), flotation, and filtering. Large thermal coal dryers using

combustible fuels or thermal oils may be used. A coal preparation plant also has unique hazards of dust and methane gas explosions and the potential for spontaneous heating inside coal piles or silos. Waste from preparation processes is pumped to a coal impoundment facility, where solids and liquids are separated and toxic or waste solids are permanently stored and environmentally monitored and controlled.

FIRE AND EXPLOSION HAZARDS

Mining and mineral processing facilities represent significant fire and explosion exposures to both personnel and production equipment and buildings.

From a personnel safety standpoint, underground mining has been by far the global loss leader in fatalities and injuries for all industries. In the 100 year period from 1900 to 1999, over 100,000 miners died from all unintentional-injury causes, including fire and explosions, in U.S. coal mine incidents alone, an average of 1040 per year. In the 10 year period from 1990 to 1999, this figure had been reduced to 450 fatalities, or an average of 45 per year. Approximately 10 to 15 percent can be attributed directly to fires and explosions.[7]

Life threatening incidents, though more common in coal mines, have also occurred in the noncoal (metal and nonmetal) mining industry. In the same 100 year period ending 1999, approximately 23,000 miners died in various incidents in noncoal mines, including fire and explosions. To put this in recent perspective, on May 2, 1972, a fire in the underground workings of the Sunshine silver mine in Kellogg, Idaho, claimed 91 lives.[8]

In the most recent 5 year analysis period (2000 to 2004) 116 fatalities have occurred in all types of mining, of which 83 occurred in underground coal mining and 16 in underground metal mines.[9]

Early in 2006 several major underground mine incidents occurred resulting in multiple fatalities and extended emergency rescue operations. At the Sago Coal Mine (West Virginia, January 2006), 11 miners died after suspected surface lightning ignited underground gases causing an explosion. Later that same month a rubber belt conveyor fire in the underground Alma coal mine (also in West Virginia) caused two fatalities and forced rescue of many others. In February 2006, a coal mine fire in Mexico caused 65 fatalities. Topping this off are an estimated 10,000 fatalities a year in Chinese coal mines.

In January 2006, heavy smoke from an incidental fire involving plastic piping in a Canadian potash (nonmetal) mine trapped 72 miners underground. All were rescued. Many additional fires occur in underground metal mines that go unreported or do not involve personnel injury.

Table 9.16.1 shows mine disasters since the early 1880s, for both coal and noncoal mines.[7] This is for all incidents, but fires and explosions, followed by collapse, represent the vast majority of multifatality disasters. Tables 9.16.2 and 9.16.3 show a listing of selected historic mine disasters.[7] Table 9.16.4 shows ignition sources of underground mine fires.

These and additional statistical information for U.S. mining can be found on the Mine Safety and Health Administration

(MSHA) website at http://www.msha.gov or at the National Institute for Health and Safety website at http://cdc.gov/niosh/mining. Recent advances in mining and safety technology and the promulgation of more stringent government regulations have reduced fatalities from underground mine fires and explosions but have not yet reached acceptable rates.

Surface mining and processing plant personnel safety exposures are not significantly different from those of other heavy industries. An exception might be in on-site explosive emulsions mixing facilities where loss of life has occurred.

Fires and explosions in mines and mineral processing plants also cause major loss of property, production equipment, buildings, and business interruption. From 1994 to 1998, mines and quarries of all types averaged $12.3 million a year in direct damage in fires reported to U.S. local fire departments.[10] In the same period, nonmetallic mineral processing and product manufacturing facilities averaged $16.1 million a year in direct damage in fires reported to U.S. local fire departments.[10] More recent statistics are not available.

The following sections further discuss important fire and explosion hazards in mining and mineral and coal processing facilities.

In noncoal underground mines, most mobile equipment is diesel powered, and so fires can result from broken or leaking hydraulic fluid, fuel, or lubricating oil lines, which spray combustible liquid mist onto a hot surface, such as an engine manifold. In recent years, diesel equipment usage has grown rapidly in underground coal mining, especially in the western states. In coal mines, the presence of coal, coal dust, and methane compounds fire hazards normally associated with diesel operations.[11]

Because prototype and first generation commercial mining systems contain both fuel sources (diesel fuel, hydraulics, hose, wiring, tires, etc.) and ignition sources (diesel engines, electrical equipment, conveyors, brakes, etc.), risks exist for onboard fires. Because these systems may be unattended, risks are compounded by the absence of an operator who could quickly detect and suppress a fire while it is still small. In a mine operated largely with automated equipment, the underground workforce would likely be quite small. In the event of a large fire, quickly marshaling a sufficient number of fire brigade members could be problematic.

Like fires on underground diesel equipment, fires on diesel-powered surface mining equipment can occur when leaking high-pressure hydraulic lines spray hot, highly combustible liquid mist onto an ignition source, such as a hot exhaust manifold or turbocharger. Fire can grow so quickly on this equipment that the operator's cab can become engulfed in flame before the driver is even aware of a fire. On large power shovels, blasthole drills, and draglines, faults in electrical equipment are a major fire hazard.

Welding and cutting operations are an important potential cause of shaft fires in both coal and noncoal underground mines. The potential seriousness of shaft fires cannot be overemphasized, because a fire in a shaft may contaminate the mine's intake air supply and/or block a critical escape route from the mine.

Exothermic oxidation reactions occur in both coal and metal sulfide ores.[12,13] When the heat these reactions generate is not dissipated, the temperature of the rock mass or pile increases. If temperatures become high enough, rapid combustion of coal, sulfide minerals, and other combustibles can result.[14] Spontaneous ignition fires can be disruptive to mine operations and difficult to extinguish, particularly if they occur in remote, abandoned mine sectors where fire-fighting access is difficult.

Heat generated by friction between a conveyor belt and a drive roller or idler can cause fires in underground mines. Despite improvements due to sequence and slippage switches, this hazard has become of renewed concern, as conveyor belt haulage has replaced rail haulage systems in older mines. Other frictional heat sources include overheated rubber tires and parking brakes on mobile equipment that are engaged during vehicle operation.

For many years, timber most commonly provided both temporary and permanent roof support for underground openings. This timber construction posed a major fire hazard. In recent years, the use of roof bolts has significantly reduced the use of timber underground. But older mines still contain large amounts of timber, and timber still supplements other means of roof support in most mines. Only about 10 percent of underground fires involve wood.[7] Timber fires tend to constitute a greater overall hazard than their frequency indicates, because timber fires can spread more rapidly, can burn longer, and can be more difficult to extinguish than fires involving most other extraneous combustible material.

The ultimate objective of underground coal mine fire protection efforts is preventing ignition of the coal. The amount of combustible material present generally limits equipment fires. Once coal ignites, however, the entire mine represents the available fuel supply. Over one-third of fires involving burning coal last longer than 24 hours, with an average duration of 6 days. Failure to extinguish a developing fire results in a 50 percent chance that more than 8 hours will be required to bring it under control and a 5 percent chance that part or all of the mine will be sealed.[15,16]

The storage, handling, and use of flammable and combustible liquids pose fire hazards for all sectors of the mining

industry. More fires in surface mines involve flammable and combustible liquids than any other combustible material. Most occur in mobile equipment. Hydraulic fluid at elevated temperature and pressure is a primary hazard.[17]

In underground mines, the storage of flammable and combustible liquids is an especially important concern. These materials ignite more easily and propagate more rapidly than ordinary combustibles involved in fires. Both flammable and combustible liquids are stored underground in most noncoal mines. In some mines, the main storage facility for diesel fuel, lubricating oil and grease, and hydraulic fluid is underground, with storage facility capacities reaching 30,000 gal (11.4 m^3). The potential seriousness of a fire in an underground flammable and combustible liquid storage area prompted extreme care in storage areas' design, plus the implementation and strict enforcement of safe operating procedures. As a result, few fires have been reported in such storage areas.[17]

Mine Explosion Hazards

Practically all underground coal and many noncoal mine explosions start with methane ignition. Methane is a colorless, odorless gas usually present in coal seams and sometimes in the rock strata above and below coal seams.[18] It is also found in some noncoal mines. During mining, methane escapes into the mine and is transported by the mine's ventilation airflows. In a properly designed and operated ventilation system, the airflows dilute the methane, render it harmless, and carry it away. However, if ventilation is inadequate, or if a large amount of methane releases suddenly (in a methane outburst, for example), dangerous and explosive methane-air mixtures can form. Even when the average methane concentration is below dangerous levels, explosive mixtures may form in pockets or layers.

The high number of explosions can be attributed to the small amount of methane necessary to produce an explosive mixture in air and to the low energy required to ignite a methane-air mixture. The lower explosive limit (LEL) for methane in air is 5 percent. As little as 0.3 mJ of electrical energy can ignite methane under proper conditions. This charge is equivalent to 1/50 of the static electricity the average person accumulates walking across a carpeted floor on a dry day.[19]

If an explosion propagates more than a few hundred feet, coal dust, swept off the floor, roof, and side walls of the mine entry, becomes the most important fuel source. The LEL for a suspension of high-volatile bituminous coal dust in air is 0.05 oz/ft^3 (28 g/m^3). Methane's presence in the atmosphere increases the hazard by producing a linear reduction in the LEL for coal dust. In the absence of methane, electrical or frictional sparks or explosives can ignite coal dust. Much more energy is required for ignition if methane is not present. Methane ignitions generally are the trigger for secondary coal dust explosions. The flame provides the necessary ignition source, and the shock wave causes settled coal dust to become airborne.[20]

The destructive potential of ignitions and explosions results from the high-temperature flame fronts and the static and dynamic pressures produced. Flame temperatures of 3600°F (1982°C) and static pressures in excess of 50 psig (345 kPa) are possible. Dynamic, or "wind," pressure is directional and depends on the air velocity the explosion produces, which, in turn, depends on the static pressure.

Table 9.16.4 shows ignition sources of recent mine explosions and methane ignitions. Frictional sparking between rock surfaces and cutting bits, continuous miners, roof bolters, cutting machines (undercutters), face drills, and longwall equipment caused over 85 percent of these ignitions and explosions in underground coal mines. Other possible sources of frictional sparking are drill steel striking machine frames, sandstone hitting sandstone or other hard rock during a roof failure, and mobile vehicle brake linings.

Welding and cutting operations are another leading cause of mine explosions and ignitions. In underground coal mines, the trend since 1970 has been increasing numbers of explosions and ignitions caused by welding and cutting operations.[21,22]

About 2.5 percent of underground coal mine ignitions and explosions result from electric arcs. This figure is surprisingly low, considering the extensive use of electrical equipment in underground coal mine face areas and the low electrical energies required to ignite methane.[22]

One cause of explosions in metal mines is sulfide dust ignition during a blast.[23] As noted earlier, ore minerals in many metal mines are metallic sulfides and are combustible under certain conditions. In some cases, the blast may create a combustible dust that the flame produced from the explosive or blasting agent can ignite.

Mineral Processing and Coal Preparation Facility Fire and Explosion Hazards

The principal fire exposures in mineral and coal processing plants include those from polymeric (plastic or rubber-based) construction and process materials and flammable or combustible fluids, reagents, solvents, and fuels.

Polymeric materials include rubber or plastic linings inside of vessels, piping, pumps, and cyclones in concentrator mills. Rubber linings are used for acid and abrasion resistance and are very common, widespread, and create high "hidden" combustible loading in an often otherwise noncombustible facility. Piping, vessels, and emission control systems may feature glass fiber reinforced plastic (FRP) or other plastic construction materials, as might the wall or roof systems, especially where corrosion is a concern. Electrolytic and leaching processing buildings using acid-based solutions are commonly constructed of plastic, or if older, of wood.

A typical concentrator mill or coal preparation plant will have rubber belt conveyors; plastic-insulated electric cables in vaults, tunnels, or under floors of control rooms; and rubber-lined equipment, as depicted in Figure 9.16.17. If plastic or other combustible construction is present, a high combustible loading can exist. Rubber liner fires can be particularly insidious as they cannot be easily accessed for manual fire fighting, fixed automatic protection like sprinklers can rarely be installed so as to be effective on fires in these relatively inaccessible products, and the fire can spread internally with liberation of dense black smoke, hampering fire fighting.

Oils, fuels, reagents, and lubricants are also common but often scattered or concentrated in dedicated rooms or areas.

FIGURE 9.16.17 Rubber-Lined Tank with Fire Warning Label (Source: Property Loss Prevention Data Sheet 7-12, "Mining and Ore Processing Facilities"; © 2006 Factory Mutual Insurance Company. Reprinted with permission. All rights reserved.)

FIGURE 9.16.18 Large Haul Truck in Equipment Maintenance Garage (Source: © 2006 Factory Mutual Insurance Company. Reprinted with permission. All rights reserved.)

Large rotating mills require both hydraulic fluids under high pressure as well as lubricating fluids. Flotation processes use combustible (often alcohol-based) or diesel fuel-like reagents to separate ores and undesirable materials. Toxic reagents such as sodium cyanide, though noncombustible, can hinder manual fire-fighting response. Transformers, commonly in indoor vaults or outdoors in power distribution yards, have large quantities of combustible cooling and dielectric oil.

Combustible or flammable fuels are used for heating and processing. Dryers using hot thermal oil are common for coal and molybdenum processing. Thermal oil fires create high heat of combustion, and an atomized spray of hot oil might cause an explosion in a small confined room. Diesel fuel and natural gas are commonly piped into processing plants and, if released, can cause serious fire damage to property.

Mine sites, especially surface mines, typically have very large, high bay mobile equipment garages, which can house multiple haul trucks or other large vehicles for maintenance, as depicted in Figure 9.16.18. These buildings can be several hundred feet long and have roofs up to 75 ft (25 m) high. Significant combustible loading exists from rubber tires, fuel, and hydraulic and lubrication oil systems. Trucks are often parked side by side with fueling and/or lubrication bays located between trucks. A fire originating in one truck—caused by overheated tires or a fuel spill—could spread throughout the entire facility if not properly protected and arranged.

Coal preparation plants present special fire hazards in addition to those described for ore processing plants. A particularly important special hazard is the combustibility and hazard characteristics of the coal itself. Coal can spontaneously heat in piles or in bins and silos without external ignition sources. Methane gas can be given off, causing localized fires or igniting dusts. Uncontrolled coal spillage inside buildings can contribute to combustible loading. Fires in rubber belt conveyors pose a particular risk in coal preparation plants, as ease of ignition is significantly reduced by the presence of the combustible material being conveyed.

A major fire hazard in ore processing and coal preparation facilities is cutting and welding. Hot work on dry rubber-lined piping or tanks can ignite the internal lining causing unrestricted fire spread. Hot work over open rubber-lined tanks can allow hot slag to fall into tanks igniting the liners. Fire can spread to adjacent vessels via lined pipes. Severe damage to production equipment and buildings can result.

Hot work operations can also ignite combustible reagents, plastic construction, lubricants, and rubber conveyor belts. Rubber conveyor belts, especially in coal handling facilities, continue to be a major cause of fire loss in the mining industry (Table 9.16.5). Other possible ignition sources are transformer or electrical cable arcing and spontaneous heating of coal or sulfide ores.

Explosion hazards in mineral processing facilities include those from gaseous or liquid fuel-fired process heaters, boilers, roasters and dryers, low-flashpoint solvents, flammable gas vapors in closed vessels, and high-pressure vessels. For example, by-product waste hydrogen gas is generated in leaching vessels

TABLE 9.16.5 Coal Industry Conveyor Belt Fires, 1978–1999

Probable Cause	*Number of Losses*	*Percentage of Number*
Open flame	6	25
Spontaneous ignition	5	21

where zinc is reacted with acids and in some electrolytic cell processes.

Pressure oxidation, acid or caustic leaching reactors, digesters or their associated flash tanks (common on gold, nickel, and bauxite plants) may fail catastrophically under pressure due to corrosion, causing severe pressure-volume (PV) rupture events, which can destroy equipment and buildings for many hundreds of feet. In July 1999, a digester-flash tank pressure vessel explosion occurred at an alumina processing facility in Louisiana, injuring seven and destroying most of the plant.[7]

Blasting emulsion-mixing facilities can detonate, causing widespread damage if not well separated from processing plants.

Combustible dusts, prevalent in coal handling facilities, can also be present in metal ore plants. For example, highly explosive, fine zinc powder is intentionally produced for seed material in zinc processing facilities.

Downstream metal refining processes may also have molten metal-water reaction explosion hazards. In contact with water high-energy rapid-phase transition explosions can occur.

Coal preparation plants have serious explosion exposures from fugitive coal dusts and methane gas, as well as aforementioned hazards typical to all processing plants. Cement plants often use coal for firing kilns and this procedure has led to coal dust explosions in these facilities.[7]

Ignition sources for explosions include poorly rated electrical equipment, compounded by poor housekeeping and poor ventilation. Lack of fuel burner management controls on fired heaters, dryers, roasters, and boilers has contributed to internal explosions.

FIRE AND EXPLOSION SAFEGUARDS

Fire and explosion safety in the mining and mineral processing industries is based on the same general principles of restricting or limiting combustible loading, ignition source prevention, early warning and detection, fixed protection (suppression), and emergency response capability as those that apply to all industrial facilities. However, due to inaccessibility, special requirements are needed for underground mines that are not needed in normal industrial plants.

The following sections, broken down separately by mining and mineral processing operations, are intended to provide only a general flavor of the different approaches to fire and explosion safety in this industry. They are not intended to represent a comprehensive list of solutions or mandatory requirements.

Many federal and state regulatory laws cover fire safety for both mining and processing occupancies. The MSHA is the principal federal mine regulatory organization in the United States. The MSHA may also regulate surface mineral processing plants if on or near the mine site, but the U.S. Department of Labor, Occupational Safety and Health Administration (OSHA) may regulate the same facility if located remote from the mine. NFPA codes are available for underground mining, underground mobile equipment, and surface coal preparation plants. NFPA 120, *Standard for Fire Prevention and Control in Coal Mines,* contains fire protection requirements for underground coal mines. NFPA 122, *Standard for Fire Prevention and Control in Metal/Nonmetal Mining and Metal Mineral Processing Facilities,* covers requirements for underground metal and nonmetal mines.

There are no public domain standards or codes that provide specific fire protection guidelines for mineral, coal, and metallurgical processing plants other than general NFPA industrial codes. FM Global publishes a comprehensive Loss Prevention Data Sheet, DS 7-12, *Mining and Ore Processing Facilities,* which covers property loss prevention and protection for these occupancies.[21] Various publications and books on mine safety and technology also are available from the Society of Mining and Exploration (SME) located in Littleton, Colorado.

Fire Prevention

Where fires involving certain combustible materials are of sufficient frequency and/or severity, and where suitable and less hazardous substitutes for those materials are available, using less hazardous materials is preferred or, in some cases, mandated by law. Examples of less hazardous materials include fire resistive hydraulic fluids, conveyor belting, hydraulic hoses, and ventilation tubing; all are required in underground mines under certain conditions.[24–26] In some cases, highly toxic products of combustion resulting from the burning of certain materials may prompt substitution with less hazardous materials. For example, many countries have banned polyurethane foam, once widely used in underground mines for ventilation seals. Even more basic is good housekeeping to prevent unsafe accumulations of trash, oily rags, coal dust, and other combustible materials.

Combustible loading and continuity of combustibles in mineral and coal processing buildings should be limited as far as practical. When possible, plastic and wood construction materials are to be avoided for both buildings and equipment. If the use of plastic cannot be avoided, an effort should be made to use fire-resistive or fire-retardant materials or materials that have been listed with low flame spread characteristics.

Rubber liners for equipment and vessels are common and cannot always be eliminated. Ceramic and special metal alloys, though more costly, can be substituted for rubber if done early in the design stage.

Similar to underground mines, the use of less hazardous hydraulic fluids and fire-retardant conveyor belting is preferred in processing buildings. Whether on the surface or underground, combustible fuels and reagents need to be properly arranged with catch pans or dikes where appropriate, located in dedicated rooms, and fitted with safety shutoff valves.

Fire sources nonessential to the mining process can be banned altogether. Examples are prohibitions on open fires and smoking. Means to prevent unwanted heat buildup, such as slippage and sequence switches on conveyors and thermal cutouts on electric motors, are also common.

Many combustible materials and potential ignition sources are essential to mining and processing operations. Fire safety depends on preventing contact between the ignition source and the fuel source. For example, precautions are taken during welding and cutting operations. When welding cannot be performed in fire-safe enclosures, areas are wet down and, if practical,

nearby combustibles are covered with fire-resistive materials or relocated. Fire extinguishers must be readily available and a fire watch posted for as long as necessary to guard against smoldering fires. This is particularly important for rubber-lined equipment in processing plants. On mobile equipment, hydraulic fluid, fuel, and lubricant lines can be rerouted away from hot surfaces, electrical equipment, and other possible ignition sources. Spray shields also can be installed to deflect sprays of combustible liquid from a broken fluid line away from a potential ignition source. Areas with a high loading of combustible materials, both underground and surface, such as timber storage areas, explosives magazines, flammable and combustible liquid storage areas, and shops, can be designed to minimize possible ignition sources. Potential sources of ignition, such as power substations, battery chargers, and electric motors, can be kept clear of extraneous combustible material.

Within the past 5 years a number of very serious fires have occurred in mineral solvent extraction plants. These fires, although not causing fatalities, produced in excess of $500 million in financial property and business interruption damage. Improper plant layout, spacing, drainage, protection, and use of combustible or frangible pipe and vessel construction materials were all major factors in the loss severity in these incidents. Conventional fire protection systems were seriously challenged in many of these incidents due to poor layout and construction materials. In some cases the fire protection systems failed entirely to limit fire impact.[27–33]

Explosion Prevention

Mining. Coal dust and methane are the primary fuels involved in underground coal mine explosions. Methane also may be present in noncoal mines.[34] Although every attempt is made to minimize the generation of coal dust in mining processes, the tiny amount of dust sufficient to propagate a coal dust explosion is virtually unavoidable. Indeed, a layer of dust on the floor just 0.005 in. (0.012 mm) thick, if suspended in air, can propagate an explosion; less is necessary if methane is present. Bituminous coal dust properly mixed with an inert material, such as pulverized limestone, dolomite, or gypsum (rock dust), does not propagate an explosion.[7] Hence, regulations require that the incombustible content of dust in coal mines be frequently checked and followed by rock dusting if necessary to ensure incombustibility.

Methane is treated in two ways. More commonly, it is diluted by ventilation air and exhausted from the mine. However, "degassification" in advance of mining may be practiced where levels of methane are unusually high.[35,36]

Every effort is made to eliminate extraneous ignition sources from the environment. Smoking is prohibited in coal mines, and electrical equipment operating where methane may be present must be "permissible" or "intrinsically" safe. Permissible electrical equipment has been tested by the federal government and designed, constructed, and installed so that its operation will not cause a fire or explosion. Use of explosionproof enclosures, specially designed plugs and receptacles, automatic circuit-interrupting devices, and voltage limitations are typical. Intrinsically safe equipment has been tested by the federal government and determined to be incapable, under normal or abnormal conditions, of releasing sufficient electrical or thermal energy to ignite an explosive gas mixture. Some success has been achieved in reducing frictional sparking at the face by using slower bit rotation, novel bit designs and bit materials, and specially engineered water sprays.[29–33] In coal mines, explosives must be permissible and used in strict conformance with special blasting regulations. Where sulfide dust explosions are possible in metal mines, special anti-incendive blasting agents are available.[19] In both coal and noncoal mines where methane is present, diesel-powered equipment must also be permissible.

Because of geologic nonuniformity, varying mining rates, atmospheric pressure, and other factors, methane is not uniformly liberated into mine ventilation air from the workings. In addition, methane and ventilation air may not mix completely and may form explosive pockets or layers, even though the average methane concentration is below the LEL. Thus, diluting and draining methane cannot always be relied on to produce nonexplosive atmospheres. Great effort has been devoted to developing safer procedures for ventilating active coal mine working areas, both longwall and room-and-pillar, to minimize the occurrence of localized pockets of explosive methane-air mixtures.[37–39] Methane checks are made frequently with handheld and machine-mounted methanometers. If the methane levels reach or exceed a predetermined point, all electrical equipment is shut down.

Ore Processing and Coal Preparation Plants. Unique explosion hazards are also present in surface mineral processing plants, especially in coal preparation plants or in other facilities (for example, cement plants) where coal is commonly used as a fuel. Coal dusts are controlled by proper design, maintenance, and operation of coal pulverizers, collectors, and handling systems. Nitrogen inerting may be used to eliminate oxygen during transfer or storage. Where possible, coal dust handling equipment is located outdoors.

Frequent and dedicated housekeeping of fugitive dusts is paramount. Proper ventilation and detection is installed for areas where methane gas might be present, for instance, in coal conveyor tunnels or silos.

In buildings with combustible dusts or flammable gases, classified or intrinsically safe electrical equipment is installed similar to underground mines. Electrical switch rooms and control rooms are pressurized to prevent dust or gas entry. NFPA 68, *Standard on Explosion Protection by Deflagration Venting,* and NFPA 69, *Standard on Explosion Prevention Systems,* cover dust and gas explosion hazards in detail for industrial facilities.

Early Fire Detection and Warning

The time elapsed between a fire's onset and its detection is critical, because fires tend to grow in size and intensity with time. Early fire detection and warning systems permit the initiation of an emergency plan (evacuation, fire fighting, etc.) while the fire is still small or, ideally, while it is still in the incipient stage. Advanced fire detection and warning systems using sensitive heat, flame, smoke, and gas analyzers provide the most rapid and reliable indication of fire.[40–44]

Thermal fire detection systems are commonly installed over conveyor belts, belt drives and takeups, and other unattended equipment. In localized, high-hazard areas, such as flammable and combustible liquids storage areas, refueling areas, and shops, faster-acting fire detection devices may be appropriate. Optical flame detectors, which sense either the ultraviolet or infrared radiation a fire emits, have been used successfully.

Smoke and/or gas detection is the most cost-effective approach to providing large area, or even whole mine, fire detection coverage[22,45–58] (Figure 9.16.19). Instruments sampling the mine ventilation airstreams can detect increases in particulates, or smoke, of less than 1 micrometer (1 mm) in size in concentrations as low as 1 mg/m^3 and of distinguishing diesel smoke from fire smoke.[51] Instrumentation also is available that can detect very small increases in combustion gases. For example, instruments intended for permanent underground installation can reliably detect carbon monoxide (CO) at levels as low as 2 ppm.

Products of combustion detection, such as smoke, thermal, or optical detectors, are usually provided in electrical rooms, control rooms, battery rooms, inaccessible tunnels, and concealed spaces housing cables or other electrical systems in surface processing plants.

After fire detection and notification of responsible mine officials, each miner must be warned. Telephones and messengers are sometimes used, but miners are often too remote from telephones and too widely scattered for these means to provide a timely warning. In coal mines, the most common means of fire warning are electric power shutdown and/or notification by telephone and messengers. In noncoal mines, electric power shutdown is generally ineffective because so little equipment is electrically powered. Stench warning is the most common method of emergency communication in noncoal underground mines.[59]

Wireless radio frequency communication systems have been used successfully in both coal and noncoal mines.[51] Ultrahigh-frequency systems use a "leaky feeder" transmission antenna that is installed wherever underground signal reception is desired. Miners use belt-held "walkie talkie" type or vehicle-mounted transceivers for two-way voice communication. Ultralow-frequency systems use antennae deployed on the surface that transmit signals through the earth to receivers built into miners' cap lamp battery cases or to dashboard-mounted receivers installed on mobile equipment. These systems enable one-way transmission of messages, which appear on LCD displays.[60–62]

FIGURE 9.16.19 Fire Detection Instruments in an Underground Mine

Fire Protection

The types of fire suppression equipment most commonly used in underground coal mines are portable hand extinguishers, generally multipurpose dry chemical; water hoselines and sprinkler systems; rock dust, applied manually or from a rock dusting machine; and foam generators. Fire suppression equipment in non-coal underground mines includes portable hand extinguishers and water hoselines. Fire suppression systems, manual or automatic, are becoming more common for mobile equipment, combustible liquids storage areas, conveyor belt drives, and electrical installations[17,51,59,63,64] (Figure 9.16.20). Automatic fire suppression is especially important for unattended, automated, or remote-control equipment where personnel are not present to detect a fire, activate a fire suppression system, or initiate fire-fighting operations.

NFPA 120 contains fire protection requirements for underground coal mines. NFPA 122 covers requirements for underground metal and nonmetal mines.

Where large areas of coal or timber are burning in an underground mine and fire fighting is complicated by extensive roof falls, ventilation uncertainties, and explosive gas accumulations, the only practical alternatives may be inerting with nitrogen, carbon dioxide, or the combustion products of an inert gas generator; flooding with water; and/or sealing all or parts of the mine.[65] All underground miners are trained to use basic fire-fighting equipment. However, only highly trained and specially equipped fire-fighting teams can fight advanced fires. To assist these teams in fighting advanced fires, research has investigated the technological feasibility of teleoperated, remote-controlled, fire-fighting vehicles capable of approaching fires at close range to apply fire-suppressing agents.

Mobile equipment is the primary fire hazard in surface mines. Consequently, most surface mining fire suppression equipment is specifically designed for maximum effectiveness on typical mobile equipment fires. Mobile equipment is commonly provided with one or more portable hand extinguishers. Manually or automatically actuated suppression systems may be installed for added protection.[66–71] NFPA 120 contains fire protection requirements for such mining equipment.

Mineral processing and coal preparation plants often need automatic sprinkler protection backed by an adequate and reliable industrial fire water system. Hydrants and monitor nozzles are needed for manual response. The need for protection is based on combustible loading, production importance, personnel safety, and economics and is determined by a risk study by a fire protection engineer.

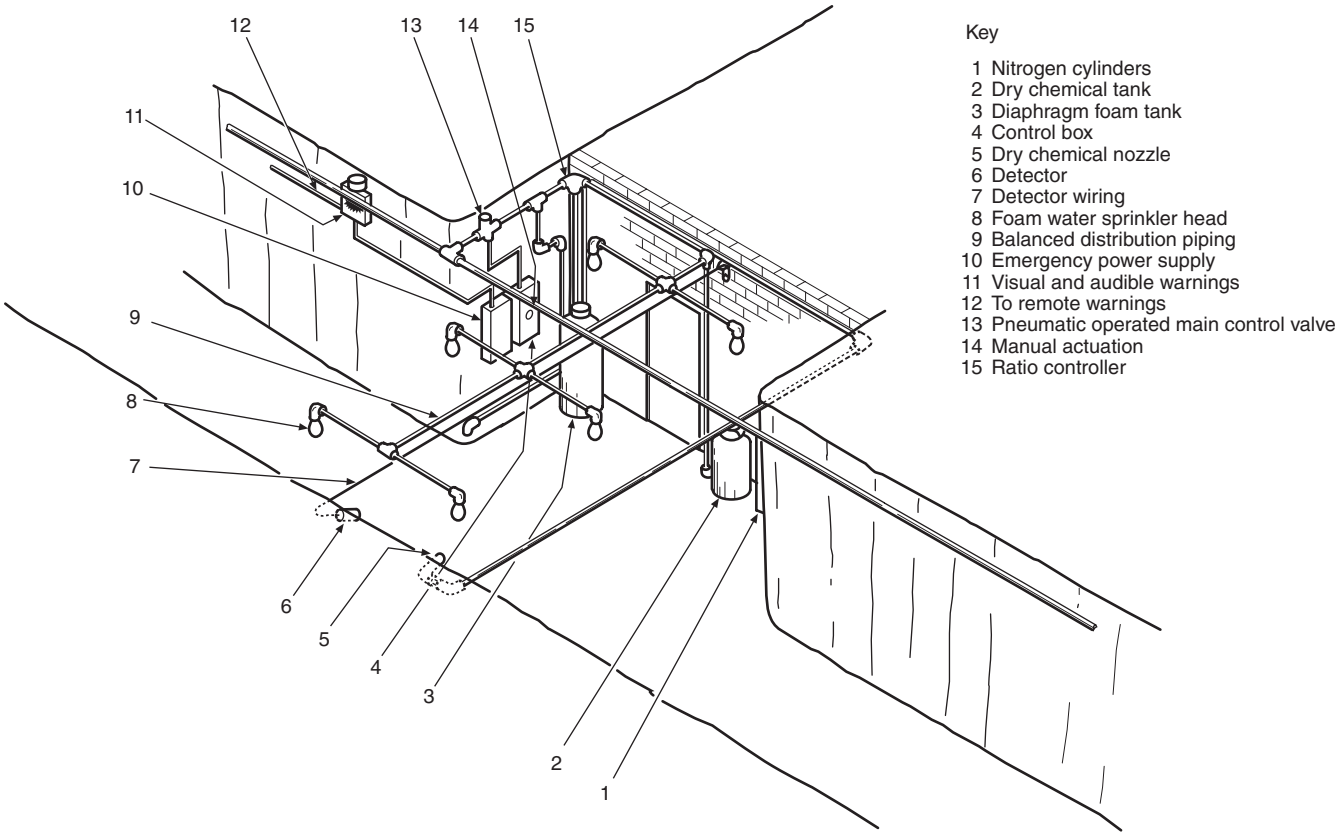

FIGURE 9.16.20 Fire Suppression System for Underground Diesel Refueling Area

Examples where automatic sprinkler protection is commonly installed in mineral processing sites are:

- Where construction is combustible and values or production reliance warrant (such as over rubber belt conveyor systems)
- Over hydraulic and lubrication oil systems for rotating equipment (such as crushers, mills, fans, and compressors)
- Over and/or inside FRP plastic equipment and exhaust duct systems
- In electrical cable spreading areas under floors, in tunnels, or in dedicated switchrooms. (An alternative to water suppression in these areas might be fire-resistive cable coatings, foam systems, or gaseous suppression systems.)
- Over important and high value transformers that use combustible insulating oil
- Over plastic electrowinning and electrorefining cells
- Over combustible or flammable reagents and fuel pumping systems for mineral solvent extraction plants
- Over power generation units that have combustible fuels or lubrication oils
- Inside combustible cooling towers for chemical processes
- Inside warehouses, mobile equipment garages, and important occupied support buildings

Foam water systems may be appropriate for certain special hazards such as reagents and fuel storage areas. NFPA 120 contains protection requirements for coal processing facilities including coal preparation plants. NFPA 122 covers requirements for surface metal and nonmetal processing facilities.

Explosion Protection

Mines. On a limited basis, some European coal mines use explosion suppression technology in the form of passive or triggered barriers. Passive barriers consist of rows of large tubs containing water or rock dust that are suspended from the roof of a mine entry. In an explosion, the pressure front that precedes the flame creates wind forces that dump the tubs' contents. The dispersed suppressants quench the flame as it passes through the entry protected by the barrier system. Triggered barriers utilize an electrically or pneumatically operated activation device that the heat, flame, or pressure of the explosion triggers to release suppressing agents stored in pressurized containers.[72–74]

Ignition suppression devices have also been developed for quenching methane ignition at its origin point, usually on a continuous mining machine or longwall shearer. These systems typically consist of a rapid-response optical detector. On sighting a fire ball of sufficient size and intensity, the detector triggers the release of a suppressing agent. The systems are designed to totally flood the area surrounding the cutting drum (roof to floor, full room width), the likely ignition source.

Surface Ore Processing and Coal Preparation Plants. To protect against damaging explosions from combustible dusts or flammable vapors, passive safety is the first step. Design of the dust handling system should address potential for dusts accumulations and release of fugitive dusts into the environment.

Examples of passive systems are using equipment strong enough to contain the forces of an explosion and using systems at negative pressure to prevent escape of dusts. Dusts carried at positive pressures inside enclosed systems can escape more easily at duct seams, joints, and broken collector bags.

Another passive system is use of nitrogen inerting to eliminate oxygen, which generally eliminates the need for other active protection systems. To supplement or replace passive systems, fixed active explosion protection can be installed to reduce the effects of an explosion or to suppress an explosion before it can cause damage.

Where possible, equipment and piping or duct systems handling dusts or vapors are located outdoors to minimize the potential for building damage or secondary explosions. Buildings or rooms that house equipment, deposits, or dusts are designed to minimize damage by the use of damage-limiting construction (DLC). DLC features a combination of wall strength and weak wall or panel emergency venting. Through proper design, based on testing of the dust or vapor to determine explosivity characteristics such as K_{st} and K_g, these wall-venting systems can effectively channel forces and limit structural damage.

Similarly, equipment, especially when located indoors, is designed using damage-limiting construction, combining vessel or pipe strength with special venting panels. When equipment that is located indoors needs to be vented, the vent system is channeled by strong ducts through exterior walls to safely discharge forces and burning material outside of the building.

When venting is impractical or a high frequency of explosions occurs (like in coal pulverizers) or when extremely high-value processes or equipment are exposed, explosion suppression systems are used. An explosion suppression system works by detecting light or developing pressure and rapidly injecting a powder or gas into the vessel. The incipient explosion is suppressed and damaging pressures are reduced. Blocking systems are also often used to prevent an explosion in one vessel from reaching another vessel via a pipe or duct. Chemical and mechanical blocking systems are available. Both work on light or pressure detection. A chemical system injects a gas or powder similar to a suppression system, blocking and suppressing the moving flame front. A mechanical system shuts the valve or gate to achieve the same end. Explosion suppression and blocking systems, as well as venting systems, are commonly installed in coal-handling systems, especially after the coal has been cleaned, dried, and pulverized.

Control of methane in coal-handling facilities is similar to methods for underground coal mines. Ventilation and detection are the primary means of protection against a buildup of gas that can cause damage if ignited. Damage-limiting construction is also used to protect against damaging methane gas explosions.

Other industrial explosion hazards, such as those that might occur inside a natural gas fueled process heater, kiln, roaster, or boiler are controlled by process controls, fuel burner management systems, and operator training. Fixed explosion protection is usually not installed on these types of equipment due to economics.

Some high-temperature roasters and zinc calciners in metallurgical refining plants have water-cooling jackets. An inadvertent release of water onto a hot sand or molten metal bed could cause a steam explosion inside the high-value production equipment, causing significant damage and production interruption. In addition to process controls and operator training, emergency explosion relief vent panels or doors are often installed on these vessels.

Many additional details on protection and design requirements for buildings and equipment handling flammable gases and combustible dusts are covered in NFPA 68 and NFPA 69. Protection requirements for explosives and blasting agents are covered in NFPA 495, *Explosive Materials Code.*

Limiting Fire Propagation

Means for confining or limiting the propagation rate of an underground mine fire can help ensure a safer mine evacuation and lessen fire-fighting hazards. In underground coal mines, oil and grease must be stored in closed, fire-resistant containers, and storage areas must be of fire-resistant construction. Transformer stations, battery-charging stations, air compressors, substations, shops, and other installations must be housed in fire-resistant areas or fireproof structures. Unattended electrical equipment must be mounted on a noncombustible surface and separated from the coal or protected by a fire suppression system. Materials for building bulkheads and seals, including wood, brattice cloth, saws, nails, hammers, plaster or cement, and rock dust, must be readily available to each working section. In underground noncoal mines, oil, grease, and diesel fuel must be stored in tightly sealed containers in fire-resistive areas at safe distances from explosives magazines, electrical installations, and shaft stations. Ventilation control stoppings and doors and fire doors are required in certain areas to prevent the spread of fire, smoke, and toxic gas.[75–77]

Providing for Miner Safety During a Fire Emergency

The primary concern during an underground fire is the safety of underground personnel. Because smoke and toxic fire gases represent the greatest threat, the mine ventilation system and its relationship to various working areas, potential fires, primary and secondary escape routes, refuge chambers, and so on are critically important. Detailed emergency planning must consider these factors. However, the complex behavior of mine fires, the flow of contaminated air through the ventilation system, and the interactions between a fire and a ventilation system that has been altered by fire-induced flow changes are normally far too complex to understand and control without specialized analytical methods. Using computer models that simulate mine ventilation systems can be very helpful in understanding these complex processes, developing and optimizing emergency plans, and

designating escape routes. Particularly valuable are advanced models that calculate ventilation changes due to a mine fire (heat-induced buoyant forces causing throttling, reversals, etc.) and can track contaminants' distribution and concentration.[51,78–80] To ensure smooth implementation of the emergency plan, miners are comprehensively trained and annually retrained in emergency procedures. Frequently performed fire drills, complete with the activation of the mine warning system, reinforce training and identify the plan's weaknesses.

Although every attempt is made to avoid such situations, evacuating miners must sometimes travel through areas contaminated by smoke and toxic fire gases. These combustion products present two hazards: (1) toxic atmospheres and (2) impaired visibility. Appropriate respiratory protection is required to safeguard miners from toxic combustion products. In coal mines, self-contained breathing apparatus, supplying a minimum of 1 hour of oxygen, must be provided.[81–83] In noncoal mines, 1-hour-rated self-rescue devices that convert carbon monoxide to carbon dioxide must be provided.

Toxic atmospheres are the principal cause of death in mine fires. However, recent research demonstrates that impaired visibility due to smoke accumulation in escapeways can become quite significant long before the concentration of combustion products becomes acutely toxic. As a result, miners lost in or disoriented by the smoke may succumb to the toxic atmosphere when they deplete their respiratory protection, even though they had adequate warning and time to escape. For this reason, smoke-free escapeways and frequent fire drills and evacuation training are especially important to familiarize miners with escape routes and evacuation procedures. To further combat the visibility problem smoke buildup causes, some mines have installed rope lifelines in escapeways. They enable miners to feel their way to safety through smoke-filled entries.

Emergency Response for Surface Processing and Coal Preparation Plants

Mineral processing sites are usually remote and will rarely have timely emergency response support from local communities for fire or explosion incidents. Larger sites have dedicated emergency response teams and are provided with structural firefighting apparatus and equipment such as fire pumper trucks. Smaller sites may only have basic fire brigades or plant emergency organizations. Large mine water haul trucks are often fitted with monitor nozzles to use for elevated conveyor fires, brushfires, and remote equipment incidents.

SUMMARY

Mining can be grouped into two broad categories: surface mining and underground mining. Surface mining methods include area strip mining, contour mining, contour pit mining, and open pit mining. Underground coal mining methods include room-and-pillar, which involves extracting coal in a regular pattern of rooms separated by pillars of in-place coal to support the roof, and longwall mining, which requires substantial artificial support. The underground mining of metals and nonmetals involves more diverse methods, including room-and-pillar, sublevel stoping, shrinkage stoping, cut-and-fill, sublevel caving, and block caving. A wide variety of ancillary operations support both underground coal mining and underground metal and nonmetal mining. These ancillary operations include inspection, maintenance, and repair of mine equipment; power distribution; ventilation; hoisting; roof control; and dewatering.

After extraction by one of the aforementioned mining methods, the mineral, structural material, or coal is transported to a processing facility, or in the case of coal, a preparation plant, for conversion to intermediate or final consumer products. The purpose of the processing or preparation plant is to size, dry, clean, chemically convert, and/or concentrate the ore or coal.

Mining and mineral processing facilities represent significant fire and explosion exposures to both personnel and production equipment and buildings. The principal fire exposures in mineral and coal processing plants include those from polymeric (plastic or rubber-based) construction and process materials and flammable or combustible fluids, reagents, solvents, and fuels. Hot work is a major fire hazard in ore processing and coal preparation facilities.

Fire and explosion safety in the mining and mineral processing industries is based on restricting or limiting combustible loading, ignition source prevention, early warning and detection, fixed protection (suppression), and emergency response capability.

Chapter 17

Oxygen-Enriched Atmospheres

Revised by
Keisa Rosales ❑ Joel M. Stoltzfus

Chapter Contents

Fire Hazards
Ignition and Combustion of Materials
Design of Systems for Oxygen-Enriched Atmospheres
Fire Extinguishment in Oxygen-Enriched Atmospheres

Key Terms

activation energy, autoignition temperature, flashpoint, lower flammable limit, minimum ignition energy (MIE), oxygen compatibility assessment, oxygen-enriched atmosphere (OEA), spontaneous ignition temperature, upper flammable limit

Oxygen is a clear, odorless, tasteless, colorless element. It is most commonly found in the gaseous state and comprises approximately 21 percent of the atmosphere. As the most common oxidizing agent in the atmosphere, oxygen can react with many materials in highly exothermic reactions. An oxygen-enriched atmosphere (OEA) is defined as an atmosphere in which the concentration exceeds 21 percent by volume, or the partial pressure of oxygen exceeds 160 torr (21.3 kPa), or both (Table 9.17.1).

Oxygen supports combustion and is necessary for plant and animal life. The concentration of oxygen available in the atmosphere is generally sufficient for human needs during normal conditions of health and for most combustion applications. Further, it has many uses under different circumstances. Oxygen-enriched atmospheres are commonly used in medical applications, industrial processes, underwater tunneling and caisson work, deep-sea exploration, spaceflight operations, and commercial and military aviation. Oxygen-enriched atmospheres can develop inadvertently at any time when oxygen or compressed air is transported, stored, or utilized.

The preparation of oxygen conventionally involves the compression of air, followed by cooling and reexpansion, which is repeated until the temperature of the air falls below the critical pressure of oxygen and causes it to liquefy. Fractional distillation of the liquid air then separates its various gaseous components. The oxygen is then collected and may be stored as a compressed gas or a liquid. Oxygen is also separated from air by absorption and membrane systems and by electrolysis. Because it is necessary to use oxygen for various applications, it is vital to consider the hazards involved in building oxygen systems.

This chapter discusses the fire hazards that may be associated with oxygen-enriched atmospheres. Methods that can reduce and protect against fire hazards are also discussed. When working in oxygen-enriched environments or introducing components to oxygen systems, the risks need to be understood and managed fully. Proper management of fire hazards requires a systematic analytical approach, such as an oxygen compatibility assessment.

Further information concerning oxygen-enriched atmospheres can be found in the following chapters: Section 6, Chapter 1, "Fire Hazards of Materials"; Section 6, Chapter 10, "Gases"; Section 6, Chapter 11, "Medical Gases"; Section 6, Chapter 12, "Flammable and Combustible Liquids"; Section 8, Chapter 11, "Fluid Power Systems"; Section 9, Chapter 12, "Fire Protection of Laboratories Using Chemicals"; and Section 20, Chapter 15, "Health Care Occupancies." See also Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems."

FIRE HAZARDS

The phenomenon known as *fire* is a chemical reaction between a fuel and oxygen. The initiation and rate of the reaction is subject to the laws of chemical kinetics. The degree of fire hazard

Keisa Rosales is a chemical engineer at the NASA Johnson Space Center White Sands Test Facility. Her expertise is material compatibility testing and fire hazard assessments of oxygen systems.

Joel M. Stoltzfus is a mechanical engineer at the NASA Johnson Space Center White Sands Test Facility. He has worked in the field of oxygen system design, testing, and analysis for 28 years.

TABLE 9.17.1 Partial Pressure of Oxygen in a Rarefied or Compressed-Air Atmosphere

Total Absolute Pressure				Altitude Above or Depth Below Sea Level (Air or Sea Water)		Partial Pressure of Oxygen if Atmosphere Is Air (torr[a])	Concentration of Oxygen if Partial Pressure of Oxygen Is 160 torr (% by Volume)
Atmospheres	*torr*	*psia*	*kPa*	*m*	*ft*		
1/5	152	2.9	20.0	11,735	38,500	32	100.0[b]

[a]This column shows the increased available oxygen in compressed-air atmospheres.
[b]Oxygen-enriched atmosphere.
Source: NFPA 53, *Recommended Practice on Materials, Equipment, and Systems Used in Oxygen-Enriched Atmospheres,* Table C.1.2.1, 2004, p. 53-15.

varies with the concentration of oxygen present, the diluent gas, and the total pressure. In most commonly encountered oxygen-enriched atmospheres, an increased fire hazard is produced by the increased partial pressure of oxygen (e.g., in an atmosphere of compressed air). However, an oxygen-enriched atmosphere does not necessarily produce an increased fire hazard. Certain oxygen-enriched atmospheres can exhibit combustion-supporting properties similar to ambient air, whereas others are incapable of supporting the combustion of normally flammable materials. For example, a 4 percent oxygen mixture in nitrogen or helium with a total pressure of 12 atm (1216 kPa) will not support the combustion of paper, even though the partial pressure of oxygen is 365 torr (48.7 kPa). However, different concentrations and pressures may accelerate the combustion of materials, facilitate ignition, and, in general, increase fire hazard. Most commonly encountered oxygen-enriched atmospheres fall into this last category (see Table 9.17.1).

Fires and explosions can occur in many diverse circumstances involving intentional and unintentional oxygen-enriched atmospheres. Among them are the following:

1. Transport, transfer, and production of oxygen, including truck delivery of liquid oxygen, leakage or venting from storage or dispensing equipment, and recharging of containers
2. Medical applications involving inhalation therapy, life-support systems, resuscitation procedures, hyperbaric chambers, and anesthesia
3. Industrial applications in petrochemical processing, steel manufacturing, mining, secondary treatment of municipal and industrial wastewaters, manufacturing microchips, paper and pulp bleaching procedures, fire flooding in tertiary oil recovery, and caisson work and underwater tunneling
4. Aerospace activities that involve the use of liquid oxygen in liquid-fueled rockets and aviator breathing systems. Gaseous oxygen is used in the NASA space shuttle orbiter at concentrations as high as 25.9 percent oxygen under normal conditions, and the space station is designed to use a 10.2 psia (70.3 kPa) 30 percent oxygen atmosphere.
5. Test systems, ground support equipment, laboratory piping systems, and acteylene/oxygen torches using oxygen-enriched and high-pressure oxygen environments
6. Inadvertent oxygen-enriched atmospheres that may result from improper design, malfunction, or improper use of oxygen storage or dispensing equipment. Oxygen is more soluble in aircraft fuel than nitrogen and, if such fuel is exposed to air for a significant period of time, enough oxygen may dissolve in the fuel and release during flight because of the decreased atmospheric pressure to create a hazardous oxygen-enriched atmosphere.
7. Inadvertent substitution of oxygen for air or nitrogen
8. Organic, inorganic, or particulate contamination. Contamination control in oxygen systems and components is imperative to minimize hazards and component failures in oxygen systems. Contamination must also be controlled to ensure an acceptable product. The level of cleanliness required is a function of the system design and operational conditions. Ideally, the systems and components should be dismantled and the parts cleaned as individual items. This choice is often not viable, and the best that may be done is to remove the functional components, clean those separately at the piece-part level, and flush the piping system in place. Before developing or introducing a component to an oxygen system, the material should be assessed for risks. The oxygen compatibility assessment discussed in this chapter provides a process for identifying hazards and managing risks.

Further, an oxygen-enriched atmosphere may develop in situations where nitrous oxide is employed. Two common nitrous oxide applications are (1) medical, for example, as a mild

anesthetic agent and (2) industrial, as a propellant in aerosol products. The use of other oxidants, for example, chlorine, chlorates, nitric oxide, and ozone, may result in enhanced combustion. Appropriate safety literature, such as materials safety data sheets (MSDSs), should be consulted.

IGNITION AND COMBUSTION OF MATERIALS

Hazards are always present when using oxygen. Most materials will ignite at considerably lower temperatures in oxygen-enriched environments than in air, and once ignited, combustion rates are greater in oxygen-enriched environments. However, these hazards do not preclude the use of oxygen.

Activation Energy and Ignition Mechanism

Flames involve strongly exothermic reactions between oxidants and fuels, producing combustion products at high temperatures. In general, for a fuel molecule and an oxygen molecule to interact chemically, sufficient energy has to be imparted to these molecules to enable a collision between the two to result in a chemical transformation. The minimum energy for the molecules to react is referred to as the *activation energy.* If the energy released by this reaction is imparted to adjacent molecules in the form of heat, the temperature of the gas will increase. An increase in gas temperature increases the number of molecules with energy equal to the activation energy and increases the reaction rate. As the temperature further increases, enough fuel and oxygen molecules react with enough additional energy released to enable the reaction to become self-sustaining until one or both of the reactants have been consumed and the combustion ceases.

The minimum ignition energy for combustion will vary with the type of ignition source, the specific chemical nature and physical character of the fuel, and the composition and pressure of the atmosphere. Though combustion is typically accompanied by a gas- or vapor-phase combustion reaction, certain materials, for example, metals, can burn in liquid or solid phase; that is, a condensed-phase reaction.[1–5] If the reaction is to continue in the vapor phase, as in the case of solids or liquids, sufficient thermal energy first needs to be supplied to convert a part of the fuel to vapor. In all cases, for the combustion to proceed, the ignition source has to impart energy to the fuel at a faster rate than the fuel loses energy. A source of heat sufficient to ignite the materials of construction or contaminants in a system is referred to as an *ignition mechanism*.

The ignition mechanisms of principal concern for oxygen-enriched atmosphere application can be categorized into two types: ignition caused by internal heating (self-heating) or external heating. The physical and chemical mechanisms involved in ignitions caused by external heating and those caused by self-heating are different. There are situations that overlap, but this division proves convenient both in the scientific world and in practice. Most ignitions encountered are due to external heating. For example, if a match ignites paper, or a halogen lamp ignites a curtain, the source is external. When a pile of linseed oil–soaked cloths bursts into flame, the cause is internal heating. Internal heating is more complicated than external heating, because factors such as airflow or exact details of the oxidation chemistry, which are of minor importance in external ignitions, become of major concern. Table 9.17.2 provides a list of ignition mechanisms.

TABLE 9.17.2 Ignition Mechanisms

Internal Heat Source	*External Heat Source*
Particle impact	Thermal ignition
Rapid pressurization	Lightning
Flow friction	Explosive charges
Resonance	Personnel smoking and open flames
Mechanical impact	Fragments from bursting vessels
Galling and friction	Welding
Fresh metal exposure	Thermal combustion engine exhaust
Static discharge	Mechanical impact
Electrical arc	
Chemical reaction	
Thermal runaway	

In general, the greater the oxygen concentration, the lower the energy required for ignition and the faster the flame spread rate. Figure 9.17.1 depicts, in an oversimplified manner, the effects of variations in oxygen concentration and environmental pressure. For a fixed-volume percent of oxygen, the minimum ignition varies inversely with the square of the pressure. There exists a minimum pressure below which ignition will not occur. As the temperature of a given system increases, less and less

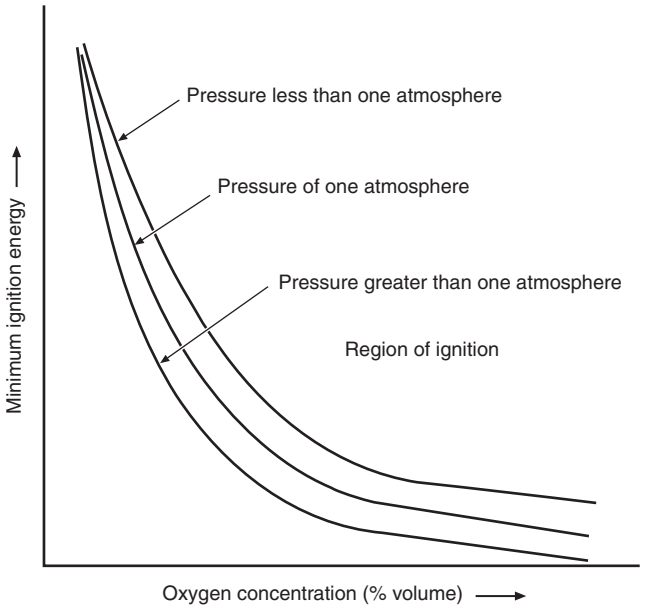

FIGURE 9.17.1 Effects of Variations in Oxygen Concentration and Environmental Pressure on the Minimum Ignition Energy

energy is required to ignite the mixture until it reaches a sufficiently high temperature to ignite spontaneously. This minimum temperature is known as the autoignition or spontaneous ignition temperature.

The likelihood of ignition and the rate of flame propagation of a combustible are primarily influenced by the oxygen content in the environment. Thus, a minimum amount of oxygen must be present for a flame to propagate, regardless of the ratio of the fuels to inert gases present. Effects on ignition energy requirements by typical ignition sources will vary with the particular inert gas present and are a function of the heat capacity and thermal conductivity of these gases in the atmosphere.

Combustion is a complex sequence of chemical reactions between a fuel and an oxidant, accompanied by the evolution of heat and, usually, by the emission of light. The rate of combustion process depends on the chemical nature of the fuel and oxidant, their relative concentrations, environmental pressure and temperature, and other physical parameters, for example, geometry and ventilation.

Combustible Gases, Vapors, and Liquids

Once ignition occurs, the propagation of combustion requires a continued supply of fuel and oxidant. The limits of flammability represent the extreme concentration limits of a combustible in an oxidant through which a flame, once initiated, will continue to propagate at the specified pressure and temperature. In the case of combustible gases, vapors, and liquids, two types of mixtures, homogeneous or heterogeneous, can exist within the atmosphere. A homogeneous mixture is one in which the components are intimately and uniformly mixed so that any small volume is representative of the whole. If the mixture is not homogeneous, it is necessarily heterogeneous.

Figure 9.17.2 shows that, for liquid fuels in equilibrium with their vapors in air (or in oxygen), a minimum temperature exists for each fuel above which sufficient vapor is released to form a flammable vapor-air (or vapor-oxygen) mixture. The experimentally determined value of this minimum temperature is commonly referred to as the *flashpoint.*

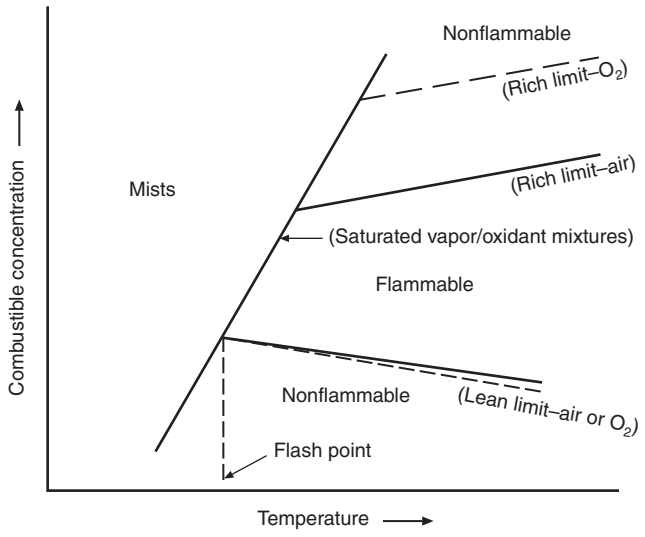

FIGURE 9.17.2 Minimum Temperature for Flammable Vapor Mixtures

The total environmental pressure also has an effect on the limits of flammability (Figure 9.17.3). For a given atmospheric composition, an increase in pressure generally broadens the flammability range. The low-pressure limit is dependent on the particular fuel and oxidant, as well as the temperature, size, geometry, and physical orientation of the confining vessel. The quenching or low-pressure limits are represented in Figure 9.17.3 by broken lines to indicate their dependency on surroundings.

The lower limit of flammability is of great interest, because it defines the minimum combustible concentration required for the propagation of flame throughout the particular mixture. The minimum temperature at which a lower limit concentration can exist depends on the volatility of the combustible and corresponds roughly to the flashpoint of the combustible. Flammable liquids have flashpoints in air of less than 100°F (38°C) (Table 9.17.3). Also, fuel-air mixtures formed at or above their flashpoint temperature will propagate flame if ignited. In oxygen, flashpoints of combustibles are slightly lower than those in air. Where fuel mists or foams are formed, the mixtures may propagate flame at temperatures far below the flashpoints of the fuels.

Typically, the lower flammability limits for most hydrocarbon fuels, anesthetics, and solvents are between 1 and 5 percent by volume in air or oxygen at 1 atm pressure. In comparison, the values for most lubricants are less than 1 percent by volume because of the higher molecular weights of such fluids. Further, lubricants need much higher temperatures, for example, 200 to 700°F (93 to 371°C), to form lower-limit flammable mixtures than do paraffins or other hydrocarbons.[6] Although most lower flammable limits in oxygen do not differ greatly from those in

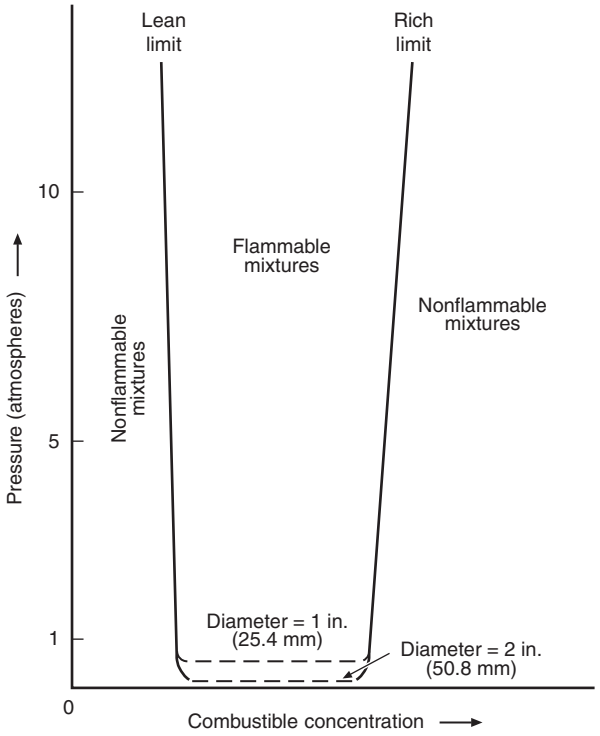

FIGURE 9.17.3 Effects of Pressure on Limits of Flammability

air, the upper flammable limits usually require much higher oxygen concentration, which tends to be about 50 percent for many materials (see Table 9.17.3).

Combustible Solids—Nonmetals

The burning of solid combustibles requires the consideration of only heterogeneous fuel-oxidant systems. As in the case of flammable liquids and gases, the flame reaction occurs in the gas phase. Once a particular solid combustible has been ignited, flame propagation requires that a portion of the heat of combustion be fed back to the solid fuel to cause its vaporization or pyrolysis, or both, thereby making additional gaseous fuel available to mix with the oxidant. The flame process is of the diffusion type.

The fire resistance of a material is an important selection property when designing an oxygen component or system. Nonmetals are especially sensitive to stresses, such as temperature, time, pressure, abrasion, light, particle impact, tensile or compression forces, or any other force that may cause aging. After a period of time, the material can *metamorphosize* into something other than its initial condition. Some changes due to aging or oxidation may be the loss of mechanical properties and temperature resistance, changes in ignition and propagation properties, and particle generation. Metals can form oxide layers, which generate particles, cause loss of strength, enhance surface roughness that results in leak paths, and decrease service life.

Figure 9.17.4 depicts the effects of oxygen content and pressure on the flame spread rate. Note that increasing the partial pressure of oxygen at a constant environmental pressure may change the classification of a material from the nonflammable to the flammable category. For materials already in the flammable category based on 21 percent oxygen, further increases in the oxygen partial pressure result in higher flame spread rates.

Organic materials in the form of finely dispersed dust clouds are extremely susceptible to combustion. Typically, spark ignition energies are less than 0.1 J. Single fibers of organic materials (e.g., lint, cotton tufts, and fluffy fabrics) may be ignited by a 0.02 J static spark in 100 percent oxygen but not in 64 percent oxygen.[7] Textile fabrics (cotton and wool used in clothing) can be ignited with a spark energy as low as 2.3 J in 100 percent oxygen, whereas, in normal air, a spark energy of at least 193 J is required.[8]

Combustible materials, when heated, may self-ignite at relatively low temperatures that approach the spontaneous or autogenous ignition temperatures ([SIT] or [AIT], respectively) obtained under ideal test conditions. As shown in Figure 9.17.5, the AIT rapidly decreases with increasing pressure up to approximately 1000 psi (7 MPa), after which the AIT remains essentially constant (Table 9.17.4).

The majority of the materials commonly used in the home and workplace are flammable in air. Chemical additives to plastics and textile fabrics, such as halogens, borax, phosphates, and various metal oxides, are effective in reducing both ignitability and flammability and have been found to be effective for many materials in atmospheres containing up to 30 to 35 percent oxygen. However, it should be mentioned that materials treated with some fire retardants will burn differently than nontreated materials and may generate corrosive or toxic vapors during the combustion process. The hot plate ignition temperatures and the flame resistance of several materials are shown in Tables 9.17.5 and 9.17.6.

The oxygen index test is commonly used to evaluate the ignition and propagation properties of materials in oxygen-enriched atmospheres. Many commonly used materials will ignite and burn in as little as 16 percent oxygen; however, fluorocarbon plastics did not propagate flames in 100 percent oxygen. The oxygen index values for a number of materials are shown in Table 9.17.7.

Electrical wiring insulation is a critical application of polymeric materials. Commonly used polymers are Teflon (PTFE), Nomex, Kapton, Kynar, silicone, polyolefin, and

polyvinylchloride. Of these, Teflon (PTFE) is the most ignition and flame resistant in oxygen-enriched atmospheres. Kapton is resistant to ignition in oxygen-enriched atmospheres, but is susceptible to arc tracking. Potting compounds, circuit boards, and other components of the electrical system can also contribute to the fuel supply.[9,10]

The rate at which flame spreads under a given set of conditions in an oxygen-enriched atmosphere is the single most important property to fire hazard development in such an atmosphere. The rate of flame spread over the surface of a given combustible material provides an indication of the speed at which a fire involving the combustible will develop (Table 9.17.8). Flame spread rates are much greater in an upward direction, due to the buoyant convection, than in the horizontal and downward directions. The rate of flame spread increases with (1) an increase in the oxygen concentration at constant pressure or (2) an increase in total pressure at a constant percentage of oxygen. Table 9.17.9 shows typical data for the burning of filter paper over a wide range of pressure and atmospheric conditions.

Several test methods for determining flame spread rate include the following:

1. NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials*
2. ASTM E162, *Standard Test Method for Surface Flammability of Materials Using a Radiant Heat Energy Source*
3. ASTM D568, *Standard Test Method for Flammability of Flexible Plastic*
4. ASTM D1230, *Standard Test Method for Flammability of Apparel Textiles*
5. ASTM D2863, *Standard Test Method for Measuring the Minimum Oxygen Concentration to Support Candle-like Combustion of Plastics (Oxygen Index)*
6. ASTM G125, *Standard Test Method for Measuring Liquid and Solid Material Fire Limits in Gaseous Oxidants*
7. ASTM E84, *Standard Test Method for Surface Burning Characteristics of Building Materials*

For each method, selected materials are tested under conditions of intended use prior to use in oxygen-enriched atmospheres.

Combustible Solids—Metals

The burning of metals can occur either in the vapor phase or in a condensed-phase reaction and, therefore, can require the consideration of both homogeneous and heterogeneous fuel-oxidant systems. Once a particular metallic combustible has been ignited, propagation of the combustion, whether burning in the vapor phase or condensed phase, requires that a portion of the heat of combustion (assuming the ignition source has been removed) be fed back to the solid fuel to cause it to heat past the ignition point.

All metals, with the possible exception of the noble metals—gold and platinum—can be expected to ignite in oxygen at some elevated temperature and pressure. Metals most subject to ignition hazards are those configured with high surface-to-volume ratios, such as dusts, thin sheets, wires, and wire meshes. When the structural elements of systems containing pressurized oxygen ignite and burn, the results are often catastrophic, due to the explosion-like release of high-pressure gases and ejection of burning debris. Ignition mechanisms include mechanical impact, particle impact, friction, electrical arc and spark, resonance, rupture, exposure of fresh metal surfaces, and promoted ignition. The most ignitable common metals are titanium, magnesium, and lithium; the least ignitable are nickel, copper, and cobalt. Increase in oxygen pressure and concentration promotes the ignition of metals at lower temperatures.[11]

As with nonmetals, the extent of combustion and flame propagation for metals depends on a number of factors, including the absolute pressure, ambient temperature, fuel and oxidizer composition, geometric shape and temperature of the fuel sample, and direction of combustion front. Depending on these factors, the combustion front in metals can propagate at greatly varying rates. For example, a 0.13 in. (3.3 mm) diameter 316 stainless steel rod burning upward in 1000 psi (7 MPa) oxygen will propagate at about 0.43 in./sec (11 mm/sec), whereas a 0.13 in. (3.3 mm) diameter 6061 aluminum rod will burn at 2.5 in./sec (64 mm/sec).[12] In general, the combustion front propagation rate increases with increasing ambient pressure, oxidizer concentration, ambient temperature, and decreasing sample dimensions.[13,14]

Flammability limits per se do not exist for most structural metal alloys, because they burn mostly in the liquid rather than the vapor phase. However, two measures of the relative flammability of metals exist that are of practical value: (1) the minimum

oxygen pressure required to support combustion of a standard sample (threshold pressure) and (2) the minimum oxygen concentration required to support combustion of a standard sample at a given pressure (oxygen index). Data on the threshold pressures and oxygen indices of several metals and alloys are provided in Table 9.17.10 and Figure 9.17.6, respectively.

DESIGN OF SYSTEMS FOR OXYGEN-ENRICHED ATMOSPHERES

A systematic approach should be used to minimize the risk of fire and the potential effect of a fire on personal safety and the safety of the system before designing systems associated with oxygen-enriched atmospheres, such as the following: gas and compressed air supplies, welding applications, spacecraft propulsion and ground support equipment, self-contained underwater breathing apparatus (SCUBA), and medical applications (including home assisted-breathing apparatus).

Oxygen Compatibility Assessment

The oxygen compatibility assessment process provides a tool for identifying and addressing the fire hazards in an oxygen system with the primary goal of determining the likelihood of a fire occurring in an oxygen system.[15,16] The oxygen compatibility assessment process may be used as both a design guide and an approval process for components and systems. Figures 9.17.7 and 9.17.8 provide an example of an oxygen compatibility assessment and show the complete analysis of a single component. The suggested oxygen compatibility assessment procedure is as follows:

1. Determine the most severe operating conditions.
2. Assess the flammability of the system materials.
3. Evaluate presence and probability of ignition mechanisms.
4. Determine the kindling chain, which is the potential for a fire to breach the system.
5. Determine the reaction effect, which is the potential loss of life, mission, and system functionality as the result of a fire.
6. Record the results of the analysis.
7. Review the results to obtain consensus from others involved in the process.
8. Finalize, archive, and transmit assessment.

Worst-Case Operating Conditions. To ascertain the ignition and flammability risks for a component or system, one must first understand the worst-case operating environment for the application. Increased oxygen concentration, temperatures, pressures,

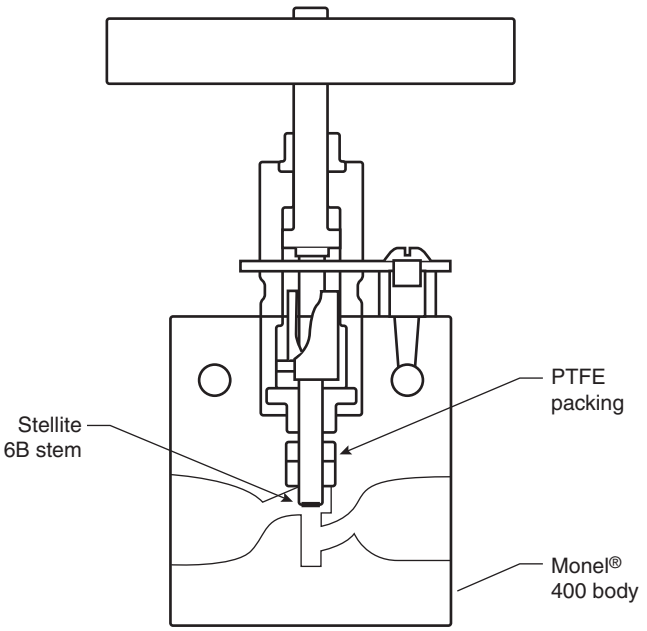

FIGURE 9.17.7 Oxygen Compatibility Assessment Example (Note: Monel® is a trademark of Special Metals Corporation)

flow rates, and contamination can contribute to the ignition and flammability risks for a system or component. Therefore, it is necessary to quantify each of these before analyzing a system or component.

Flammability Assessment. The configuration of a system or component significantly influences the ignitability and flammability of the materials of construction. Therefore, a cross-sectional diagram (e.g., machined cutaway) of the component and system flow schematic is important to reference when performing the oxygen compatibility assessment.

With few exceptions, materials become more flammable in oxygen as pressures increase. This includes metals, plastics, elastomers, lubricants, and contaminants. In fact, almost all polymer materials are flammable in 100 percent oxygen at atmospheric pressure. Several test methods have been developed to determine the relative flammability of materials. American Society for Testing and Materials (ASTM) Manual 36 and Standards G63 and G94 provide more information on determining the flammability of materials based on current data. Unfortunately, material flammability is affected by many factors and, therefore, absolute flammability thresholds are difficult to establish without testing the actual use configuration. As such, much of the oxygen compatibility assessment process focuses on the presence and probability of ignition mechanisms.

Ignition Mechanisms. The most effective way to analyze the ignition risks in a system is to methodically analyze the system for known ignition mechanisms. Ignition mechanisms occur inside and outside the oxygen-wetted portion of the component or system. For ignition mechanisms to be effective, certain elements must be present. These characteristic elements are unique for each ignition mechanism and each element is necessary for an ignition to occur. If any one characteristic is not present, the ignition mechanism will not occur. Conversely, if all the characteristic elements are present, ignition is possible.

Kindling Chain. The ability of a fire to propagate and burn through a component is called kindling chain. Kindling chain begins when a material is ignited, and the material's heat of combustion is sufficient to heat and ignite the surrounding materials leading to a burnthrough of the component. A burnthrough is considered unlikely when the materials are nonflammable or an unfavorable configuration is present. A burnthrough is considered likely when most materials (including the body) are flammable and a configuration favorable for burn propagation is present.

Material Flammability

Part	Category	Material	Flammability	Notes/Recommendations
Stem	Metal	Haynes 6B Stellite	F	Stellite 6B is flammable as a ⅛ in. rod in 100% oxygen at pressures above 2500 psia (ASTM STP 986, pp. 28–53). Note: the threshold pressure has not been found but is known to be between 1000 and 2500 psia.
Trim	Metal	Monel® 400	F	Thin cross sections of Monel® are flammable in 100% oxygen at ambient pressure (ASTM STP 1040, pp. 178–194).
Inner sleeve	Metal	Monel® 400	F	Thin cross sections of Monel® are flammable in 100% oxygen at ambient pressure (ASTM STP 1040, pp. 178–194).
Packing	Soft good	PTFE	F	PTFE is flammable in 100% oxygen at ambient pressure (ASTM STP 812, pp. 56–67).
Body	Metal	Monel® 400	N	Monel® is nonflammable as a ⅛ in. rod in 100% oxygen at pressures up to 10,000 psia (ASTM STP 1040, pp. 54–75).

Ignition Hazard

Hazard Type	Ignition Hazard	Notes/Recommendations
Flow friction	1	In this component, the seals are well-supported and unlikely to be damaged. However, the pressure is high. Therefore ignition by flow friction is considered remotely possible. It is recommended to promptly repair leaks or to replace components that persistently leak.
Frictional heating	0	Friction is present as the stem moves inside the housing. However, the frictional forces are low due to low side loads and the forces needed to produce ignition are not present. Therefore, ignition due to frictional heating is considered not possible.
Particle impact	0	High velocities will exist in this component at the stem/seat opening. The Monel® body is nonflammable; however, the Stellite stem is flammable in these conditions. This valve is located downstream of a 20 micron filter, which limits the size and amount of particles that may enter this valve. In addition, any impacts on the stem would be at oblique angles. Therefore, ignition due to particle impact is considered not possible.
Rapid pressurization	0	This valve has a metal-to-meal seat, the soft goods are well protected, and this component is not the only dead end.

Reaction Effect

Reaction Effect	Notes/Recommendations
A	There is a credible ignition mechanism present. However, there is no kindling chain present to cause component burnthrough since the body material is nonflammable. Therefore, reaction effect is considered negligible.

History of Use

History of Use	Notes/Recommendations
+	Similar components have a successful history of use at WSTF.

FIGURE 9.17.8 Oxygen Compatibility Assessment Example (Note: Monel® is a trademark of Special Metals Corporation)

Reaction Effect. As stated earlier, the effects of an oxygen system can be very severe. The effects of a fire on personnel, mission, and system objectives are assessed by determining the reaction effect. This value is primarily assigned based on a fire that breaches the pressure containment of a system.

History of Use. The history of use is determined by whether the component has experienced routine operation/cycling in similar or more severe conditions over an extended period of time. History of use is given as successful, negative, no known, or unknown.

Results. Documentation of the results of the compatibility assessment is recommended. An oxygen compatibility assessment report can facilitate the communication and dissemination of the results to interested parties and record the findings for future reference. The report should identify the components with the highest probability of fire. The oxygen compatibility assessment report may also recommend changes to design, materials, and procedures that mitigate the fire hazards identified.

Oxygen System Design

In addition to evaluating the fire safe characteristics of all materials involved in oxygen-enriched environments under the end-use performance conditions, oxygen service durability is evaluated by (1) accelerated time tests for deterioration and (2) high-energy tests for degradation. The acceptability of candidate materials for oxygen-enriched atmosphere systems applications is, in part, based on data developed by tests, such as:

1. ASTM G72, *Standard Test Method for Autogenous Ignition Temperature of Liquids and Solids in a High-Pressure Oxygen-Enriched Environment*
2. ASTM G74, *Standard Test Method for Ignition Sensitivity of Materials to Gaseous Fluid Impact*
3. ASTM G86, *Standard Test Method for Determining Ignition Sensitivity of Materials to Mechanical Impact in Ambient Liquid Oxygen and Pressurized Liquid and Gaseous Oxygen Environments*
4. ASTM G124, *Standard Test Method for Determining the Combustion Behavior of Metallic Materials in Oxygen-Enriched Atmospheres*
5. ASTM G125, *Standard Test Method for Measuring Liquid and Solid Material Fire Limits in Gaseous Oxidants*
6. ASTM G127, *Standard Guide for the Selection of Cleaning Agents for Oxygen Systems*

Other tests are available for the determination of flashpoints and fire points; upward/downward combustion propagation rates; calorific fuel values (heat of combustion); electrical wire insulation, coating, and accessory flammability; electrical overload and hot-wire ignition; odor; toxicity; and off-gassing.

Electrical equipment used in oxygen-enriched atmospheres is limited to that approved at the maximum anticipated oxygen pressure and concentration. Because most commonly used metals burn freely in oxygen-enriched atmospheres, electrical contacts that do not burn in normal atmospheres could burn away and initiate insulation fires in an oxygen-enriched atmosphere. Fire-resistive encapsulation, electrical mineral insulation, and noncombustible organometallic or ceramic (cermet) have been found to be effective for power cables.

The following firestopping design techniques can minimize ignition potential and fire spread for systems in oxygen-enriched atmospheres:

1. Avoid mass concentration of combustible materials near potential heat or ignition sources.
2. Use spatial separation and configuration to minimize or eliminate flame propagation paths.
3. Create "thermal damping" by judicious placement of fire-resistant heat-sink masses.
4. Install flashover barriers.
5. Create sealed packaging, for example, inerted compartmentations, fire-resistant encapsulation, and so on.
6. Install automatic fire monitoring, for example, infrared thermography, fire detectors, and so on.
7. Use hose line flashback arresters (consult Compressed Gas Association, Inc. [CGA], TB-3, *Hose Line Flashback Arresters*).

The design of systems that will be used in oxygen-enriched atmospheres should be undertaken only by experienced personnel. All materials that come into contact with oxygen-enriched atmospheres should be cleaned to remove all foreign material. To aid in the education of designers, ASTM Committee G4 has developed a standards technology training course, "Fire Hazards in Oxygen Systems," which is accompanied by a course textbook, *Fire Hazards in Oxygen Systems.* This course was developed by a committee whose members were from oxygen manufacturers, government, equipment suppliers, and users. The course is based on the experience of committee individuals and their respective organizations. Course content was derived from many of the following documents:

1. BS 4N 100-2, *Aerospace Series—"Specification for Aircraft Oxygen Systems and Equipment Part 2—Tests for the Compatibility of Materials in the Presence of Oxygen"—Autogenous Ignition Temperature Tests*
2. BS 4N 100-2, *Aerospace Series—"Specification for Aircraft Oxygen Systems and Equipment Part 2—Tests for the Compatibility of Materials in the Presence of Oxygen"—LOX Mechanical Impact*
3. CGA G-4.1, *Cleaning Equipment for Oxygen Service*
4. CGA G-4.4, *Industrial Practices for Gaseous Oxygen Transmission and Distribution Piping Systems*

FIRE EXTINGUISHMENT IN OXYGEN-ENRICHED ATMOSPHERES

Fire-extinguishing systems for use in oxygen-enriched atmospheres face many requirements in addition to those required for conventional systems because of ignition susceptibility, increased flame spread rate and burning intensity, and the flammability of normally flame-resistant materials. In general, these requirements cannot be satisfied by the simple extension of traditional extinguishment techniques. Special instruction and training of emergency personnel is required, as well as careful selection of extinguishing agents and systems.

Most common materials exhibit increased burning rates in oxygen-enriched atmospheres. To protect occupants and real property, fire extinguishants must (1) act rapidly to be effective, (2) be inherently nontoxic, and (3) not produce toxic or corrosive decomposition products.

Water has proved to be an effective extinguishant in oxygen-enriched atmospheres when applied in sufficient quantities. Water at a spray density of 1¼ gpm/ft^2 (50 L/min/m^2) applied for 2 minutes will extinguish cloth burning in 100 percent oxygen at atmospheric pressure. The application method of the water is all important. Water extinguishing systems must be carefully designed such that (1) all protected space is covered by the minimum spray density, and (2) water is distributed to a depth sufficient to extinguish stratified fires in nonhomogeneous materials, for example, layers of cloth in clothing.

The use of conventional halogenated extinguishants has been restricted by the Montreal Protocol, due to the ozone-depleting potential of the agents themselves as well as their decomposition products. Halon® 1301 (bromotrifluoromethane) has proved to be effective in extinguishing fires in oxygen-enriched atmospheres. See Section 17, Chapter 6, "Halon and Halon Replacement Agents and Systems."

Use of other extinguishants has been examined. Diluents, such as carbon dioxide and nitrogen, have been employed. Carbon dioxide systems have become widely used in unoccupied computer rooms. Note, however, their use must be restricted in occupied areas. No reliance should be placed on blankets made of Nomex®, wool, or fiberglass.

New technology in the use of high-expansion, water-based foams has resulted in improved extinguishing properties. However, the applicability of these agents to each particular candidate system must be carefully evaluated with regard to the available space, required time, and application methods. More data have become available on the use of low-expansion foam and dry chemical extinguishants in normal atmospheres, but their applicability in oxygen-enriched atmospheres is still unknown.

Rapid flame spread in oxygen-enriched atmospheres requires that fire-extinguishing systems be capable of fast automatic actuation by fire detectors, as well as by manual actuation. Fixed systems utilize an extinguishing agent acceptable for use on fires in oxygen-enriched atmospheres, and automatic actuation occurs in less than 1 second of the perception of detectable flame. In addition to the automatic fixed system in occupied areas, a manually operated water hose not less than ½ in. (13 mm) inside diameter, and with an effective nozzle pressure of not less than 50 psi (345 kPa) above the ambient pressure, is usually provided.

SUMMARY

Fire hazards that may be associated with oxygen-enriched atmospheres can be effectively reduced through understanding the risks and planning preventive measures. The degree of fire hazard varies with the concentration of oxygen present, the diluent gas, and the total pressure. An oxygen-enriched atmosphere may not necessarily produce an increased fire hazard. However, different concentrations and pressures may accelerate the combustion of materials, facilitate ignition, and in general increase the fire hazard. Oxygen system engineers and facility managers should consider the ignition and combustion of materials, design of systems for oxygen-enriched atmospheres, and fire extinguishment in oxygen-enriched atmospheres before designing oxygen systems or implementing new materials within an existing system. A systematic approach to evaluating the risks

was provided in this chapter. The oxygen compatibility assessment allows personnel to follow a step-by-step procedure that will determine areas of concern and, ultimately, prevent damages to a system or personal injuries. The intent of this chapter is to increase the reader's awareness of the special nature of oxygen-enriched atmospheres and to apply that awareness to the safe use and design of oxygen systems.

SECTION 10

Building Services

L. Jeffrey Mattern

10.1 Emergency and Standby Power Supplies
10.2 Heating Systems and Appliances
10.3 Building Transportation Systems
10.4 Air-Conditioning and Ventilating Systems
10.5 Ventilation of Commercial Cooking Operations
10.6 Boiler Furnaces

All occupancy classes have at least some of the building services described in this section. With loss of these services, many operations would be forced to shut down. As a result, building services are critical to the continuity of the primary function of the business. The purpose of this section is to describe primary building services, highlight the hazards associated with a specific service, and provide a description of fire prevention and fire control concepts.

In some particularly critical operations, loss of power can cause significant damage to process equipment and in-process goods. Chapter 1, "Emergency and Standby Power Supplies," provides information on the components that, alone or in combination, form emergency and standby power systems.

Three chapters in the section cover equipment associated with heating and cooling systems. Chapter 2, "Heating Systems and Appliances," addresses topics such as fuel burners, ducts and pipes, chimneys and vents, chimney and vent connectors, and fireplaces and fireplace stoves. Chapter 4, "Air-Conditioning and Ventilating Systems," includes explanations of system types and operation, fresh air intakes, air filters and cleaners, fans and controls, and unit air conditioners, as well as techniques for restricting the spread of smoke and fire and energy conservation considerations. Chapter 6, "Boiler Furnaces," describes the combustion process, fuels, and oil- and gas-burning systems. It then discusses topics such as pulverized coal systems, fluidized bed combustion, boiler-furnace hazards, and small boilers.

Chapter 3, "Building Transportation Systems," examines the various building transportation systems—elevators, escalators, dumbwaiters, and moving walks—that transport people or materials vertically or horizontally in a building. The discussion is intended to complement NFPA *101®*, *Life Safety Code®*, and *NFPA 5000®*, *Building Construction and Safety Code®*, requirements that equipment for elevators and the like be installed in accordance with ASME A17.1, *Safety Code for Elevators and Escalators.*

Chapter 5, "Ventilation of Commercial Cooking Operations," discusses ventilation systems for commercial cooking equipment, particularly in the context of fire concerns with system operation design, system component design, and system maintenance.

L. Jeffrey Mattern is retired from FM Global in Philadelphia, where his most recent positions were senior account engineer and chief engineer of mid-Atlantic operations. He has served on various NFPA technical committees and the NFPA Standards Council since 1968.

Chapter 1

Emergency and Standby Power Supplies

Revised by
Dan Chisholm, Sr.

Chapter Contents

Power Supply System Codes and Standards
Energy Sources
Engine-Driven Generator Power Systems
Other Considerations

Key Terms

alternate power supply, closed transition transfer switch, emergency power supply, prime mover, standby power supply, stored emergency power supply system, uninterrupted power supply, unit equipment

The Northeast blackout of 2003 and the hurricanes in 2005 dramatically demonstrate the need for a source of electric power independent of public electric utilities. Power interruptions occur due to natural or man-made causes. Natural causes include storms, floods, earthquakes, and the like; man-made causes are many, such as vehicles striking transformers or utility poles, equipment failure from one or more causes, and human operational error.

More generally, the electric utility industry's capacity margins have steadily declined in recent years, leaving less room to compensate for unexpected loads and events. Summer capacity margins shrank from one-fourth of capacity in the early 1980s to one-tenth in the late 1990s. Winter capacity margins shrank from one-third of capacity in the early 1980s to one-fourth in the late 1990s.[1]

The chapter provides information on the components that, alone or in combination, form emergency and standby power systems.

See Section 8, Chapter 10, "Stationary Combustion Engines and Fuel Cells," for details on safeguards for on-site fuels.

POWER SUPPLY SYSTEM CODES AND STANDARDS

NFPA 70, *National Electrical Code*®

NFPA 70, *National Electrical Code*® (NFPA 70 or *NEC*), recognizes two types of private power supply systems: emergency and standby. The latter is further subdivided into legally required standby systems and optional standby systems. Requirements for the proper installation of any of these systems are found in Articles 700, 701, and 702 of the *NEC*.

Emergency, or alternate, power systems are systems supplying power for illumination; elevators, critical heating, ventilation, and air conditioning (HVAC); fire pumps and alarms; public address systems; and other loads essential to the safety of life and property when public utility power is unavailable and where required by local, state, or federal codes (Figure 10.1.1).

Legally required standby systems are provided as an alternate source to the normal power source (e.g., a public utility), where an electric power interruption to a continuous industrial process, or institution, could endanger lives or hamper rescue or fire-fighting operations. These systems are also installed for heating, refrigeration, and ventilation systems, or to serve other electrical loads that are specified by municipal, state, federal, or other codes or by any governmental agency having jurisdiction.

Optional standby systems are intended to protect private business or property where life safety does not depend on the performance of the system. Some examples of loads that are connected to these systems are heating and cooling equipment, data processing, and communications systems.

Dan Chisholm, Sr., is president of MGI Systems, Inc., in Winter Park, Florida (http://www.mgisys.com). He is a member of the NFPA Technical Committees for NFPA 110 and the electrical section of NFPA 99. MGI Systems, Inc., is a nationally known EPSS evaluation and peer review commissioning firm.

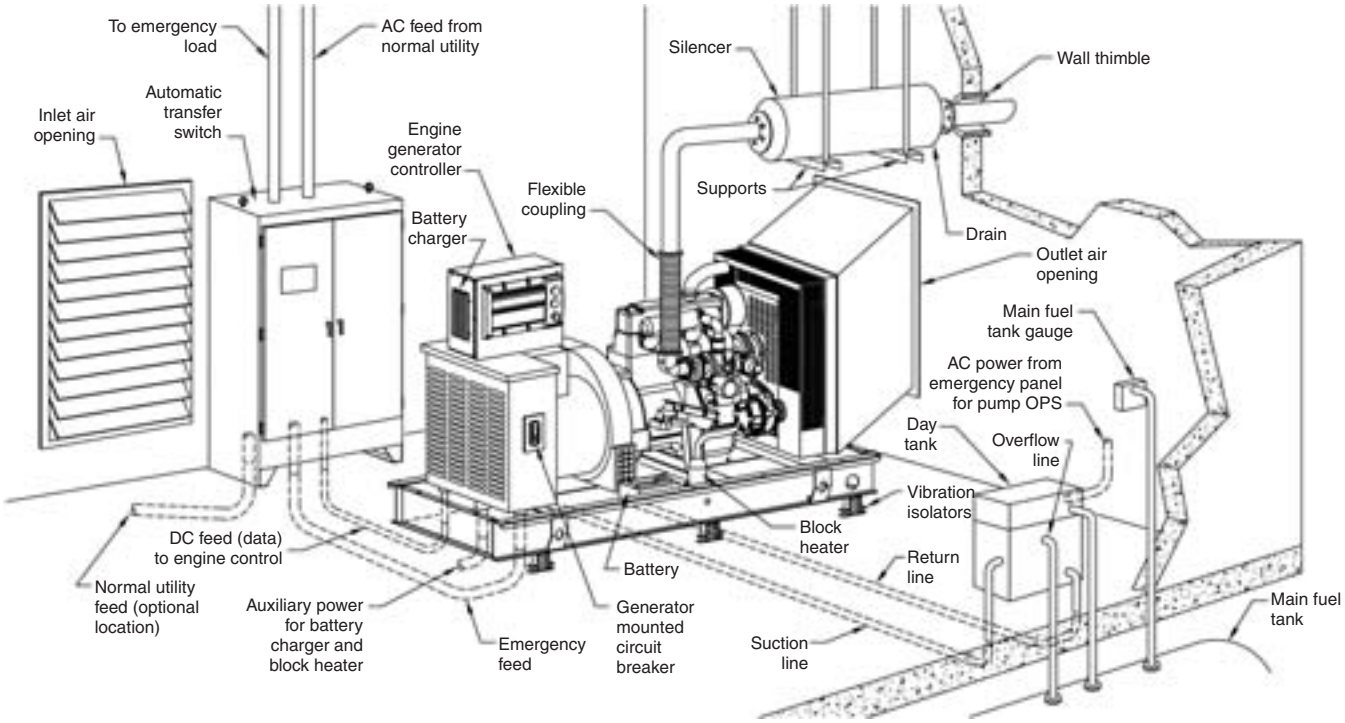

FIGURE 10.1.1 Typical Generator Installation Used to Supply Emergency Power (Source: Courtesy of Generac Power Systems)

Optional standby systems, selected by the owner, are also used on farms and in residences to supply loads during a power failure.

The loads to be served by the emergency or standby power system can be classified as critical and noncritical. Critical loads are loads that must be served within a relatively short time period after the power is needed in order to preserve life or property. Noncritical loads are all other loads that are permitted to be connected to the system.

In hospitals, alternate power source wiring and equipment are termed an Essential Electrical Distribution System. One or more on-site generators must be used to supply this system. The Essential Electrical Distribution System comprises an Emergency System and an Equipment System. The Emergency System is further divided into the Life Safety Branch and the Critical Branch. (See NFPA 99, *Standard for Health Care Facilities,* Chapter 4, "Electrical Systems.")

NFPA 110, *Standard for Emergency and Standby Power Systems*

Several terms overlap each other, for example, alternate power systems, standby power systems, legally required standby systems, alternate power sources, and so on. The terms power supply, power system, and power source are also used somewhat interchangeably. NFPA 110 places all such systems into categories defined in terms of type, class, and level, rather than using the aforementioned terms. *Type* defines the maximum allowable time that the load is without acceptable electrical power. *Class* defines the minimum allowable time that the alternate source has the capability of providing its rated load without being refueled. *Level* defines the equipment performance stringency requirements.

ENERGY SOURCES

NFPA 70 recognizes five electric sources for emergency power supplies:

1. Storage batteries
2. Generator set(s)
3. Uninterruptible power supplies
4. A separate service
5. Unit equipment

Item 4 is not recognized as an acceptable emergency power source for those occupancies covered by NFPA *101®, Life Safety Code®*. To cope with emergencies, a plaque or directory is required at each electric power source. Each sign must indicate where all other sources are located.

Energy sources for emergency and standby power supplies are generally one of the following: liquid petroleum products, liquefied petroleum gas, natural or synthetic combustible gas, or batteries. Other sources, for example, steam, rotating mass (flywheel), and compressed noncombustible gas, have limitations that restrict their use for these purposes.

On-site storage of the energy source to supply power for the duration of the need for emergency and standby power is an important consideration, especially in areas subject to severe environmental disturbances, such as storms, earthquakes, flood-

ing, and so on. As previously noted, Section 8, Chapter 10, "Stationary Combustion Engines and Fuel Cells," provides details on safeguards for on-site fuels.

Batteries

Batteries, in general, are the most dependable energy source for emergency and standby power and are primarily used for emergency lighting, either as a central battery system or as a self-contained lighting assembly defined as "unit equipment" in NFPA 70. They are also used with uninterrupted power supplies (UPS), a system that automatically provides power, without delay or transients, during a period when the normal power source is incapable of performing acceptably. A single battery or a group of batteries is limited in the amount of usable energy it is capable of delivering before becoming discharged; hence, backup to the battery source is often supplied in the form of other on-site emergency or standby power supplies.

Batteries used for this service must have sufficient capacity to supply the total emergency load for at least 1½ hours. During this time the voltage cannot drop below 87.5 percent of normal. They are usually either lead-acid or nickel-cadmium type. The lead-acid battery is less costly and requires less space for the same capacity; but the nickel-cadmium type has a longer life, more rugged construction, and requires less maintenance. Sealed batteries, that is, those not requiring periodic replacement of water, are favored for use with self-contained lighting assemblies.

After use, batteries must be recharged to have power available again when needed. A self-contained lighting assembly is normally provided with an automatic recharger and a sensing relay for determining normal power supply loss to the normal illuminating means. Consideration should be given to having the battery recharger connected to the emergency or standby power source (when such a source is installed) on loss of normal power where evacuation of the installation is not expected during a normal power outage or where a large number of people could be stranded in a high-rise building for a duration longer than the expected usual discharge time of the battery without recharging. Central battery systems and UPS systems are normally provided with more complex battery rechargers, such as dual-rate, regulated, and so on, to maximize battery life and minimize gassing.

Proper location of batteries with adequate ventilation and liquid electrolyte containment are important environmental considerations. The gaseous products of electrolysis (hydrogen and oxygen) can be a fire hazard.

Uninterrupted Power Supplies and Other Stored Energy Power Supplies

A true UPS system providing continuous and transient-free, single-phase or polyphase ac power is used to supply such critical load applications as sensitive electronic and computer equipment for data processing, life support, communications, and control equipment. Such a system, on loss of normal power, continues to supply power without waveform distortion, and the load is totally unaware of normal power loss.

There are applications where such purity is not required and either waveform distortion (transient or phase displacement of waveform) or a brief lapse of power to the load, or both, is acceptable. Economic considerations will bear upon the type of stored-energy power supply used.

Batteries, combined with rectifiers and solid-state inverters (converters of dc power to ac power), provide power to the majority of UPS systems in use. Such systems are known as static UPS systems. This system rectifies the incoming ac power to dc power, then inverts the dc power back to ac power for delivery to the load. A battery is permanently connected between the rectifier and inverter (on the dc bus) and takes over as the power source immediately upon loss of the incoming ac power. On return of the incoming ac power, the load is supplied by the incoming ac power and the batteries are recharged. The inverter serves to determine the characteristics of the ac power to the load, so that any voltage or frequency variations or transients on the incoming power are absent from the load. The rectifier is continuously sized to the capacity of the load, plus that required for battery recharging, while the inverter is continuously sized to the capacity of the load.

Other UPS systems are variations of a rotating generator driven by various drivers (engines, ac and dc motors), with or without a flywheel.

A Stored Emergency Power Supply System (SEPSS), similar to the UPS system, but economically more attractive, is one in which the normal ac power is fed through to the load with a static transfer switch transferring the load to an inverter supplied by a battery on loss of the normal ac power. The inverter receives a continuous synchronizing signal from the normal ac power, so that, on loss of this power, the inverter is still approximately in phase with the power just lost. This, coupled with a transfer time of a few milliseconds, permits the load to be without power for only a brief period and without serious transients occurring on application of inverter power. Note, however, that the inverter needs only to be sized intermittently for the load power and that the rectifier is sized only to accommodate the recharging power of the battery.

ENGINE-DRIVEN GENERATOR POWER SYSTEMS

An engine-driven generator power system usually consists of a prime mover, a governor, a generator coupled thereto (either direct or geared), transfer equipment, and distribution and protective equipment (Figure 10.1.2). Such a system is supplied for either standby or emergency service and is most common where such power is required for a considerable period of time.

Prime Mover

The prime mover can be a reciprocating engine fueled by gasoline, diesel fuel, or natural or synthetic gas. Gas turbines are also used, particularly for larger power outputs. Gasoline and natural and synthetic gas engines are less costly than diesel engines but have disadvantages that are considerable. For example, the gasoline engine and its fuel storage are more

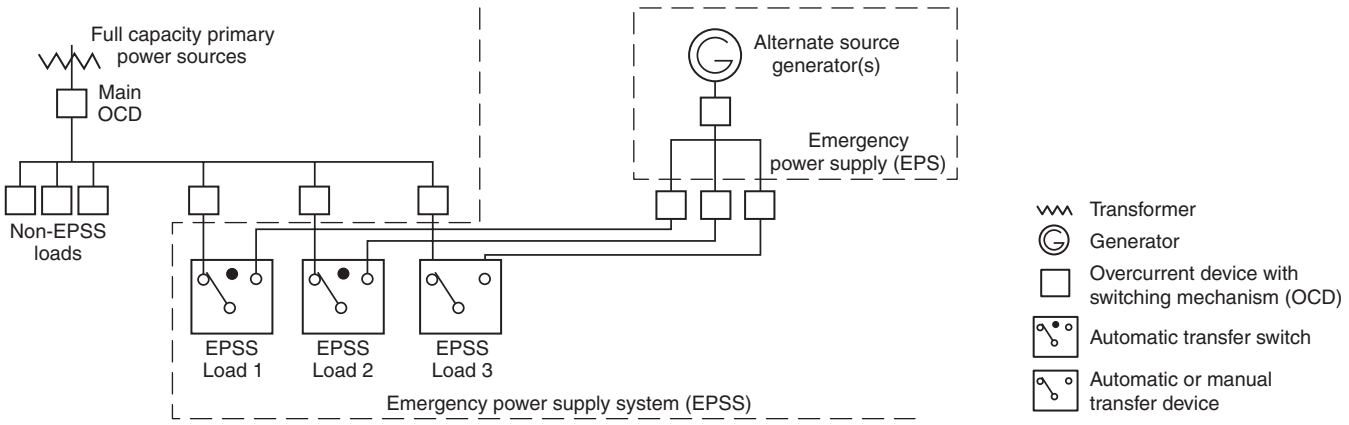

FIGURE 10.1.2 Typical Rotating Emergency Power Supply System (EPSS) (Source: NFPA 110, *Standard for Emergency and Standby Power Systems,* 2005, Figure B.1a)

susceptible to fire and explosion. Also, the natural gas engine usually obtains its energy supply from an off-site gas utility, a supply that might not be available at the same time that the normal power supply is unavailable (for this reason, an on-site fuel supply might be required by the authority having jurisdiction).

Gas turbines are much smaller than reciprocating engines of the same output and operate at much higher speeds. They require no cooling-water connection and burn natural gas, kerosene, diesel fuel, or fuel oil. They are, however, quite inefficient and are slow in coming up to full speed (more than 10 seconds).

The prime mover and its associated auxiliary equipment are required by the *NEC* to have the following characteristics for emergency service:

1. The prime mover must start automatically and come up to full speed and power capability within 10 seconds of demand.
2. A minimum on-site fuel supply permitting full engine-generator output for 2 hours or more must be available.
3. When water-cooled engines are used (generally above 50 kW), the municipal water supply cannot be used for cooling (i.e., municipal water supply input, waste to drain output).
4. When a battery is used for engine starting, the battery must have an automatic charging means independent of the prime mover.
5. When the prime mover requires more than 10 seconds to come up to full speed and power capability, an auxiliary power supply can supply the required power (within 10 seconds) to the load, provided it can continue to do so until the load is assumed by the prime mover.

Governor

A governor maintains an approximately constant speed of the prime mover throughout the full power output range by varying the fuel input to the prime mover. Governors can be mechanical, electrical, hydraulic, or a combination thereof.

Generator

Generators convert the mechanical shaft output of the prime mover into the electrical power for use by the loads connected thereto. The performance of the generator and its voltage regulator under varying load conditions must be considered in determining its suitability. The output voltage of a generator drops suddenly when a load is applied and rises suddenly when a load is removed. At present, generators larger than a few kilowatts in size have automatic voltage regulators that quickly bring the voltage back to the specified value. The initial voltage drop is important because if the drop is excessive, even for a few cycles, electromagnetic components—for example, relays and motor starters—might drop out and might or might not, depending on circuitry, reclose when the voltage is restored, or they might cycle open and closed repeatedly, causing equipment damage.

Voltage rise (overshoot) on load removal can cause damage to equipment remaining connected. The initial voltage drop is not usually of concern when the loads being connected are within the ratings of the generator. However, it is customary to exceed the rated current of the generator by two to three times during motor starting only. The initial voltage dip during these current overloads is, therefore, one of the limiting factors in sizing the generator. The performance of the generator when subjected to a short-circuit or heavy overload condition is also a matter of consideration. Under this condition, the generator current output decays with time, a characteristic inherent in the generator, so that, in a relatively short time, the current lessens to a magnitude of only several times its rating. If the decay rate is too rapid, it might not be possible to have selective tripping of overcurrent devices in the current loop.

Transfer Equipment

Electromechanical automatic transfer switches are normally used to transfer selected loads to the engine generator power supply when the normal source fails. The transfer switch senses normal power (usually all phases) and, on loss of normal power, automatically signals the prime mover to start. A brief time delay

is generally built into the transfer switch logic to delay the signal so that a momentary normal power interruption or flicker does not activate the prime mover (NFPA 110, 8.4.5(1)(a) requires a minimum 1-second delay for diesel engines). The transfer switch also senses the voltage and frequency of the generator output and, when these reach acceptable levels, either immediately thereafter or after a time delay (for selective load pickup), the switch transfers the load to the engine generator output. On restoration of the normal power supply to acceptable levels, the transfer switch might transfer the load automatically (usually after a time delay to allow for permanent normal power restoration—NFPA 110, 8.4.5(3) requires a minimum of 5 minutes) back to the normal source, or manual transfer of the load might be required, the choice having been originally made by the characteristics of the load. Transfer switches, in general, immediately retransfer the load back to the normal source (if available and at an acceptable level) should the emergency source fail. Maintenance of a transfer switch might require deactivation of loads connected to the switch while the maintenance is being performed. Some loads are so critical that such deactivation is unacceptable. In such cases, the transfer switch is furnished with an isolation bypass switch, making it possible for the load to be served by the normal or emergency source while the automatic transfer switch is being serviced.

Distribution and Protective Equipment

Distribution of the available auxiliary power (emergency or standby) concerns itself with the loads served, the order of priority, and the total loading of the engine generator set. Protection concerns itself primarily with equipment protection and with continued availability of power to unfaulted loads on a system electrical fault.

Engine generator set loading prioritizes the need for power and the magnitude of the various loads. Critical loads must be served first, followed by noncritical motor loads. A motor load produces large power and kVA load on first starting, which influences momentary voltage and frequency output of the generator, causing a decrease in each. Step loading of the engine generator set is accomplished by using multiple transfer switches, timed to operate in sequence in the order of priority. Other more complex arrangements with programmable controllers or computers are sometimes used.

Permissible loading of the engine generator set during periods of loss of normal power is governed by codes and standards. Generally, during such periods, it is permissible to use available power not being used for critical loads to power noncritical loads and to resort to load-shedding techniques to pick up the critical loads when needed.

Protection, although generally in accordance with established procedures for the normal power supply, must take into account the usual situation of limited power availability of the engine generator set versus the larger power availability of the normal source. As indicated earlier, generators, under short-circuit or heavy overload conditions, have collapsing outputs such that the sustained total current output of the generator drops to a magnitude comparable to its full-load value. Rapid clearing of the fault is essential (prior to the drop in current to its sustained value); otherwise the protective device will not see the short-circuit condition. Rapid fault clearing is also important to enable the generator to reestablish itself (voltage restoration) and continue to serve the loads still connected to it.

Closed Transition Transfer Switches (CTTS) are now being specified by design engineers to mitigate problems during scheduled testing of the EPSS, both during the split second of transferring to emergency power and the retransferring back to normal power. During a normal power outage, the CTTS cannot prevent the short duration of power loss while the generator is coming up to speed, but can prevent power "blips" on the return to normal power. Soft-load transfer switches can prevent frequency "sags" during the planned transfer of loads to the alternate or normal power sources.

OTHER CONSIDERATIONS

Peak Shaving

Multiple-engine generator sets are sometimes used to supply emergency and standby power. Such sets are usually operated in parallel, with load-shedding provisions incorporated should one of the sets fail. Because of the sizable monetary investment in an emergency or standby power system, some installations use the engine generator set in conjunction with the normal power supply for peak-shaving purposes. Peak shaving is the transfer of some loads from the normal power source to the auxiliary power source during periods of maximum loading of the normal power source. The economic benefit of peak shaving is a result of the utility rate structure. If a user can keep the ratio of maximum (or peak) power usage to average power usage low, then the utility charge is lessened. By transferring selected loads to the engine generator set during periods of peak power usage, the aforementioned ratio is lowered.

Motor-Starting Methods

Motor-starting methods for large motors are another significant consideration. Two matters of concern are the power required from the prime mover and the kVA required from the generator. Selection of the proper type of reduced voltage starting is equally important. Open-transition reduced voltage starting is not a recommended method, nor is primary resistance reduced voltage starting. Autotransformer starting and closed-transition wye-delta starting are generally preferred to other methods.

SUMMARY

Electrical power interruptions can occur from natural causes, such as storms, floods, and earthquakes, or from man-made causes, such as human operational errors or accidents to, or failure of, equipment. Such power interruptions as well as the rising threat of electrical power shortages and associated blackouts or brownouts point to the need for an independent source of power.

This chapter examined the components of emergency standby power systems, including batteries, uninterruptible power supplies and other stored energy power supplies, and

engine-driven generator power systems—the latter consisting of a prime mover, a governor, a generator, transfer equipment, and distribution and protective equipment. The chapter also discussed two other considerations—that is, peak shaving, whereby some loads from the normal power source are transferred to the auxiliary power source during periods of maximum loading of the former, and motor-starting methods.

Chimneys
Fireplaces and Fireplace Stoves

Key Terms

appliance (fuel burning), appliance (heat producing), appliance (heating and cooking), chimney, coal fuel, creosote, fluidized bed, fuel, fuel gas, fuel oil, room heater, vents

Heat-producing appliances and associated equipment are among the most prevalent causes of fire because they operate at temperatures above the ignition temperature of many common materials. In addition, combustion-type appliances can sometimes involve the hazards of an accumulated combustible mixture, the discharge of unburned fuel, and possible exposure of fuel to ignition sources.

Additional information about heating systems and appliances can be found in Section 2, Chapter 1, "Physics and Chemistry of Fire"; Section 6, Chapter 10, "Gases"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 3, "Storage of Gases"; Section 8, Chapter 8, "Industrial and Commercial Heat Utilization Equipment"; Section 8, Chapter 13, "Electrical Systems and Appliances"; Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems"; and Section 10, Chapter 6, "Boiler Furnaces."

For additional information on carbon monoxide, see Section 6, Chapter 2, "Combustion Products and Their Effects on Life Safety." Also see Section 14, Chapter 9, "Carbon Monoxide Detection in Residential Occupancies."

For additional information on CFBs, see Section 10, Chapter 6, "Boiler Furnaces."

FUELS AND METHODS OF FIRING

Combustion can be defined as a chemical reaction between a fuel and oxygen with evolution of heat and light. In a fuel-burning, heat-producing device, this reaction needs to be continuous so a balance will be established between the rate at which oxygen, or air, and fuel are supplied and the rate at which heat and the products of combustion are removed. Complete combustion (also known as stoichiometric combustion) takes place when all of the fuel is oxidized by the air supplied to it. Air left over after complete oxidation is called excess air. If only enough air is supplied for complete combustion, perfect combustion can theoretically result under suitable conditions. Because perfect combustion is impractical in most heat-producing appliances, the appliances operate with some excess air.

Air for combustion is supplied in two ways: (1) primary air is introduced through or with the fuel, and (2) secondary air is supplied to the combustion zone. In some cases, all of the air supplied is primary air, whereas in others only part is primary air and the balance is secondary air.

Incomplete combustion in a fuel-burning device can produce hazardous carbon monoxide. This condition indicates poor efficiency, because the fuel is not completely oxidized, and the total heating value of the fuel is not obtained. Incomplete combustion usually results from inadequate air supply, insufficient mixing of air and gases, or a temperature too low to produce or sustain combustion.

Solid Fuel—Coal

Coal is one of the principal solid fuels used in heat-producing appliances. There are a number of types of coal, each having widely different characteristics. In many cases, there is no distinct line

Peter J. Gore Willse, P.E., is director of research at Swiss RE Global Asset Protection Services, Avon, Connecticut. He is a member of the Technical Committees on Boiler Combustion System Hazards and Ovens and Furnaces.

of demarcation between them, and the qualities of one type can overlap those of another. Pulverized coal systems, however, require the use of coals having characteristics within the specific range of the coal-handling and coal-burning equipment.

The seven principal types of coal used in heat-producing appliances follow.

Anthracite. Anthracite is a clean, dense, hard coal. It burns with a minimum of smoke and has a minimum dust hazard during handling.

Semianthracite. Semianthracite coal has a higher volatile content than anthracite but not as hard.

Bituminous. This type includes many types of coal with different properties, depending on where they are mined. It gives off considerable smoke and soot if improperly fired. Bituminous coal can be subject to spontaneous heating under some storage conditions and has a dust hazard during handling.

Semibituminous. This dusty soft coal tends to break up. It can be subject to spontaneous heating under some storage conditions. It normally produces less smoke than bituminous coal.

Subbituminous. Subbituminous coal is subject to spontaneous heating under some storage conditions. It burns with very little smoke or soot.

Lignite. This coal has a woody structure and normally a high moisture content. It is subject to spontaneous heating under some storage conditions. It burns with little smoke or soot.

Coke. Coke is a product of the destructive distillation of coal. The type of coke produced is determined by the coal used and the temperatures and time of distillation. Petroleum coke is produced from the destructive distillation of oil.

Combustion of Coal

When coal is burned in a firebox, oxygen in the air passing through the grate (primary air) unites with the carbon in the lower portion of the fuel bed, called the oxidation zone, to form carbon dioxide. Some of this carbon dioxide is then reduced to carbon monoxide in the upper part of the fuel bed, called the reduction zone. Gases liberated from the fuel bed are carbon monoxide, carbon dioxide, nitrogen, and some oxygen. Oxygen from the air admitted over the fuel bed (secondary air) combines with some of the carbon monoxide to form carbon dioxide. When fresh coal is applied to the fire, moisture is driven off as steam and the hydrocarbon gases are distilled, combined with oxygen, and burned above the grate in what is called the distillation zone.

Methods of Firing Coal

Coal is fired either manually or automatically by stokers, pulverized fluidized bed coal burners, or in fluidized bed boilers.

Hand Firing. There are many acceptable hand-firing methods. With highly volatile coals, the objective is to leave a suitable bed of glowing fuel to ignite the gases as they are driven off from the fresh coal charge; otherwise the gas might accumulate and explode. Draft regulation is the only automatic feature of a hand-fired furnace. Draft can be controlled by a room thermostat, steam pressure, or water temperature. But, as with any hand-fired solid fuel, the fire is continuous, and overtemperature conditions are difficult to control unless the fire is continually attended.

Mechanical Stokers. Mechanical stokers are classified according to their coal burning capacities and range from those that handle 10 lb (4.5 kg) per hour to those handling over 1200 lb (540 kg) per hour. A stoker feeds fuel to the combustion chamber and usually supplies air for combustion under automatic control. There are four basic types of stokers: (1) underfed, (2) overfed, (3) traveling and chain grate, and (4) spreader, with fired grate or continuous ash discharge.

Underfed stokers move the coal by screw conveyor or rams (Figure 10.2.1). Overfed stokers feed the coal pneumatically or by rotors. Spreader stokers feed coal by rotors or paddles and discharge onto stationary or traveling grates. Stokers feed from hoppers or directly from bins. They are equipped with fueling controls that either change the firing rate or stop the fuel altogether. Some stokers are equipped with a control that will stop the feeding of fuel if the fire goes out.

Pulverized Coal Systems. Pulverized coal systems are of two general types: (1) the direct-fired, or unit, system, and (2) the storage, or bin, system. In the direct-fired system, raw coal is fed directly to a pulverizer where it is pulverized, mixed with air, and blown to the burners. In the storage system, coal is delivered to a raw fuel bin and then passed to a pulverizer where it is reduced to a powder and dried for storage in a pulverized fuel bin before delivery to the furnace.

Fluidized Bed. There are two major types of fluidized bed boilers—atmospheric and pressurized. In either case, fuel such as coal, wood, agricultural waste, industrial waste, or municipal waste, can be burned. In the case of coal, it is crushed into particles and injected inside the unit (Figure 10.2.2). It is suspended on upward-blowing jets of air much like a ping pong ball bobbing on top of the exhaust of a wood shop vacuum cleaner. The

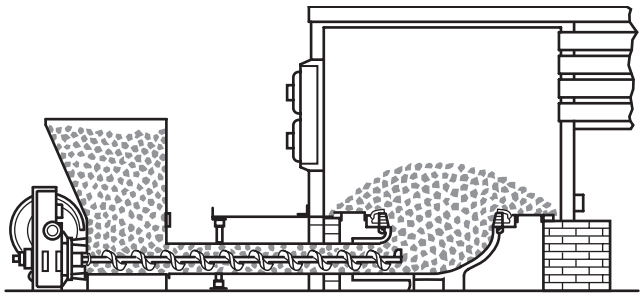

FIGURE 10.2.1 One Type of Underfed Coal Stoker

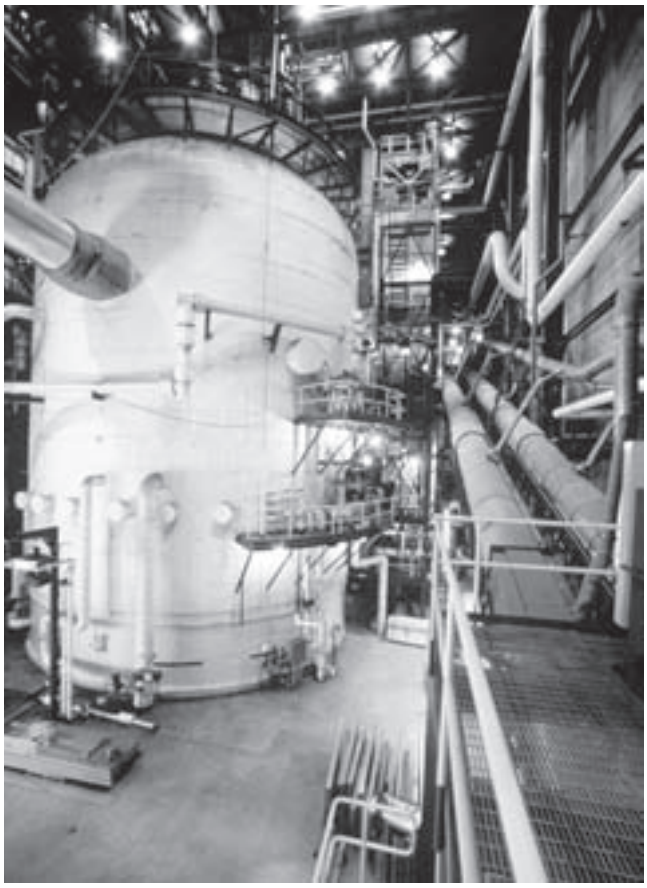

FIGURE 10.2.2 Fluidized Bed Boiler (Courtesy of the U.S. Department of Energy)

floating coal—called the "bed"—spreads out over the upward-blowing air and looks like it is bubbling.

First used in the early 1980s, today's units have become more efficient. The first units operated at temperature of approximately 3000°F (1645°C); units today operate at a temperature of approximately 1400°F (760°C). Fluidized bed boilers that fire coal have limestone injected with the coal. When the coal burns, it gives off sulfur. The limestone gas in the boiler absorbs the sulfur and a chemical reaction takes place to turn the sulfur and limestone gas into calcium sulfate, which solidifies into a powder that can be removed from the boiler. Calcium sulfate is used to produce wallboard for houses.

Solid Fuels—Miscellaneous

Miscellaneous solid fuels include wood, logs, scrap lumber, and wood waste from lumber and paper mills (sawdust, shavings, bark); hogged fuel (sawmill refuse run through a disintegrator or "hog" to form uniform chips or shreds); charcoal; briquets; peat; bagasse; sugar cane; and a host of other combustibles such as tanbark, wet bark, straw, city refuse, paper, and so on. The methods of firing these fuels vary considerably with the type of device and the nature of the particular fuel.

Since the mid-1970s, the most prevalent form of solid fuel usage has been in residential cordwood stoves, furnaces, and fireplaces. Concerns about price and availability of conventional residential energy sources sparked a surge in installation and use of such devices. Although the "crisis" attitude toward conventional energy has eased, solid fuel appliances remain a popular alternative source of supplemental heating.

The rise in installation of wood-burning appliances was accompanied by a dramatic increase in heating-related home fires, especially in the early 1980s. The severity of this problem has also decreased since then, due to decreased usage of installed appliances and better installation, use, and maintenance practices. The hazards associated with wood-burning devices are discussed in detail in a later section of this chapter.

An evolution from the wood-burning stove was the introduction of pellet fuel–burning appliances in the mid- to late 1980s. Processed solid fuels of various types have long been used in commercial and industrial operations. Pellet fuel–burning appliances are relatively small-capacity residential appliances. Pellet fuel is produced by milling wood waste to fine particles, then extruding under high pressure to form pellets about ¼ in. (6 mm) in diameter by ½ to 1 in. (12 to 25 mm) long. The fuel is placed in the hopper of a pellet fuel–burning appliance, from where it is metered to a burn pot, depending on heat demand. Pellet fuel–burning appliances thus bring a degree of automatic operation to residential solid fuel usage.

Combustion of wood takes place in three stages. Unless the wood has been purposely kiln-dried before use, the first stage is the driving-off of moisture. The second stage is destructive distillation such as that which occurs in a charcoal kiln, where the heat drives off combustible gases from the wood and leaves charcoal. The third stage involves burning of the gases in the air above the wood and burning of the charcoal combined with oxygen, forming an intensely hot and luminous bed of coals. The heat from both burning gases and charcoal distills more volatiles from the wood and increases the temperature and rate of combustion. The acceleration of combustion is limited only by the rate at which air can be brought into contact with the burning wood.

Liquid Fuel—Fuel Oils

Fuel oil, like other petroleum products, is composed of varying compounds of hydrocarbons. Even the same grade of fuel oil will vary as to its chemical composition, depending on such factors as the type of crude oil used and the refining process employed.

Types of Fuel Oil. Fuel oils obtained from present-day refining processes are known as "cracked" oils and practically all petroleum products on the market today are obtained by the cracking process. No. 1 and No. 2 fuel oils, as well as those fuels commonly known as kerosene, range oil, furnace oil, star oil, and diesel oil, are broadly classed as distillate and No. 4, No. 5, and No. 6 oils (as well as Bunker C) as residuals.

Oil burners are constructed (and subsequently tested and listed by testing laboratories) for a specific grade or grades of fuel oil. For example, burners listed by Underwriters Laboratories

Inc. (UL) have the grade or grades of fuel oil that can be used in each inscribed on the UL listing mark applied to the unit (Figures 10.2.3 and 10.2.4). It is important that only the proper grade or grades of oil be used in each burner for safety as well as efficiency. Note the grade of oil satisfactory for use in the device appears at the bottom of the markers. Specifications for fuel oil are outlined by the ASTM in ASTM D396, *Standard Specification for Fuel Oils,*[1] and in Canadian Government Specification 3-GP-28[2] (Table 10.2.1).

Methods of Firing Fuel Oil

Two methods, vaporization and atomization, are used to prepare fuel oil for combustion. Air for combustion is supplied by natural or mechanical draft. Ignition is by an electric ignition system, a gas pilot, an oil pilot, or manual means. Operation can be continuous, modulating with high-low flame, or intermittent. Although most burners operate from automatic temperature- or pressure-sensing controls, some simpler types are operated manually.

Oil burners are classified in several different ways: by application, by type of vaporizer or atomizer, by firing rates, and so on. They are divided into two major groups: (1) residential and (2) commercial-industrial. Vaporizing burners and atomizing burners having capacities of not more than about 6.5 gal/hr (25 L/hr) are considered residential types and are intended to be used with fuel oils not heavier than No. 2. Most residential-type burners are the pressure atomizing type, commonly referred to as the gun type.

Vaporizing Burners. These burners include the sleeve type, the pot type, and the vertical rotary wall flame type. Sleeve-type burners (Figure 10.2.5) are used in residential heating and cooking stoves. Perforated metal cylindrical sleeves are placed in the grooves so that the space between the inner two sleeves and the outer two sleeves becomes a combustion chamber. The space between the second and third sleeves is for the purpose of furnishing combustion air. Covers with annular openings are usually placed on top of the sleeves. Sleeve burners may or may not employ wicks in the annular spaces in the base, depending on the make and type of burner. Natural draft pot burners (Figure 10.2.6) have applications similar to sleeve-type burners, while forced-draft pot burners can be used in central heating furnaces. In a vaporizing pot-type burner, the oil is introduced into the bottom of the burner and is continually vaporized by the heat of the fire. The holes on the side permit primary and secondary air to enter the burner where they mix with the oil vapors for proper combustion. The primary air is mixed with oil vapors before combustion takes place, and the secondary air is supplied to complete the combustion process. At full fire, the velocity of the vapors and the amount of air required result in

[a] It is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in the next lower grade unless, in fact, it meets all requirements of the lower grade.
[b] This table reprinted from ASTM D396. See complete specification ASTM D396.
[c] Lower or higher pour points may be specified whenver required by conditions of storage or use. When pour point less than 0°F (–18°C) is specified, the minimum viscosity must be 1.8cSt (32.0 s, Saybolt Universal) and the minimum 90 percent point must be waived.
[d] Viscosity values in parentheses are for information only and not necessarily limiting.
[e] Outside U.S., the sulfur limit for No. 2 must be 1.0 percent.
[f] The 10 percent distillation temperature point may be specified at 225°C maximum for use in other-than-atomizing burners.
[g] The amount of water by distillation plus the sediment by extraction must not exceed 2.00 percent. The amount of sediment by extraction must not exceed 0.50 percent. A deduction in quantity shall be made for all water and sediment in excess of 1.0 percent.

the flame burning only at the top of the burner. Vertical rotary wall flame vaporizing burners are used in residential boilers and furnaces for central heating. Although the gun-type burner is now the most common, many of the burners listed above are still in service.

Atomizing. These burners include high- and low-pressure types, horizontal rotary cup types, and air and steam atomizing types, the latter used primarily for commercial and industrial applications. High-pressure, gun-type burners consist of a motor, oil pump (with integral or separate pressure-regulating and shutoff valve), strainer, fan, ignition transformer, nozzle, and electrode assembly (Figure 10.2.7). The motor-driven pump draws oil from the supply tank and delivers it to the nozzle at pressures of from 100 to 300 psi (690 to 2700 kPa). The nozzle atomizes the oil into fine particles and swirls it into the combustion chamber as a cone-shaped spray where it mixes with air and is ignited. These burners are generally designed to burn No. 2 oil, although some of the larger sizes are made for No. 4 oil.

The industrial version of the high-pressure burner, known as the mechanical atomizing burner, is a high-capacity burner for use with large boilers and industrial furnaces. Figure 10.2.8 shows a typical piping arrangement for one or more burners supplied by separate pump sets.

The low-pressure gun burner is similar to the high-pressure gun burner, but differs from it in two ways. First, the burner includes an air pump to supply compressed air for atomization, and second, the oil and air are delivered to the nozzle at pressures of 15 psi (100 kPa) or less. The size ranges, ignition, and fuel used are as described for the high-pressure gun burner.

The horizontal rotary-cup oil burner atomizes the oil by spinning it in a thin film from a horizontal rotating cup and injecting high-velocity primary air into the oil film through an annular nozzle that surrounds the rim of the cup. Secondary air for combustion is supplied from a separate fan that forces air through the burner wind box. The introduction of secondary air by means of natural draft is not recommended. These burners are used for firing boilers and furnaces and can be used singly or as multiple units on a single appliance. No. 2 fuel can be used with some of the smaller sizes, but Nos. 4, 5, and 6 are generally used with the larger sizes (Figure 10.2.9).

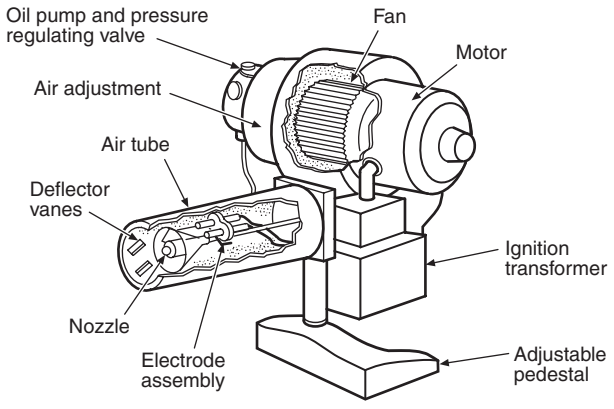

FIGURE 10.2.7 High-Pressure Atomizing Oil Burner

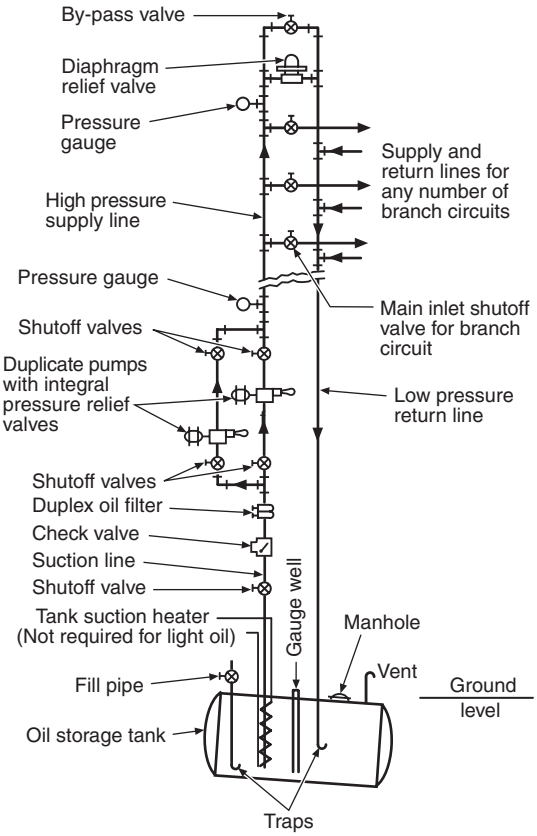

FIGURE 10.2.8 Typical Piping Arrangement for Burners Supplied by Separate Pump Sets

In the steam atomizing burner, atomization is accomplished by the impact and expansion of steam. Oil and steam flow in separate channels through the burner gun to the nozzle where the steam and oil mix before being discharged through an orifice into the combustion space. This type of burner is used mainly on large

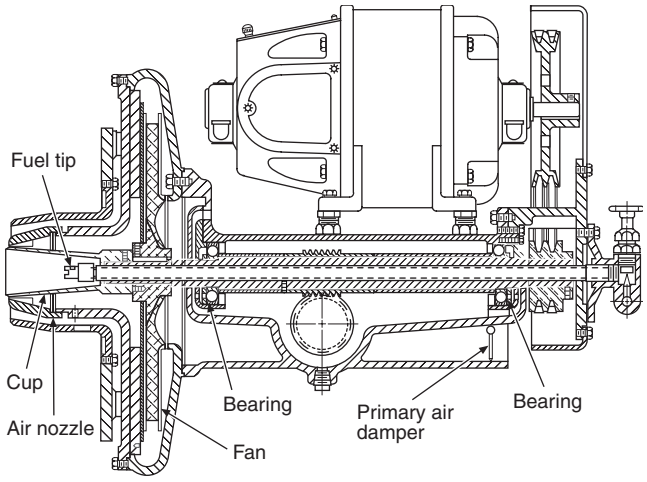

FIGURE 10.2.9 Horizontal Rotary-Cup Oil Burner

boilers generating steam at 100 psi (690 kPa) and higher and having capacities above 12,000,000 Btu per hour (3.5 MW) input.

Air-atomizing burners are designed to use compressed air at either high or low pressure for atomization. The high-pressure burner is nearly identical with the steam atomizing burner in design and application. Some burners operate well with either medium.

The low-pressure air atomizing burner uses comparatively large volumes of air at low pressure of 5 psi (35 kPa) or less. Air from the blower passes through the burner body and is discharged through annular slots between the body and the nozzle tip, where it meets the film of oil at an angle as it issues from the tip. The impact of the air stream upon the oil film produces a fine mist that is projected into the combustion space. These burners can be fired with either light or heavy oil and are most often used to fire industrial heating and processing furnaces (Figure 10.2.10).

Combination oil and gas burners, which combine the features of certain oil burners with provisions for burning gas, have been developed, permitting the operator to choose either fuel as circumstances dictate.

Fuel Oil Storage

Details on the installation of fuel oil tanks and related piping are described in NFPA 31, *Standard for the Installation of Oil-Burning Equipment.* NFPA 31 directly covers the installation of underground tanks, tanks inside buildings, and outside aboveground tanks that do not exceed 660 gal (2500 L). Larger outside aboveground tanks are covered by Chapter 4 of NFPA 30, *Flammable and Combustible Liquids Code.* The installation requirements of NFPA 31 differ somewhat from those in NFPA 30, which is more general in nature and covers liquids with a wider range of flashpoints used in a variety of locations and occupancies.

Corrosion of Tanks. Internal corrosion of fuel oil tanks caused by electrolytic action of water on steel can be a major problem. Corrosion and subsequent leakage are actually more of an environmental problem than a fire hazard. Fire can occur, however, when a burner is located in a pit in the basement of a building and oil from a leaking tank flows into the pit. Two generally accepted procedures are recommended to minimize corrosion. The first is to slope the tank toward one end and connect the burner supply line to the bottom of the tank at that end. In this way, water does not accumulate in the tank. The small quantity of water, which originates from condensation within the tank, is small enough to not affect operation of the burner. The second method is to add a small amount of an alkaline solution to the oil itself or directly to the tank at periodic intervals.

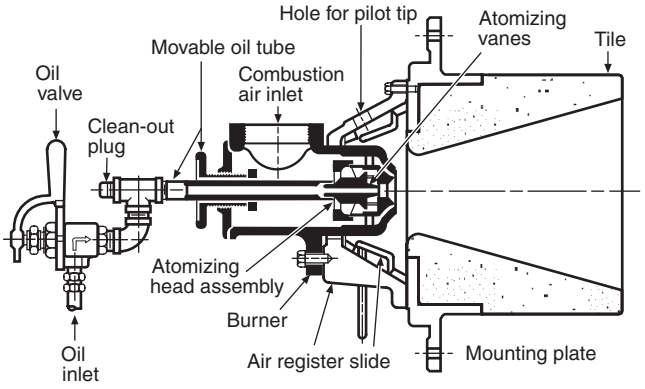

FIGURE 10.2.10 Low-Pressure Air Atomizing Oil Burner

Tanks in Buildings. NFPA 31 currently permits installation of tanks inside buildings as follows:

- On any floor, up to 60 gal (227 L) capacity
- On the lowest floor (basement, cellar, etc.), up to an individual capacity of 660 gal (2500 L)
- On a higher floor level (such as an attached garage of a split-level house) where there are no floors or spaces directly beneath and where all openings to the rest of the structure are provided with a means to prevent spread of spilled fuel into the structure, up to an individual capacity of 660 gal (2500 L)

In each case, the tank(s) are unenclosed, that is, are not in a dedicated room. The aggregate capacity of all tanks connected to any one burner or any one group of burners cannot exceed 660 gal (2500 L), and the total aggregate capacity of all such tanks, unenclosed, cannot exceed 1320 gal (5000 L). A distance of at least 5 ft (1.5 m) must be maintained between each tank and any fire or flame, either in or external to any fuel-burning appliance. Furthermore, such tanks must not obstruct quick and safe access to any utility service meter, switch panel, or shutoff valve.

Tanks larger than 660 gal (2500 L) can be installed in buildings, provided they are located in an enclosure constructed of walls, floor, and ceiling that provide a fire resistance rating of not less than 3 hours. The walls must be bonded to the floor to effect a liquid-tight seal. The ceiling and walls of the enclosure must be independent of the building, except that an exterior wall having a fire resistance rating of not less than 3 hours can serve as a wall. Any opening into the enclosure must have a noncombustible sill or ramp at least 6 in. (150 mm) high. Since such openings are Class A (horizontal) openings, they must be provided with self-closing fire doors. Enclosures of this type are found only in commercial or industrial buildings.

A recent change to NFPA 31 allows up to five 275 gal (1040 L) tanks to be installed unenclosed and cross-connected, so as to allow a single fill connection and single vent, but only if the fill and vent piping are pre-engineered so that all tanks are filled simultaneously at the same rate.

Outside Aboveground Tanks. Under the following conditions, tanks can be installed outside aboveground in built-up areas. Such tanks are allowed to be located immediately adjacent to buildings, without having to meet the separation distances of NFPA 30, but must be kept away from an adjacent property line. Not more than one or two tanks having an aggregate capacity of 660 gal (2500 L) are permitted to be connected to any one oil burner or any one group of oil burners.

Individual tanks exceeding the 660 gal (2500 L) limit can be installed, but must meet all relevant requirements of NFPA 30 for separation distance, spill control, emergency venting, and so on.

Underground Tanks. Tanks can be installed underground. Such tanks must conform to types recognized by NFPA 31 and must be installed in accordance with NFPA 30. Both documents impose requirements dealing with location of tanks in relation to building foundations or footings, separation to property lines, protection against traffic (i.e., vehicle movement over the tanks), and dislocation of tanks due to high ground water or flooding. See NFPA 30 for additional information on protecting fuel oil tanks in areas subject to flooding.

Centralized Oil Distribution System. A system of piping that supplies oil from a central tank or tanks to a number of buildings, manufactured homes, recreational vehicles, and so on, is allowed under certain conditions. For details covering such systems see NFPA 31.

Fill and Vent Pipes. Underground tanks, including tanks buried beneath buildings, must have fill and vent pipes that terminate outside the building. Vent openings and vent pipes must be large enough to prevent abnormal pressure within the tank during filling and, in any case, must not be smaller than 1¼ in. (30 mm) nominal pipe size for tanks up to 660 gal (2500 L) capacity. Larger tanks must have vent pipes of larger nominal size.

Tanks located inside buildings must have fill and vent pipes that terminate outside the building. Vent openings and vent pipes must be at least 1¼ in. (30 mm) nominal pipe size for tanks up to 660 gal (2500 L) capacity and correspondingly larger for tanks of greater capacity.

Outside aboveground tanks must have vent openings and vent pipes large enough to prevent abnormal pressure within the tank during filling and, in any case, must not be smaller than 1¼ in. (30 mm) nominal pipe size for tanks up to 660 gal (2500 L) capacity. Larger tanks must have vent pipes of larger nominal size.

Gauging devices are required, but on inside tanks they must not allow oil or vapor to be discharged into the building. Test wells are not allowed on inside tanks. Piping to the burner(s) and the required accessories are covered in NFPA 31.

Small-Capacity Tanks. There are several types of small tanks used with cooking appliances and room heaters. An auxiliary tank of not over 60 gal (227 L) capacity is allowed between the burner and the main fuel supply tank. An unenclosed supply tank of not more than 10 gal (38 L) capacity for an individual appliance is permitted, provided it is placed not less than 2 ft (0.6 m) from a source of heat either inside or outside the appliance being served, and provided that the temperature of the oil in the tank will not exceed 25°F (–4°C) above room temperature at the maximum firing rate.

Integral tanks are furnished by manufacturers as a component part of some oil-burning appliances, for example, kerosene and oil stoves. Stoves with integral tanks (not over 5 gal [20 L] capacity) operate on the gravity or barometric feed principle. The tank reservoir oil and the burner oil are at the same level. As the oil level drops due to burning, oil runs into the reservoir from the tank, either because a float drops and opens a valve (gravity feed) or because air enters the tank through the cap and allows oil to enter the reservoir until it covers the air opening (barometric feed).

NFPA 31 contains specific provisions on supply tanks for kerosene and oil stoves, portable kerosene heaters, and conversion range oil burners. The intent of these provisions is to prohibit contamination of storage containers with other types of fuel. Contamination can lead to explosion or flare-up in the equipment.

Liquid Fuels—Miscellaneous

Alcohol, gasoline, crankcase oils, and used oils are used for some heat-producing appliances and equipment to a limited extent. Alcohol stoves and torches and gasoline torches are examples. NFPA 31 gives additional basic requirements for safe storage practices for these fuels.

Gas Fuels

Generally, gas-fired, heat-producing devices and equipment use natural gas, LP-gas (liquified petroleum gas), an LP-gas/air mixture, or mixtures of these gases. Natural gas is the most commonly used gas fuel in the United States, because gas transmission pipeline systems supply most areas of the country. LP-gas-fired heating devices also are popular, particularly in sparsely settled areas and in recreational vehicles. A number of other flammable gases are used as fuel in many industrial processes for special purposes.

Natural gas consists principally of methane and some ethane, propane, butane, and small amounts of carbon dioxide and nitrogen. Fuel gases can be made in a variety of ways from coal or by the cracking of oils. Liquified petroleum gases are largely propane, propylene, butane, and butylene, or mixtures of these gases.

Typical calorific values of various gases as fuel are given in Section 6, Chapter 10, "Gases." Various procedures for sampling, analyzing, measuring, and testing gaseous fuels are outlined in 13 ASTM standards, which have been compiled in the publication ASTM *Standards on Gaseous Fuels.*[3]

Methods of Firing Fuel Gases

Air is either mixed with gas at the burner of a gas-fired appliance or premixed with gas. A wide variety of types and sizes of burners are used to mix the gases effectively under different conditions. Every burner is designed to transform the potential energy of the fuel gas into useful heat, which can be absorbed in the most effective manner.

Injection (Bunsen) Burners. Injection-type gas burners are popular in residential and commercial gas appliances and, to a lesser extent, in industrial gas-fired appliances. A jet of gas injects primary air for combustion into the burner and mixes it with the gas. This mixing occurs before the gas reaches the burner ports or point of ignition. Figure 10.2.11 shows a typical injection-type gas burner.

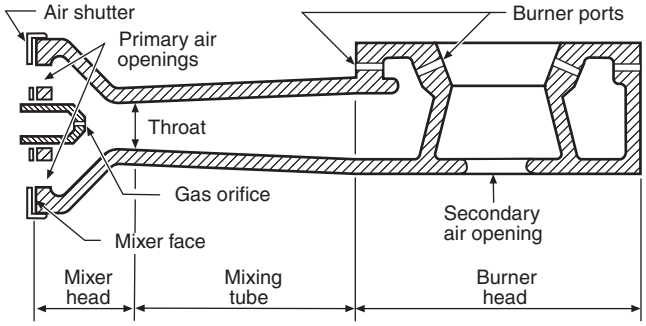

FIGURE 10.2.11 Typical Injection-Type Burner

Luminous or Yellow-Flame Burner. In the luminous or yellow-flame burner, only air externally supplied at the point of combustion is used for burning the gas. The flame is produced without premixing air with the gas.

Catalytic Burners. Another type of burner is the catalytic burner that permits combustion of the gas at temperatures well below the normal ignition temperature of fuel gas/air mixtures.

Power Burners. In a power burner, either gas or air or both are supplied at pressures exceeding the line pressure of the gas and atmospheric pressure of the air. The added pressure is applied at the burner. When air for combustion is supplied by a fan ahead of the appliance, the appliance is known as a forced-draft burner. A premixing burner is a power burner in which all or nearly all of the air for combustion is mixed with the gas as primary air (air that mixes with the gas before it reaches the burner port or ports). A pressure burner is supplied with an air/gas mixture under pressure (usually from 0.5 to 14 in. of water [0.1 to 3.5 kPa] and occasionally higher).

Figure 10.2.12 illustrates some of the types of industrial appliance gas burners.

Interchanging Gases. Changing from one kind of gas to another can cause serious problems unless the appliance is designed to accept the change. Appliance designs certified by CSA International (formerly the American Gas Association [AGA]) laboratories are tested for satisfactory performance with one or more gases as requested by the manufacturer. These include natural and mixed gases, as well as LP-gas and LP-gas/air mixtures. The specific gas or gases that can be used in an appliance are marked on the appliance. Although such appliances may be converted in the field to any one of the marked gases, the conversion can require some interchange of parts and involves some element of hazard unless carefully performed by experienced, qualified personnel.

Appliance and Piping Installation

Installation, alteration, and repair of gas appliances and gas piping should be done only by qualified agencies fully experienced in this work. Provisions outlined in NFPA 54, *National Fuel Gas Code,* provide the necessary guidance. Gas must be turned on *only after* the system has been thoroughly tested to be certain there is no leakage. All air in piping must be purged, as a remaining slug of air will extinguish the flame. When gas flows again, unburned gas will escape, resulting in a potentially hazardous condition.

The uncontrolled flow of unburned gas into any gas appliance could form an explosive gas/air mixture. Safeguards to prevent this are extremely important, particularly in industrial and other large gas-burning devices. Without such safeguards, unburned gas can accumulate in combustion chambers or ovens at the time of lighting or when the gas pressure fluctuates. If the pressure is reduced below a certain point, the flame might be extinguished. With a subsequent return of normal pressure, unburned gas might continue to flow. An increase in pressure might increase the velocity of flow through the burner in excess of the flame propagation rate. This will force the flame away from the burner. A number of automatic devices are available to safeguard against this hazard and are commonly found on the larger installations.

Electricity

Most electrical heating appliances for heating small rooms and for other small heating jobs involve resistor heating elements, which are usually one or more metal alloy wires, nonmetallic carbon rods, or printed circuits. Resistor heating is used in radiators, unit heaters, convectors, central hot water systems, central warm air heating systems, and panel-type radiant heat installations for walls, floors, and ceilings. Resistor heating is also used for household electrical appliances, such as stoves, irons, and toasters.

Controls. Automatic regulation of the electrical input (usually through proportional-type step controllers) allows heaters to be energized and de-energized in increments small enough to prevent excessive total operation of all heaters during temperature drops.

Method of Installation. Electric heating systems should be installed in accordance with NFPA 70, *National Electrical Code®*.

CONTROLS FOR FUEL BURNERS

The uncontrolled flow of unburned fuel into appliances and burners can lead to serious consequences. When fired with pulverized coal, gas, or oil, a combustible mixture could accumulate within the confines of the appliance or equipment. If ignited, it could result in an explosion. To guard against the discharge of unburned fuel or improper mixtures of fuel and air, certain controls are required for all fuel burners.

Primary Safety Controls

These required controls cause the fuel to shut off in the event of ignition failure or flame failure. Except for pot-and-sleeve-

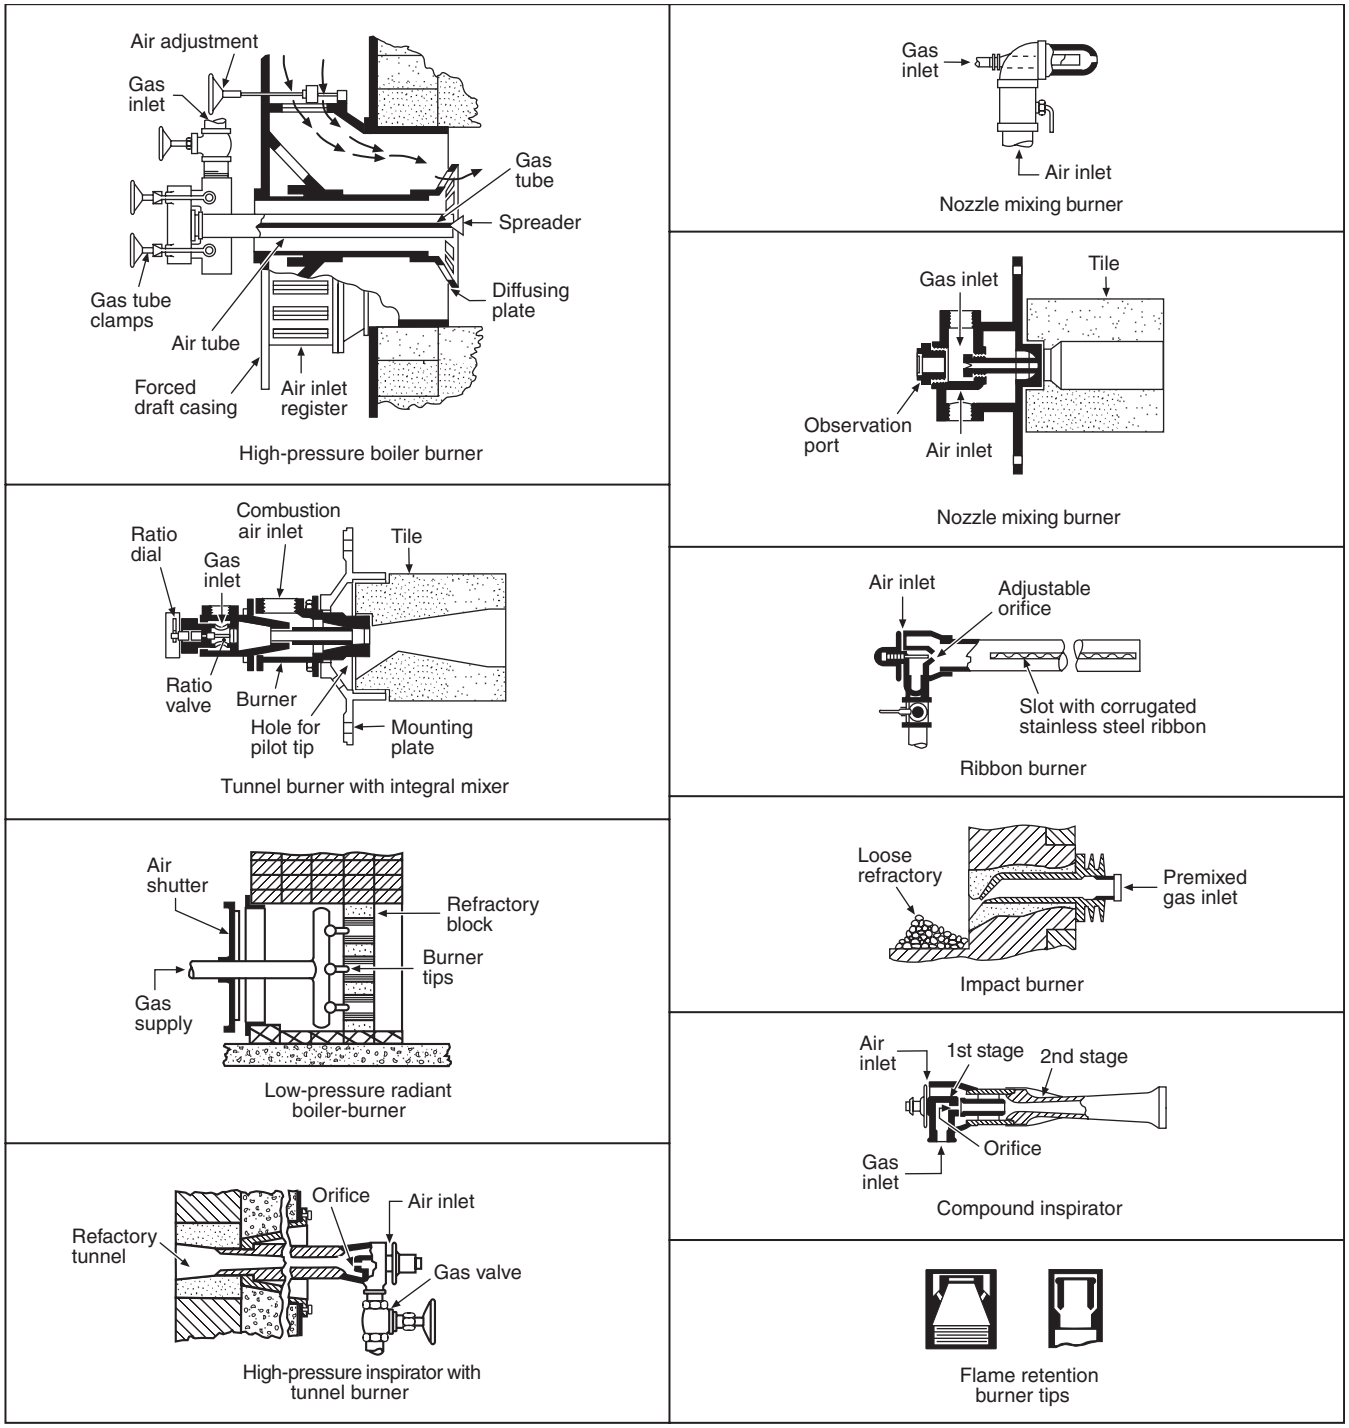

FIGURE 10.2.12 Types of Industrial Appliance Gas Burners

type vaporizing burners, shutoff is usually accomplished via a primary safety control. For gas appliances, an automatic gas ignition system is used. Both types of controls sense the presence or absence of flame. Upon ignition or flame failure, they cause the fuel to be shut off in the prescribed period of time. All fuel to the burner should be shut off. Primary safety controls usually provide for starting and stopping the burner in response to changes in demand (room thermostat, process controller, etc.). Controls for commercial and industrial burners may provide a purge period for air to flow through the appliance prior to starting fuel flow. The control also prohibits main burner fuel from being admitted until the control has proved the existence of the ignition flame.

The discharge of unburned oil from pot-and-sleeve-type vaporizing burners should be prevented by a constant level

valve or by barometric feed. Each of these provisions maintains a predetermined level of oil in the burner below any point of overflow.

Air/Fuel Interlocks

If the safe operation of a burner depends on a forced or induced draft fan or air compressor to supply combustion air, an interlock is needed to shut off fuel in case the air supply is interrupted.

Atomizer/Fuel Interlocks

In an oil-burning system, where air, steam, or other means for atomization can be interrupted without stopping oil delivery to the burner, an interlock must be provided to immediately shut off the oil if atomization fails.

Pressure Regulation and Interlocks

Gas burners and pressure-type oil burners require uniform fuel pressure so fuel burns safely and efficiently. Pressure regulators are used to maintain uniform fuel pressures. In situations where fuel pressure fluctuations can be expected, pressure interlocks are provided, which shut off the fuel to the main burners when the pressure is too low or too high for safe operation.

Oil Temperature Interlocks

Oil burners requiring heated oil for satisfactory operation are equipped with a low oil temperature switch to prevent the burner from starting or to shut it down if the oil temperature falls below the required minimum.

Manual Restart

If a burner is not equipped to provide safe automatic restarting after shutdown, its control system must be arranged to require manual restarting after any control operates to extinguish the burner flame.

Remote Shutoff

It is good practice to provide a remote control for manually stopping the flow of fuel to the burner. An identified switch in the burner supply circuit, placed near the entrance to the room where the burner is located, can be used with electrically powered equipment. A valve in the fuel supply line, operable from a location reached without passing near the burner, can also be used.

Safety Shutoff Valves

Safety shutoff valves prevent the abnormal discharge of fuel. They should be constructed so they cannot be readily restrained or blocked in the open position. Such valves should automatically close when de-energized, regardless of the position of any damper-operating lever or reset handle. Electrically operated valves should not need to be energized to close. Pressure-operated valves should close upon failure of the operating pressure.

Safety Control Circuits

Safety control ac circuits are of the two-wire type with one side grounded. They must not exceed a nominal 120 V and must be protected with suitable fuses or circuit breakers. All switches should be in the hot ungrounded line. The accidental grounding of such a circuit will not cause a required safety control to be bypassed.

Appliances and equipment fired with fuel burners require some additional controls to avoid excessive pressure, temperature, or other abnormal conditions. These controls are covered later in this chapter.

Appliances listed by testing agencies are equipped with all the required safety controls. The application of controls to fuel-burning systems assembled in the field or intended for specific applications should be entrusted only to people specializing in this work. The standards pertaining to fuel-burning equipment referenced in the bibliography include specific information on controls essential to safe operation of fuel-burning equipment.

Safety controls are generally preset by the manufacturer or the installer. Any alteration of these settings or bypassing any safety control could lead to serious consequences. When a faulty control is replaced, a similar model and setting should be used. Figures 10.2.13 and 10.2.14 illustrate typical arrangements of safety valves and interlocks for industrial gas and oil burners, respectively.

HEATING APPLIANCES AND THEIR APPLICATIONS

Central heating appliances, room heating appliances, and miscellaneous heat-producing devices, which are fired by the various fuels and methods discussed, are described here.

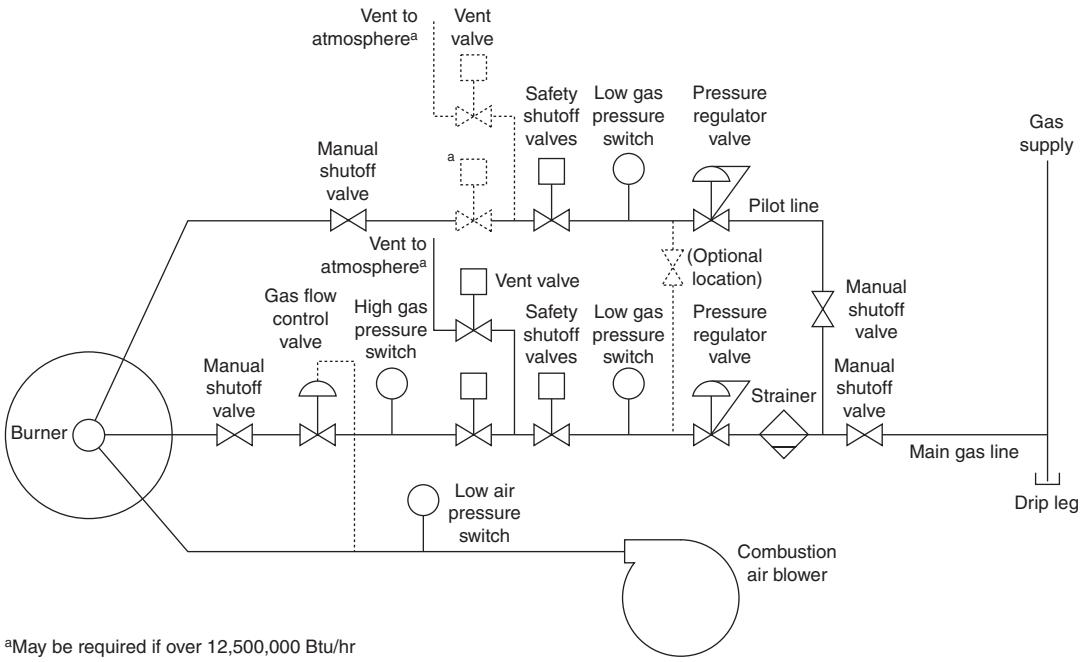
Central Heating Appliances

Central heating appliances are divided into four broad categories: (1) boilers, (2) central furnaces, (3) floor furnaces, and (4) wall furnaces.

Boilers. Boilers are either of the steam or hot water type and are constructed of cast iron or steel (Figure 10.2.15). The *ASME Boiler and Pressure Vessel Code*[4] defines low-pressure boilers (for low-pressure steam heating, hot water heating, and hot water supply) as those steam boilers that operate at pressures not exceeding 15 psig (100 kPa) and hot water boilers as those that operate at pressures not exceeding 160 psi (1100 kPa) and at temperatures not exceeding 250°F (120°C). The *ASME Boiler and Pressure Vessel Code* also covers the construction of power boilers and locomotive boilers.

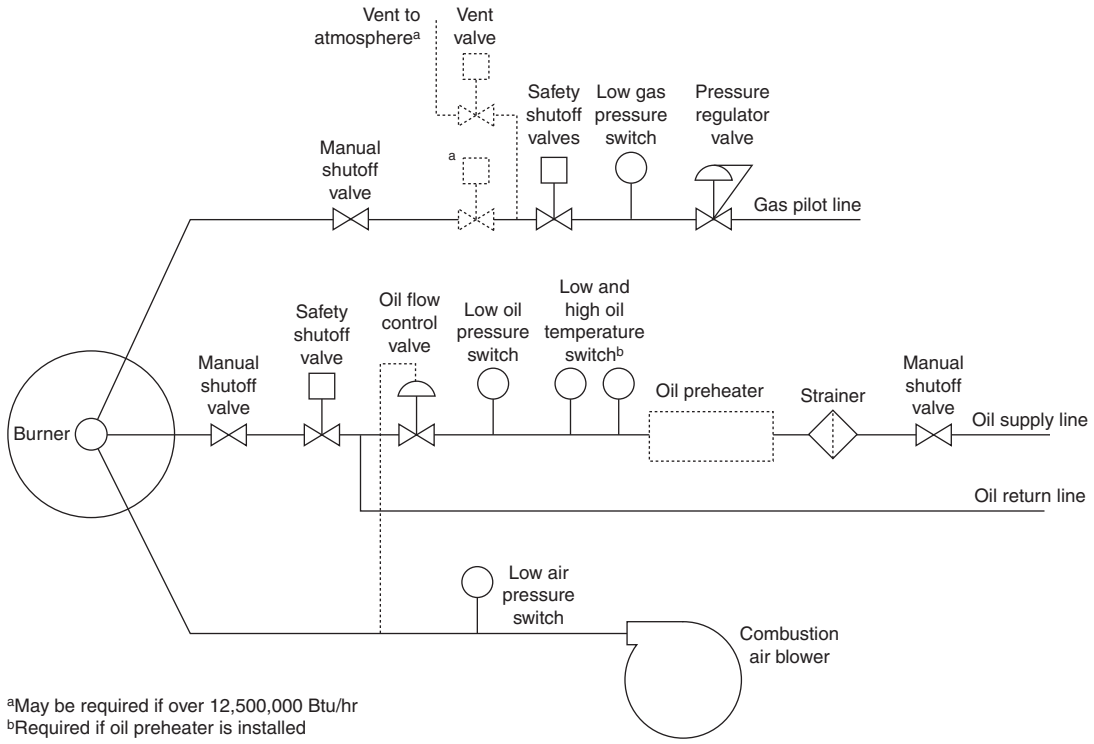
Boilers are equipped with safety devices to prevent overpressure conditions. Automatically fired boilers also have controls that will shut off the burner or electric heating elements under low water conditions or when a predetermined pressure or temperature has been reached.

The fire problems of boilers include their mountings and clearances to combustibles. Explosions resulting from



[a]May be required if over 12,500,000 Btu/hr

FIGURE 10.2.13 Typical Safety Valves and Interlock Arrangement for Industrial Gas Burner



[a]May be required if over 12,500,000 Btu/hr
[b]Required if oil preheater is installed

FIGURE 10.2.14 Typical Safety Valves and Interlock Arrangement for Industrial Oil Burner

unburned fuel accumulations in the combustion chamber or due to overpressure conditions could rupture fuel lines, thus contributing to the potential for subsequent fire or explosion damage.

Central Warm Air Furnaces. The residential types currently installed in the United States are usually equipped with circulating fans, filters, and other features that make them, in effect, air-conditioning systems.

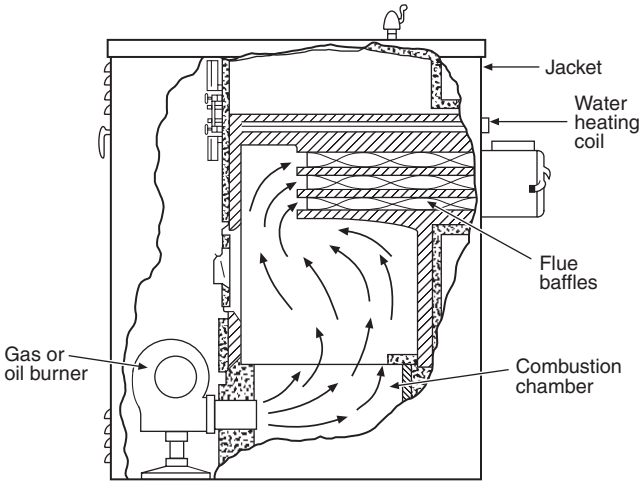


FIGURE 10.2.15 Oil-Fired Steam Boiler

Central warm air furnaces are of the following types:

1. Gravity—depends primarily on the circulation of air by gravity.
2. Gravity with integral fan—fan is an integral part of the furnace construction and is used to overcome internal resistance to airflow.
3. Gravity with booster fan—fan does not restrict flow of air by gravity when fan is not operating.
4. Forced air—equipped with fan that provides the primary means of circulating air (Figure 10.2.16).

Forced-air central warm air furnaces are classified according to the direction of airflow through them, that is, as horizontal, upflow, or downflow.

Gravity furnaces are floor mounted and can heat only spaces above them. Forced-air furnaces can be floor mounted or suspended and can be found on almost any floor of a building, including the attic and roof.

Under some conditions of operation, plenums of warm air heating furnaces can become hot enough to ignite adjacent unprotected woodwork. Clearances or insulation are necessary in these instances. (Complete requirements for installation of systems in residences can be found in NFPA 90B, *Standard for the Installation of Warm Air Heating and Air-Conditioning Systems.*)

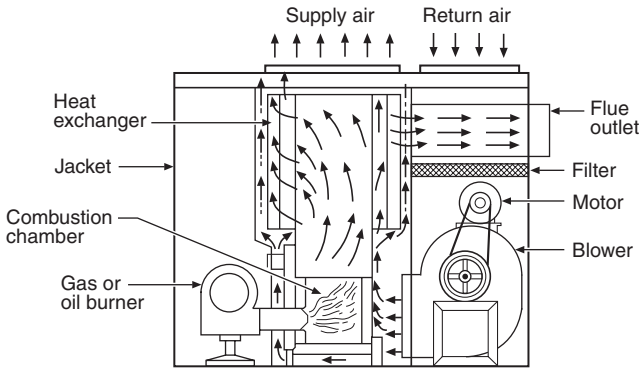

FIGURE 10.2.16 Oil-Fired Forced-Air Furnace

Automatic controls, also called high-limit controls, can shut off the fuel or electric supply whenever the air in the furnace warm air plenum or at the beginning of the main supply duct—at a point not affected by radiated heat—reaches 250°F (120°C) or less, depending on the type of furnace and its installation (Figure 10.2.17). Automatic controls cannot be set above prescribed temperature limits. Some furnaces used only with special duct systems are factory equipped to permit temperatures above 250°F (120°C) at the inlet of the supply ducts.

Central warm air furnaces also can cause fires due to inadequate clearances to combustible construction, lack of proper limit controls, heat exchanger burnouts, and other causes associated with lack of proper installation, servicing, and maintenance.

Pipeless Furnaces. Pipeless furnaces are essentially gravity warm air furnaces that are not connected to ducts. The furnace is mounted directly under the space to be heated. All the air heated in its outer jacket is discharged through a register above the heat exchanger. They are used for heating small homes and other small one-story properties.

Pipeless furnaces can produce dangerously high temperatures, particularly if the air circulation is restricted. For example, if the register in the floor of a small hallway heats adjoining rooms by air circulating through opened doors, the temperature of the entire hall might be raised to a dangerous degree if the doors are closed tightly at a time when the furnace is in full operation. Fires also can occur when clothing left to dry above a central floor register is ignited. It is good practice to equip automatically fired pipeless furnaces with limit controls.

Floor Furnaces. Most oil- and gas-fired floor furnaces are designed so they can be installed in combustible floors (Figure 10.2.18); however, they should not be installed in combustible floors if they have not been listed by a testing laboratory for such use. Clearances should be sufficient not only to protect

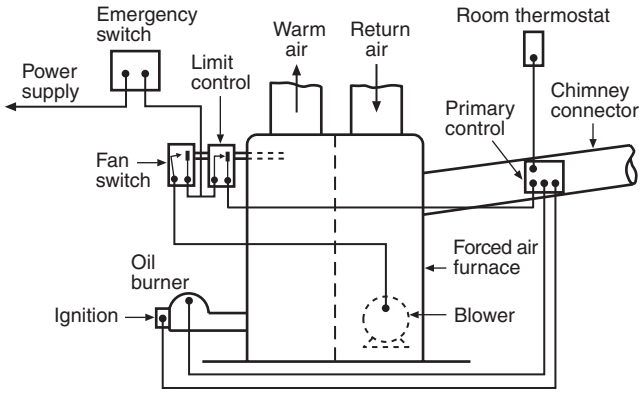

FIGURE 10.2.17 Control Wiring Schematic of Oil-Fired Forced Warm Air Furnace. Certain primary controls are mounted on the burner assembly.

combustible floors and walls, but also to keep the furnace casing and the piping connected to it out of contact with earth or damp materials. Temperature limit controls are provided on floor furnaces to shut off the fuel supply when the temperature of the discharged air reaches a predetermined level.

In auditoriums, public halls, or assembly rooms, floor furnaces should not be installed in the floor of any aisle, passageway, or exitway. Floor furnace registers can become hot enough to cause burns under some conditions; therefore, registers in dwellings should not be located in passageways to bathrooms, where persons would be likely to step with bare feet. Users should be warned against covering registers or placing clothing on them to dry. Older types of floor furnaces do not have a temperature limit control and can become dangerously hot if the air passages are blocked with dust and lint. Inspection and vacuum cleaning or hand removal of this blockage is essential for continued safe operation.

Wall Furnaces. Wall furnaces are self-contained indirect-fired gas or oil heaters installed in or on a wall. They supply heated air directly to the space to be heated, either by gravity or a fan through grilles on openings or boots in the casing supplied by the manufacturer. The furnaces may be of the direct-vent type or are vent- or chimney-connected, depending on the fuel. Limit controls limit outlet air temperature. The fire problems with recessed wall furnaces are similar to those encountered with most warm air furnaces. A wall furnace installation is shown in Figure 10.2.19.

Duct Furnaces. Duct furnaces are installed directly in ducts of some warm air and air-conditioning systems and depend on air circulation from a blower not furnished as a part of the furnace. They can be oil or gas fired or electrical and are equipped with a limit control to shut off the fuel supply or electricity at excessive temperatures.

When duct furnaces are used in conjunction with refrigeration coils in a combined heating and cooling system, the furnace

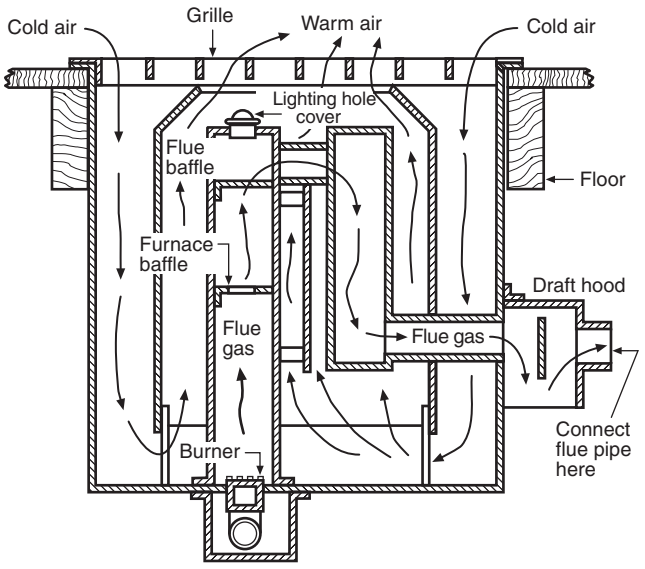

FIGURE 10.2.18 Typical Floor Furnace

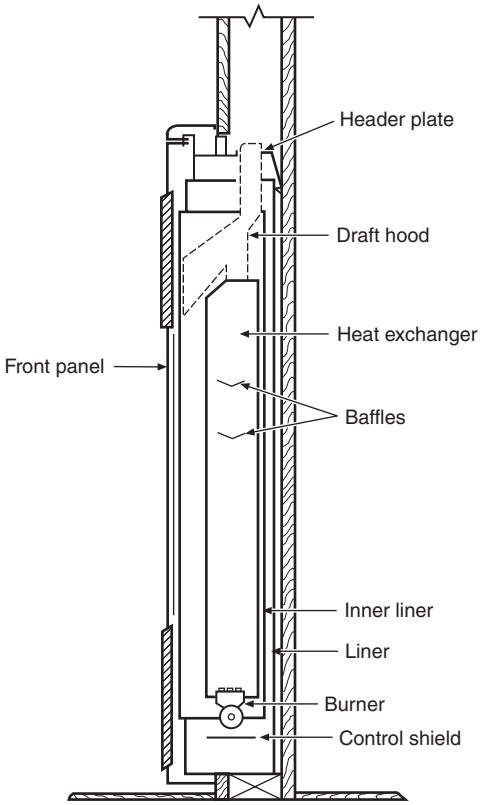

FIGURE 10.2.19 Typical Gas-Fired Wall Furnace

should be located upstream from the refrigeration coil or parallel with it to prevent condensation from corroding the furnace. There are, however, furnaces made of corrosion-resistant material, which may be installed downstream from the refrigeration coil. When the furnace is located upstream from the refrigeration coil, the coil should be designed so that excessive pressures and temperatures will not develop in the coil. A duct furnace installation is shown in Figure 10.2.20.

Warm Air Heating Panels. These are used in low-temperature, forced-air systems to circulate warm air through plenums or chambers that have one or more surfaces exposed to the space to be heated. NFPA 90B gives recommendations for the use, construction, and installation of these panels.

Radiant Heating. Radiant heating uses panels of hot water piping or electric heating elements that usually operate at moderate temperatures. The panels are embedded in plaster walls or ceilings or in cement floors. Hot water pipes or electrical equipment in radiant systems should conform to standard installation practices. NFPA 70 contains specific recommendations on the installation of electrical space heating equipment.

Heat Pumps. A heat pump is a type of forced-air heating system in which refrigeration equipment is used in such a way that heat is taken from a heat source and given up to the conditioned space when heat service is wanted and is removed from the space

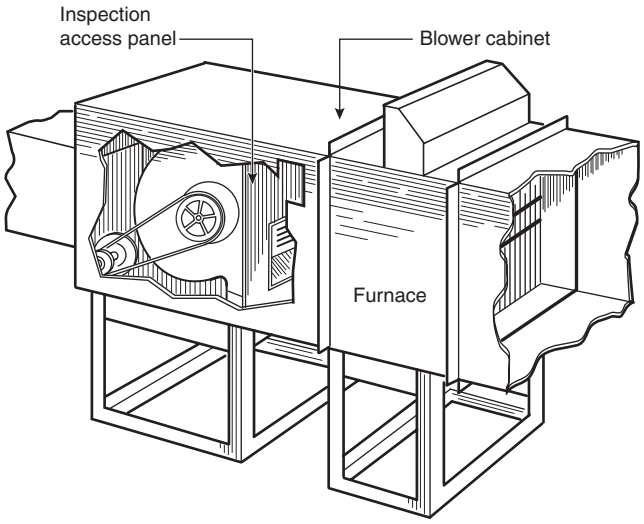

FIGURE 10.2.20 Duct Furnace Installation

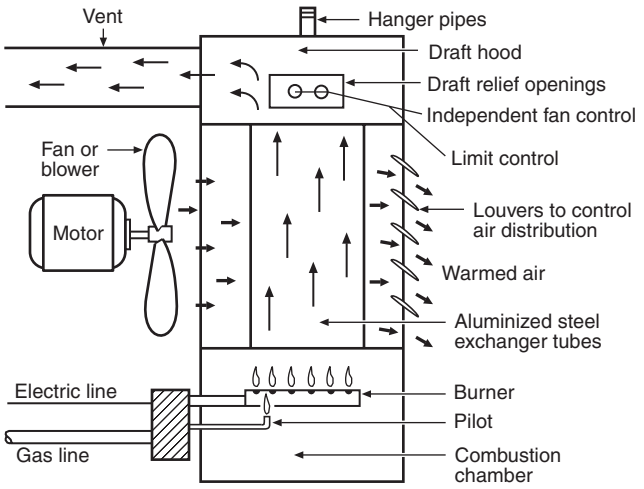

FIGURE 10.2.21 Typical Gas-Fired Unit Heater

and discharged to a heat sink when cooling and dehumidification are desired. These systems frequently have supplemental heating units. In such cases, the units are equipped with an interlock to prevent the unit from operating unless the indoor air circulating fan on the system is running. The units also have temperature limit controls. Hazards are those presented by power, refrigeration equipment, and heat units, if these are part of the system.

Unit Heaters

Unit heaters are classed as self-contained, automatically controlled, chimney- or vent-connected air heating appliances with an integral means for air circulation. They can be floor mounted or suspended and are equipped with temperature limit controls. The term *unit heater* as used in NFPA standards is intended to cover appliances for heating nonresidential properties. Thus, it excludes room heaters, floor furnaces, and similar devices. More specifically, a unit heater is an appliance consisting of a heating element and fan housed in a common enclosure and placed within or adjacent to the space to be heated. Unit heaters should not be confused with heat exchangers, which are equipped with fans to circulate heated air. In the latter type, hot water or steam is piped from a heating unit to the heat exchanger in the area to be heated.

Unit heaters that are designed for connection to a duct system can be considered as central heating furnaces and should be provided with the same safeguards. A typical unit heater is shown in Figure 10.2.21.

Room Heaters and Cooking Appliances

A room heater differs from a central heating furnace in that it is a self-contained air heating appliance designed for the direct heating of the space around it. External pipes or ducts are not used to distribute the heat. Room heaters fall into two general types: circulating and radiant. A fuel-burning circulating heater has an outer jacket surrounding the combustion chamber. It is arranged with openings at the top and bottom so that air circulates between the inner and outer shell. It does not have openings in the sides of the outer jacket in order to permit direct radiation. From a safety point of view, room heaters other than those specifically designed as circulating are classified as being radiant. They include such appliances as wood and coal stoves, electric and gas logs, open-front heaters, wall heaters, gas coal baskets, and fireplace inserts. Care must be taken, especially with heaters that can be moved easily, to place the radiant type so that radiating elements and surfaces are not directed toward walls, drapes, or furniture in close proximity to the heater.

Fuel-burning heaters and residential cooking appliances should be connected to a chimney or vent, when appropriate. The exceptions are gas room heaters and gas cooking appliances listed for unvented use.

Fuel-burning room heaters are not to be installed in sleeping quarters for use of transients, as in hotels and motels, nor in institutions such as homes for the aged, sanitariums, convalescent homes, and orphanages. It is good practice to install direct-vent-type heating appliances in sleeping quarters where heaters are permitted and in rooms generally kept closed.

Solid-Fuel Room Heaters

Fires involving coal and wood stoves or room heaters have dropped dramatically since the early 1980s (Figure 10.2.22). Much of the improvement can be attributed to increased vigilance in the correct installation and operation of the appliances. Fires in solid-fuel room heaters are due primarily to two underlying conditions: (1) inadequate clearances to combustible materials and other installation deficiencies and (2) improper or inadequate maintenance. Some wood stoves need frequent charging, sometimes involving much regulating of draft controls to prevent overheating. Sometimes, too, weather conditions can affect the chimney draft, causing improper combustion.

A solid-fuel heater essentially is a fire chamber surrounded by a decorative enclosure. The chamber might be equipped with

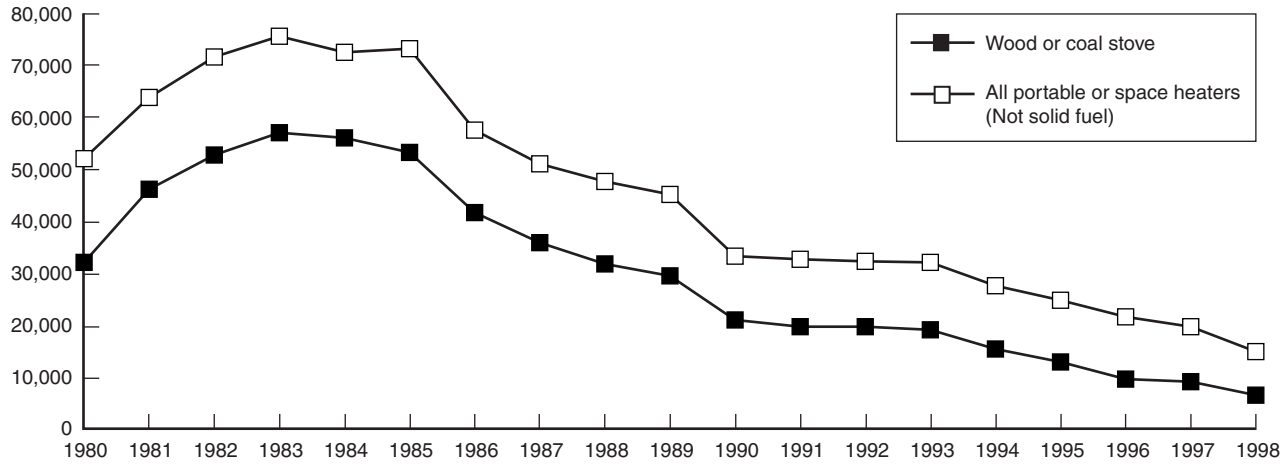

FIGURE 10.2.22 Home Fires Involving Space Heaters, 1980–1998[6]

manual draft controls or a thermostatic control and provided with a chimney connector and other parts that might be required for installation. Instructions that come with heaters that have been listed by testing laboratories are quite precise on the type of heat shielding and the clearances from combustibles that are required.

The vast majority of solid-fuel room heaters are designed to burn only wood, which is easily burned on the bottom of the fire chamber, resting on a bed of firebrick, ashes, or sand. For coal, a grate or other provision to supply air below the fuel bed is needed.

Unless a special chimney is called for by the listing or installation instructions (as in the case of room heaters for use in manufactured homes), the typical solid-fuel heater can be connected to either a standard masonry chimney or any listed factory-built chimney. Laboratory tests for listing heaters establish the dimensions required for adequate clearances. Because clearances from large heaters can exceed 36 in. (0.9 m), the tests may be performed with supplemental heat protection or shielding for walls. For proper clearances and floor protection, see the section of this chapter on installation.

Hazards with Solid-Fuel Room Heaters

Overfiring. If an appliance is overheated deliberately or through neglect, there is a severe and immediate hazard if the unit or its connector glows even a very dull red. Control is to simply close doors and air dampers until things cool down.

Careless Handling of Ashes Containing Live Coals. Ashes should never be collected in combustible containers, nor should the containers ever be placed on a combustible floor.

Inadequate Connector Clearance. Problems involving connector clearance include violations of the required 18 in. (457 mm) clearance or lack of adequate protection where a single wall connector must penetrate a combustible wall to join a masonry chimney. Reduced connector clearances are permissible in some instances, such as the entry of single wall connectors into listed supports for factory-built chimneys. The reduced clearances have been validated by tests and are described in the installation instructions for listed heaters (Figure 10.2.23).

Creosote Accumulation and Fires. Creosote is a collection of tars and other hydrocarbons produced by the pyrolytic distillation of wood. Under ideal conditions, these products are consumed in the flames of a wood fire. When wood is burned in a stove under air-limited conditions, it might not be entirely burned and could deposit on surfaces of the stove, connector, and chimney. Creosote is combustible and, if ignited, can fuel a

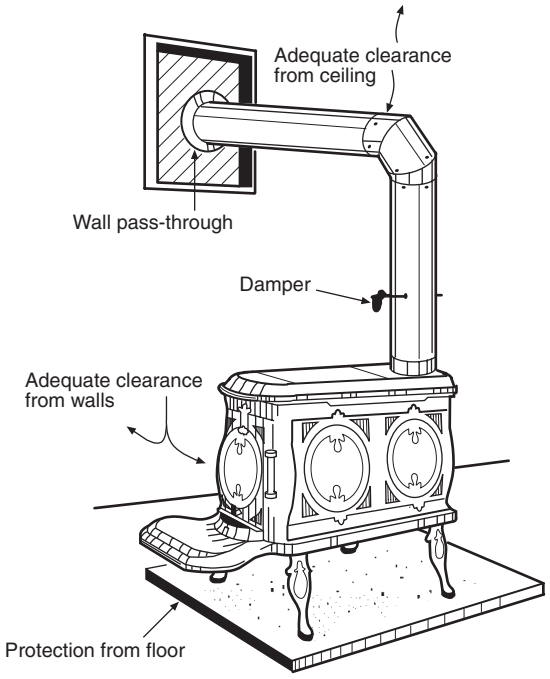

FIGURE 10.2.23 Adequate Clearances Necessary to Ensure Safe Operation of Coal and Wood Stoves

dangerous fire in portions of the venting system not designed to withstand combustion. The fire can damage the system components or spread to the adjacent structure.

Airtight wood stoves, when operated with draft controls restricted or with large fuel loads, can cause a significant buildup of creosote in a short period of time. Therefore, frequent inspection, and, when required, cleaning of the chimney system is necessary when these appliances are used.

The species and moisture content of the wood are not major determinants of the rate of creosote buildup, but habits of stove operation are. Proper sizing of the stove, with respect to the heating need, will help minimize the production of creosote by reducing the need for air-limited, low-temperature operation. The user should avoid long, extended burn cycles and large loads of fuel. The control of creosote and chimney fires is discussed in more detail under "Hazards of Chimneys," later in this chapter.

Restaurant Cooking Appliances

Restaurants employ a variety of cooking devices such as ranges, deep-fat fryers, steamers, broilers, hot plates and griddles, portable ovens, and others. These devices, like other heat-producing devices, require careful installation to avoid overheating of adjacent combustibles. In some of them, grease accumulates, adding to the fire hazard. NFPA 54 contains requirements for the installation of gas-fired restaurant cooking appliances. Ventilation of fixed restaurant cooking equipment is covered in NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations.*

Miscellaneous Heat-Producing Devices

There are so many miscellaneous heat-producing devices that it is unrealistic to treat each individually in this chapter. Certain basic principles apply to all of them, however, including provision for adequate clearances to combustibles, venting products of combustion, adequate air for combustion and ventilation, proper burner controls to safeguard against the hazard of the fuel, proper storage and handling of the fuel, and safety controls to safeguard the heat-producing device.

Testing laboratories test and list many miscellaneous types of heat-producing appliances, such as direct-fired heaters, incubators, lanterns, forges, and torches.

Kerosene Stoves. Self-contained, self-supporting kerosene-burning ranges, room heaters, or water heaters are not connected to chimneys but are equipped with integral fuel supply tanks not exceeding 2 gal (7.6 L) capacity. Terms often applied to kerosene room heaters are cabinet heaters and space heaters. Since they are not connected to chimneys, they can be moved rather easily although they are not considered portable. This feature of kerosene stoves can permit the creation of severe fire and life hazards due to improper placement of the stoves in relation to nearby combustibles and paths of exitways. Kerosene stoves listed by testing laboratories incorporate fire protection features that might be missing from those not listed. Among the more important features of listed stoves are the types of construction materials, primary control valves, and drip pans used in them.

Portable Kerosene Heaters. Portable kerosene heaters are similar in the potential for hazard to kerosene stoves because they are not connected to a chimney and are not required to have a permit for installation and use. The hazard in their use, however, is increased by their even greater portability. They are also subject to misfueling, substitution of gasoline or other inappropriate fuel, and refueling when hot, which can produce flammable vapors. The safest heaters incorporate fire safety features not included in others, such as special types of latching devices and integral sheet-metal trays under the burners to catch oil drips. They usually employ wick-type burners integral with the oil reservoir. Portable kerosene heaters should include a tip-over switch that automatically snuffs the burner if the unit is jostled or tipped.

Conversion Range Oil Burners. Range oil burners, which are found most frequently in the northeastern section of the United States, are designed to burn kerosene, range oil, or similar fuel. They are primarily installed in stoves or ranges originally designed to use solid fuel. They consist essentially of a single- or double-sleeve-type burner assembly, regulating valves, and an oil supply assembly with a suitable supporting stand and seamless connecting tubing. A thermal valve located in the burner compartment of the stove adjacent to the burner is installed in the oil supply line (Figure 10.2.24). Range oil burners should not be mistaken for conversion oil burners of the vaporizing-pot type designed for conversion of central heating appliances.

Salamanders. Salamanders are common miscellaneous portable heating devices. They are used at construction sites and in unheated buildings. Too frequently, a salamander consists of only a metal drum with some holes punched in it for draft and wood scrap and other construction waste materials for fuel. When constructed in this way, such devices present an acute spark hazard and the hazard of carbon monoxide poisoning because they are not chimney connected. Crude salamanders of this type, and gas- and oil-fired salamanders that have not been tested and listed by a laboratory, should not be used.

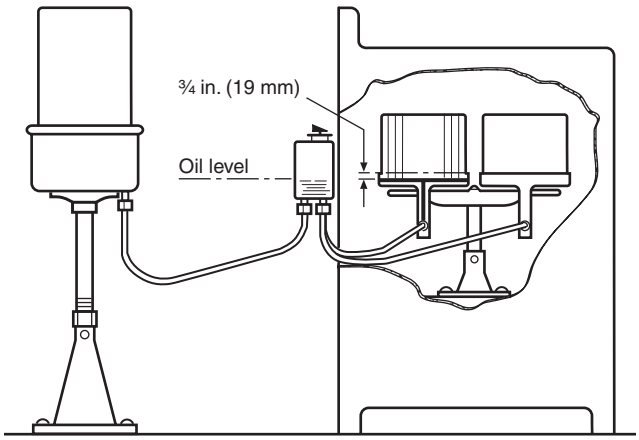

FIGURE 10.2.24 Typical Installation of Conversion Range Oil Burner

UL and CSA International laboratories test and list portable gas- and oil-fired heaters, such as salamanders. One way to use salamanders is to carry heated air indoors through flexible ducts from a heating unit located outdoors. NFPA 58, *Liquefied Petroleum Gas Code,* has extensive material on the use of LP-gas-fired portable heaters.

DISTRIBUTION OF HEAT BY DUCTS AND PIPES

Warm Air Distribution Systems

Central warm air heating systems consist basically of a heat exchanger with an outer casing or jacket that is connected to a system of ducts, air passages, or plenums that carry heated air (the supply side) to the spaces to be heated and return air (the return side) from the heated spaces to the heat exchanger.

NFPA 90B contains specific requirements for systems that are installed in one- and two-family dwellings and other occupancies not exceeding 25,000 ft^3 (700 m^3) in volume. Systems that are installed in spaces exceeding this size are covered in NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems.* This portion of the handbook is confined to a discussion of ducts for warm air heating systems installed in dwellings and other relatively small spaces.

Warm Air Supply Ducts. Warm air ducts must be installed with clearances as given in Table 10.2.2. They are substantially constructed of metal or of Class 0 or Class 1 duct materials and are properly supported and protected against injury. Duct materials are tested and listed by UL in accordance with UL 181, *Standard for Safety Factory-Made Air Ducts and Air Connectors,*[5] and are classified as follows:

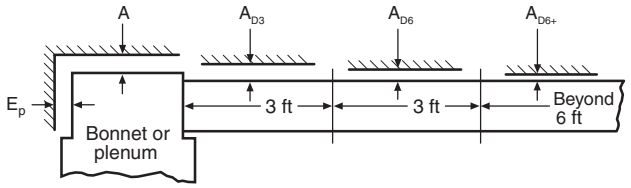
- **Class 0–Air duct.** Air ducts that have a fire hazard classification of zero (flame spread and smoke developed)
- **Class 1–Air duct.** Air ducts that have a flame spread rating of not more than 25 without evidence of continued progressive combustion and smoke developed rating of not more than 50

Supply Air Plenums. It is common practice in some localities to use the crawl space as the supply plenum for warm air heating systems when a one-story single-family house does not have a basement. These systems use a downflow furnace that discharges warm air through directional ducts into the crawl space. An opening cut in the floor of each room of the house and covered with a grille serves as the supply register. The hazards of these systems include use of combustible construction as a plenum, use of the crawl space for storage, presence of a large enclosed combustible area with no limitations on fire spread and with direct openings to every room of the house, and the possibility of reverse flow in the downflow furnace (the cold air return then becomes the supply duct). NFPA 90B gives specific recommendations and limitations applicable to the use of underfloor space as supply plenums, and it should be consulted for detailed guidance.

Horizontal supply ducts and vertical ducts, risers, boots, and register boxes within certain limits of the warm air furnace can reach temperatures that can become hazardous; therefore, safe clearances to combustibles must be maintained. The clearances required for the many possible configurations of warm air ductwork are specifically provided in NFPA 90B, which should be consulted.

Registers. To prevent excessive heat from developing in the duct system, one register or grille must be installed without a

TABLE 10.2.2 Installation Clearances, in Inches, for Horizontal Warm Air Ducts



A—Clearance above top of casing, bonnet, plenum, or appliance determined by Table 10.2.5
A_{D3}—Clearance from horizontal warm air duct within 3 ft (0.9 m) of plenum.
A_{D6}—Clearance from horizontal warm air duct between 3 and 6 ft (0.9 and 1.8 m) of plenum.
A_{D6+}—Clearance from horizontal warm air duct beyond 6 ft (1.8 m) of plenum.
E_P—Clearance from any side of bonnet or plenum.

If A Equals	*A_{D3} Equals*	*A_{D6} Equals*	*A_{D6+} Equals*	*E_P Equals*	*Method of Firing*
1	1	0	0[a]	1	Automatic oil, comb. gas-oil, or gas
2	2	0	0[a]	2	Automatic oil, comb. gas-oil, or gas
6	6	6	0[a]	6	Automatic oil, comb. gas-oil, or gas
6	6	6	1[a]	6	Automatic stoker fired[b]
18	18	6	1[a]	18	Any fuel or control

[a]Clearance A_{D6+} to be maintained to a point where there is a change in direction equivalent to 90 degrees or more.
[b]Furnace must be equipped with limit control that cannot be set higher than 250°F (120°C) and must also have a barometric draft control operated by draft intensity and permanently set to limit draft to a maximum intensity of 0.13 in. water gauge (32 kPa), otherwise clearances should be as indicated by any fuel.
For SI units: 1 in. = 25.4 mm; 1 ft = 0.305 m.

shutter and damper in the duct to it. The exceptions are automatic oil- or gas-fired systems that have approved temperature limit controls or systems with dampers and shutters designed so that they cannot shut off more than 80 percent of the duct area.

Where registers are installed in the floor over the furnace, as in pipeless furnaces or floor furnaces, the register box should consist of a double wall with an air space of not less than 4 in. (102 mm) between walls. Furnaces with a cold air passage around the warm air passage comply with this requirement.

Return Air Ducts and Plenums. The best way to conduct return air to the furnaces and duct heaters is through continuous ducts. Return ducts do not need to be made of the same materials as supply ducts except for those portions directly over the heating surface or within 2 ft (0.6 m) of the outer casing or jacket of the furnace or duct heater. They should not, however, be made of materials more combustible than 1-in. (25-mm) nominal wood boards. Underfloor spaces may be used for return ducts from rooms directly above, but such spaces should be used only if they are not more than 2 ft (0.6 m) in depth from the bottom of floor joists, are clean of all combustible material, and are tightly and substantially enclosed. A vertical stack for return air should not be connected to registers on more than one floor.

The interior of combustible ducts must be lined with metal at points where there is danger from smoldering or burning incandescent particles dropped through a register, such as directly under floor registers and at the bottom of vertical ducts.

Air Filters. Air filters should be the kind that will not burn freely or emit large volumes of smoke or other objectionable products of combustion. Filters qualifying as Class 1 and Class 2, as defined in NFPA 90B, are accepted as meeting these requirements. Only liquid adhesive coatings with a flashpoint of 325°F (163°C) or higher (Pensky-Martens closed-cup tester) are acceptable. Filters are not installed in ducts of heating systems unless the system design calls for them. Otherwise the filters may restrict the flow of air and cause dangerous overheating.

Solid Fuel Add-On Furnaces. Solid fuel add-on furnaces are designed to connect to the existing air distribution ductwork of a house and supply heated air as a supplement to the operation of the regular furnace. Most, though not all, are independently controlled, with a separate thermostat. A wood or coal fire is established in the unit, and the thermostat regulates the flow of air to the combustion chamber, and thereby the amount of heat produced. Properly installed and operated, add-on furnaces can supply all or most of the central heating needs of a home.

However, add-on furnaces can also present some unique hazards. They tend to have large combustion chambers that can be filled with a large volume of wood. When the heating need is not great, the thermostat tends to keep the fire low and smoldering, with consequent production of a large amount of creosote. Add-on furnaces and their venting systems need frequent inspection and cleaning.

NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances,* specifically prohibits the use of a chimney flue to vent both a solid fuel appliance and an appliance burning other fuels. Therefore, a properly installed solid fuel add-on furnace must have its own chimney flue, separate from that serving the conventional furnace or water heater.

The method by which the add-on is connected to existing ductwork is critical. Properly configured, the add-on will have its own distribution blower and not rely on the blower of the existing furnace. This allows the supply (hot air) plenum of the add-on to be connected to the supply plenum of the furnace; and the return (cold air) side of the add-on to draw air directly through the return ducting. This is called a *parallel* connection and allows the add-on to function identically with the conventional furnace.

A parallel connection can also be accomplished without connection of the return side of the add-on to the return ducting system. In this configuration, the add-on's blower is simply open and draws air from the surrounding area. This can cause significant depressurization of the basement, which could result in flow reversal of the add-on flue or other appliances in the area, with consequent spillage of combustion products. Such open installations are strongly discouraged.

A connection method that has been frequently used for unlisted and homemade add-on furnaces is a *series* connection. This configuration is definitely hazardous. In this form, the add-on does not have a blower, but attempts to use the existing furnace blower for air distribution. Both the return side and supply side of the add-on are connected to the existing return plenum or ductwork, with a baffle to direct the flow of return air through the add-on. As a result, hot air produced through the add-on is circulated through portions of the furnace and duct system, which were not designed for hot air. Furthermore, in a power failure the add-on will continue to produce heat, but the distribution blower will not run. Very hot air will back up and be concentrated in the return ducting system, which may be constructed of combustible materials. Fires can result from such installations.

Heating Panels. NFPA 90B recommends that heating panels be used only with automatically fired gas- or oil-burning or electric forced warm air systems that will limit furnace outlet air temperature to 200°F (93°C) or systems equipped with steam or hot-water heat exchangers utilizing steam that cannot exceed 15 psig (103 kPa) or hot water that cannot exceed 250°F (120°C).

Panels used with automatically fired forced warm air systems must be of noncombustible material or at least of material with a flame spread rating of not more than 25, as determined in accordance with NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials.*

Where the warm air supply is from a steam or hot-water heat exchanger, the panels may be made of material not more flammable than 1-in. (25-mm) nominal wood boards. No single vertical heating panel should serve more than one story of any building.

Steam and Hot-Water Pipes

The temperature of saturated steam varies with the pressure. For example, at atmospheric pressure the temperature of steam is

212°F (100°C), whereas at 25 psig (172 kPa) its temperature is 266.7°F (130.4°C). Other values of temperature of saturated steam at various pressures are given in Table 10.2.3.

Water at high temperature and pressure is also used for heating. The system pressure must always exceed the pressure at the saturation temperature to prevent the water from flashing to steam. This means that the pressure in high-temperature hot-water systems must exceed the values shown in Table 10.2.3 at the specific temperature at which the system operates. Most systems operate at temperatures between 250 and 430°F (120 and 220°C).

Recommended clearances for steam and hot-water pipes and radiators are given in Table 10.2.4.

Radiators and pipes should not be used as racks for drying purposes. Where radiators are placed in window recesses or concealed spaces, such spaces should be lined with noncombustible material, have ample air circulation, and be kept clean.

INSTALLATION OF HEATING APPLIANCES

Any source of heat is a potential fire hazard unless it is arranged to prevent the possibility of dangerous temperatures developing on adjacent combustible materials. It is possible for wood and certain other combustible materials to ignite at temperatures far below their usual ignition temperatures if they are continually exposed to relatively moderate heat over long periods of time.

TABLE 10.2.3 Temperature of Saturated Steam

35	241.0	206.8	138.1				

Note: Superheated steam has a higher temperature than saturated steam at the same pressure, depending upon the degree of superheat.
[a]Zero gauge pressure corresponds to an absolute pressure of 14.696 psi (101.329 kPa).
[b]Critical point, from Keenan's Tables.

TABLE 10.2.4 Installation Clearances for Steam and Hot-Water Pipes and Radiators

Description	Clearances *in.*	Clearances *mm*
A. Hot-water pipes and radiators supplied by automatically fired gas, gas-oil, or oil-burning boilers equipped with limit control that cannot be set to permit a water temperature above 150°F (66°C).	None	
B. Hot-water and steam pipes and radiators supplied with hot water at not more than 250°F (120°C) except as permitted in A above, and with steam at not over 15 psig (103 kPa).	1*	25*
C. Steam pipes carrying steam at pressures above 15 psig (103 kPa), but not over 500 psig (3450 kPa)	6	15

*At points where pipes emerge from a floor, wall, or ceiling, the clearance of the opening through the finish floor boards or wall or ceiling boards may not be less than ½ in. (13 mm). Each such opening must be covered with a plate of noncombustible material.

To safeguard against this possibility, heat-producing appliances must be installed with adequate clearance between the appliance and combustibles. Then, under conditions of maximum heat (long and continued exposure), the temperature of exposed combustibles will not exceed dangerous limits. Minimum clearances for various types of heat-producing devices, which should prevent the temperature from exceeding the maximum in exposed combustibles, have been determined by testing laboratories and through field experience. Table 10.2.5. gives the required standard clearances around and above gas- and oil-fired and electrical residential, commercial, and industrial heat-producing appliances. Table 10.2.6 gives clearances for solid-fuel burning appliances. The term *listed appliances,* which appears in the subheads of the tables, refers to appliances that have been tested by testing laboratories. The proper clearances for these appliances, as determined by tests, are published in a listing. The recommended clearances are also indicated either on the appliance or in the manufacturer's installation manual included with the appliance.

Examples of laboratories that test and list appliances are FM Global Research, Underwriters Laboratories Inc., Underwriters Laboratories of Canada, Intertek and Testing Services, and CSA International.

Modifications of Clearances

Listings of heat-producing appliances and methods for setting clearances between appliances and combustible surfaces are based on criteria in Underwriters Laboratories Inc. test standards:[6]

- Maximum temperature rise of 117°F (65°C) above room temperature on exposed surfaces
- Maximum temperature rise of 90°F (50°C) above room temperature on unexposed surfaces, such as beneath the appliance, floor protector, or wall-mounted protective device

TABLE 10.2.5 Standard Installation Clearances for Nonsolid Fuel Heat-Producing Appliances[a]

These clearances apply unless otherwise shown on listed appliances. Appliances should not be installed in alcoves or closets, unless so listed. For installation on combustible floors, see note b.

[a]Standard clearances may be reduced by affording protection to combustible material in accordance with Table 10.2.7.
[b]An appliance may be mounted on a combustible floor if the appliance is listed for installation on a combustible floor, or if the floor is protected in an approved manner. For details of protection, see NFPA 211.
[c]Rooms that are large in comparison to the size of the appliance are those having a volume equal to at least 12 times the total volume of a furnace and at least 16 times the total volume of a boiler. If the actual ceiling height of a room is greater than 8 ft (2.4 m), the volume of a room must be figured on the basis of a ceiling height of 8 ft (2.4 m).
[d]The minimum dimension should be that necessary for servicing the appliance, including access for normal maintenance, care, tube removal, and so on.
[e]For a listed oil, combination gas-oil, gas, or electric furnace, this dimension may be 2 in. (50 mm) if the furnace limit control cannot be set higher than 250°F (120°C), or this dimension may be 1 in. (25 mm) if the limit control cannot be set higher than 200°F (93°C).
[f]To combustible material or metal cabinets. If the underside of such combustible material or metal cabinet is protected with asbestos millboard at least ¼ in. (6.4 mm) thick covered with sheet metal of not less than 24 in. (610 mm).
[g]Clearance above the charging door should be not less than 48 in. (1219 mm).
[h]If the appliance is encased in brick, the 18-in. (457-mm) clearance above and at sides and rear may be reduced to not less than 12 in. (305 mm).
[i]If the appliance is encased in brick, the clearance above may be not less than 36 in. (914 mm), and at sides and rear may be not less than 18 in. (457 mm).

TABLE 10.2.6 Standard Clearances for Solid-Fuel-Burning Appliances

(For reduced clearances, see Table 10.2.7.) These clearances apply to listed appliances installed in rooms that are large in comparison with the size of the appliances.

[a]Provisions for fuel storage must be located at least 36 in. (914 mm) from any side of the appliance.
[b]Adequate clearance for cleaning and maintenance must be provided.
[c]For clearances from air ducts, see NFPA 90B.
[d]To combustible material or metal cabinets. If the underside of such combustible material or metal cabinet is protected with sheet metal of not less then 24 gauge (0.024 in. [0.61 mm]), spaced out 1 in. (25 mm), the distance shall be permitted to be reduced to not less than 24 in. (610 mm).

Source: NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances.*

These requirements are based on the fact that, while the ignition temperature of wood products is generally quoted to be on the order of 392°F (200°C),[7] wood that is exposed to constant heating over a period of time may undergo chemical change, resulting in a much lower ignition temperature and increased potential for self-ignition.

Mitchell[8] presents data on wood fiberboard exposed to temperatures as low as 229°F (109°C) that resulted in ignition after prolonged exposure. MacLean[9,10] reports charring of wood samples at temperatures as low as 200°F (93°C). He concludes that wood should not be exposed to temperatures appreciably higher than 151°F (66°C) for long periods. McGuire[11] suggests that the maximum safe temperatures on the surface of a combustible material adjacent to a constant heat source should be no more than 212°F (100°C).

Clearly, the ignition of wood at moderately elevated temperatures is a complex phenomenon; the length of exposure is indeed an important parameter.[12,13] Although exact limits recommended in the literature vary due to exposure time and details of the tests conducted, documented fires involving the ignition of wood members near low-pressure steam pipes[14] suggest an upper temperature limit for combustible materials exposed to long-term, low-level heating should not be appreciably higher than 212°F (100°C).

The clearances given in Tables 10.2.5 and 10.2.6 will provide reasonable protection for exposed surfaces, including those of considerable area, against assumed conditions of continuous operation of heat-producing appliances at maximum temperatures. However, if the appliance is very large, increased clearances to combustible materials might be required. This is a good reason why all appliances should be installed in accordance with the terms of their listing. Prior to and during the heating season, frequent checks should be made to assure that the area is free of combustibles.

Installing heating appliances that under normal operation will not expose adjacent combustible materials to dangerous temperatures is not sufficient. Clearances and protection also must be designed for reasonable protection when the heating device is operated at its maximum temperature. However, under any conditions of operation the temperature of the exposed combustible materials should not exceed 180°F (82°C). Some provision for ventilation, air circulation, or other method of cooling is necessary to dissipate heat.

In large rooms, a suitable clearance between a heating appliance and combustible material is all that is necessary to prevent ignition. In small rooms or poorly ventilated spaces, particularly where the size of the heating device is large in proportion to the room, dangerous temperatures could be built up no matter how

great the clearance unless some provision is made for cooling by air circulation. Only appliances designed and tested for installation in confined spaces, such as alcoves or closets, are to be installed in such spaces. The clearances specified for them are observed whether the enclosing walls are combustible or noncombustible.

Table 10.2.7 and Figures 10.2.25 through 10.2.30 show how clearances can be reduced by installing protection between the heat-producing device and the combustible material. This information is especially helpful in situations of inadequate clearance in which it would be impractical to move the heat-producing appliance.

TABLE 10.2.7 Reduction of Appliance Clearance with Specified Forms of Protection[a–j]

Clearance Reduction System Applied to and Covering All Combustible Surfaces within the Distance Specified as Required Clearance with No Protection (See Table 10.2.4)	Maximum Allowable Reduction in Clearance (%)		If the required clearance with no protection is 36 in. (914 mm), the clearances below are the minimum allowable clearances; for other required clearances with no protection, calculate minimum allowable clearance from maximum allowable reduction[i,j]			
			As Wall Protector		As Ceiling Protector	
	As Wall Protector (%)	*As Ceiling Protector (%)*	*in.*	*mm*	*in.*	*mm*
3½-in. (90-mm) thick masonry wall without ventilated air space[a]	33	—	24	610	—	—
½-in. (13-mm) thick noncombustible insulation board over 1 in. (25 mm) glass fiber or mineral wool batts without ventilated air space[b]	50	33	18	457	24	610
0.024 in. (0.61 mm) 24-gauge sheet metal over 1 in. (25.4 mm) glass fiber or mineral wool batts reinforced with wire, or equivalent, on rear face with ventilated air space[c]	66	50	12	305	18	457
3½-in. (90-mm) thick masonry wall with ventilated air space[d]	66	—	12	305	—	—
0.024-in. (0.61-mm) 24-gauge sheet metal with ventilated air space[e]	66	50	12	305	18	457
½-in. (13-mm) thick noncombustible insulation board with ventilated air space[f]	66	50	12	305	18	457
0.024 in. (0.61 mm) 24-gauge sheet metal with ventilated air space over 0.024 in. (0.61 mm) 24-gauge sheet metal with ventilated air space[g]	66	50	12	305	18	457
1 in. (25 mm) glass fiber or mineral wool batts sandwiched between two sheets 0.024 in. (0.61 mm) 24-gauge sheet metal with ventilated air space[h]	66	50	12	305	18	457

[a]Spacers and ties must be of noncombustible material. No spacers or ties are to be used directly behind appliance or conductor.

[b]With all clearance reduction systems using a ventilated air space, adequate air circulation must be provided as described in Figure 10.2.27. There must be at least 1 in. (25 mm) between the clearance reduction system and combustible walls and ceilings for clearance reduction systems using a ventilated air space.

[c]Mineral wool batts (blanket or board) must have a minmum density of 8 lb/ft^3 (128.7 kg/m^3) and have a minimum melting point of 1500°F (816°C).

[d]Insulation material used as part of clearance reduction system must have a thermal conductivity of 1.0 (Btu·in.)/(ft^2·hr·°F) or less. Insulation board must be formed of noncombustible material.

[e]If a single-wall connector passes through a masonry wall used as a wall shield, there must be at least ½ in. (13 mm) of open, ventilated air space between the connector and the masonry.

[f]There must be at least 1 in. (25 mm) between the appliance and the protector. In no case must the clearance between the appliance and the wall surface be reduced below that allowed in the table.

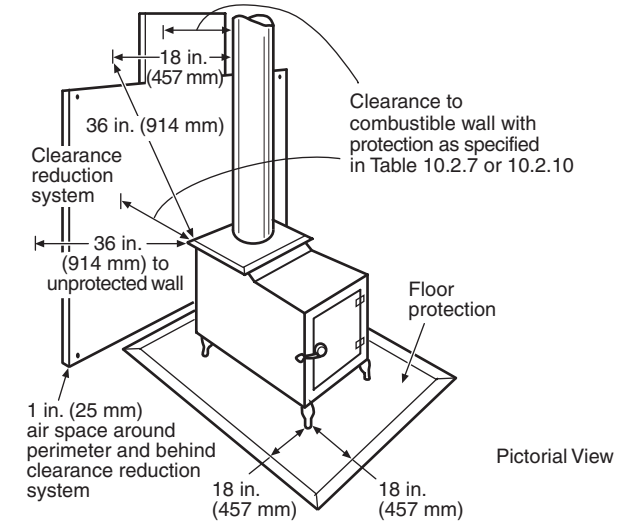
[g]Clearances in front of the loading door or ash removal door, or both, of the appliance must not be reduced from those in Section 9.5 of NFPA 211.

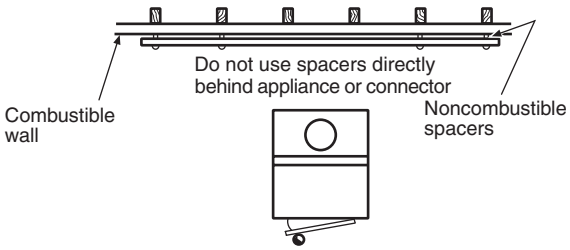
[h]All clearances and thicknesses are minimums; larger clearances and thicknesses shall be permitted.

[i]To calculate the minimum allowable clearance, the following formula can be used: $C_{pr} = C_{un} \times (1 - R/100)$, where C_{pr} is the minimum allowable clearance, C_{un} is the required clearance with no protection, and R is the maximum allowable reduction in clearance.

[j]Refer to Figures 10.2.28 and 10.2.29 for other reduced clearances using materials found in (c) through (j) of this table.

Source: NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances*.





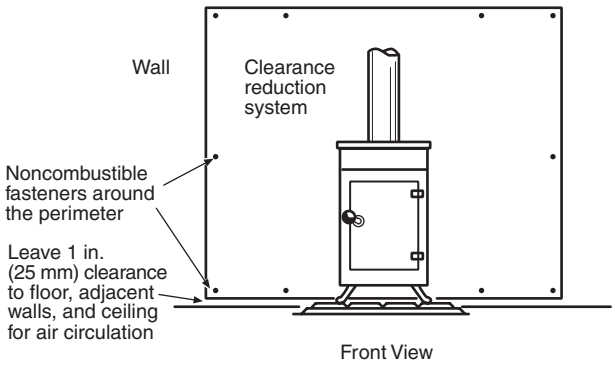


FIGURE 10.2.25 Clearance Reduction System for a Heat-Producing Appliance. The system is a barrier of metal, metal and insulating material, or masonry heat-resistive material with an air space between the barrier and a combustible surface.

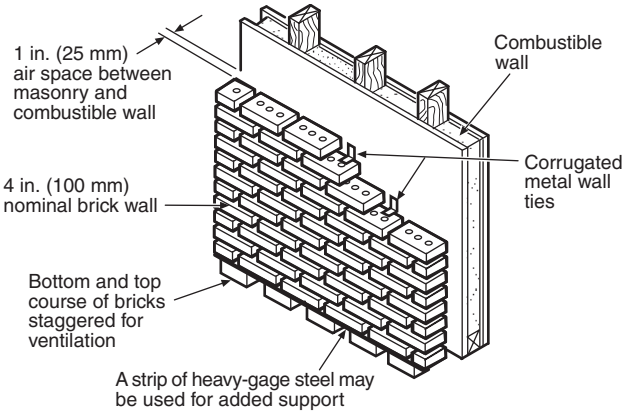
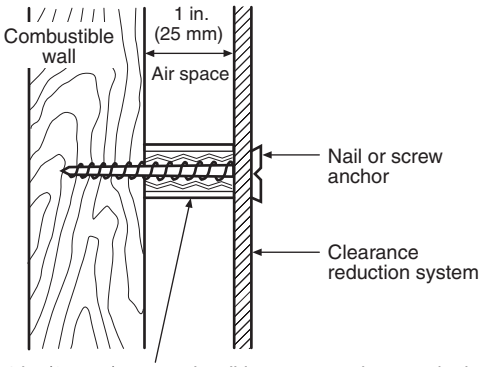


Note: Do not place masonry wall ties directly behind appliance or connector.

FIGURE 10.2.26 Masonry Clearance Reduction System



1 in. (25 mm) noncombustible spacer, such as stacked washers, small-diameter pipe, tubing, or electrical conduit.

Masonry walls may be attached to combustible walls using wall ties.

Do not use spacers directly behind appliance or connector.

FIGURE 10.2.27 Anchoring a Clearance Reduction System to a Combustible Wall

Clearance Reduction Systems. If the air space between heating appliances and combustible material is small, a barrier of metal, metal and insulating material, or masonry heat-resistive material should be installed. Metal and masonry shields, or clearance reduction systems, tend also to distribute the heat, preventing in some measure its building up at one location. Except for specific systems described in Table 10.2.7, an air space must be left between the shields and the heat-radiating surface on one side and between the barrier and the combustible material on the other. The air currents set up by this procedure will prevent the combustible material from attaining a dangerous temperature, even with the smaller clearance.

Limitations of Insulation

To make certain that insulating material will provide adequate protection, one needs to understand its limitations. The insulation can be used on the heating appliance or in combination with sheet metal and air spaces (see Table 10.2.7) if its value under such circumstances has been verified by tests. Many heat-producing appliances have built-in insulation, which makes it safer to reduce the required clearances to combustible material.

Insulation alone, however, is not sufficient. Regardless of the thickness of insulation, long continued heat can eventually penetrate it. However, if some method is used to conduct the

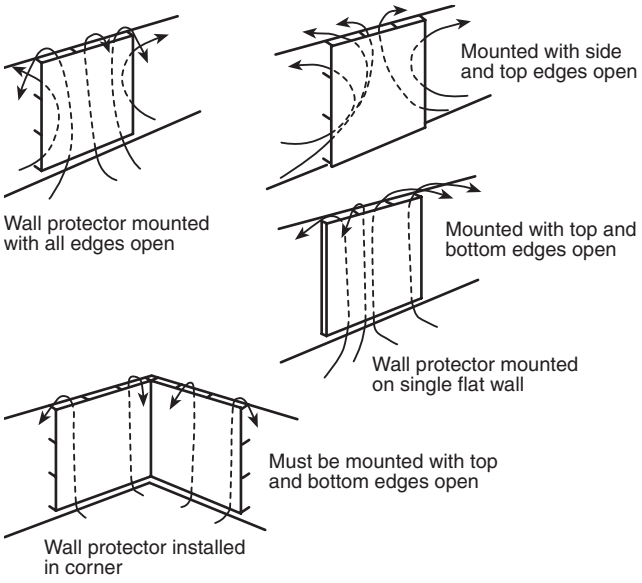


FIGURE 10.2.28 Airflow Patterns for Various Configurations of Clearance Reduction Systems Having an Air Space Between the Barrier and the Combustible Surface It Protects

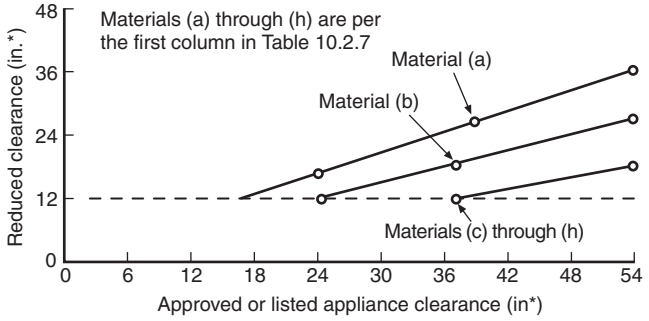
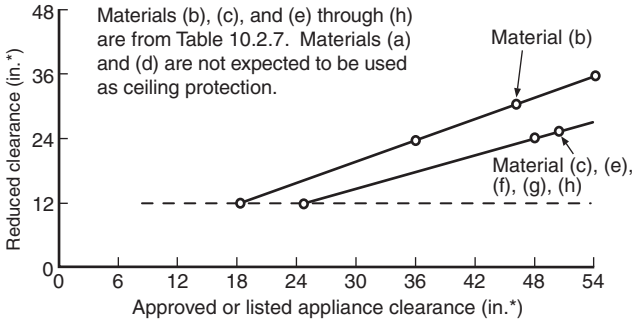
heat away before it reaches the combustible material, the insulation will provide adequate protection.

Continued high temperatures over long periods of time can cause fires under apparently safe conditions. Figure 10.2.31 shows fires caused under conditions that the layperson might consider safe. Solid masses of brick or concrete or plaster finish might not provide any fire protection under some circumstances,



*1 in. equals 25 mm.

FIGURE 10.2.29 Wall Protection Using Materials Specified in Table 10.2.7



*1 in. equals 25 mm.

FIGURE 10.2.30 Ceiling Protection Using Materials Specified in Table 10.2.7

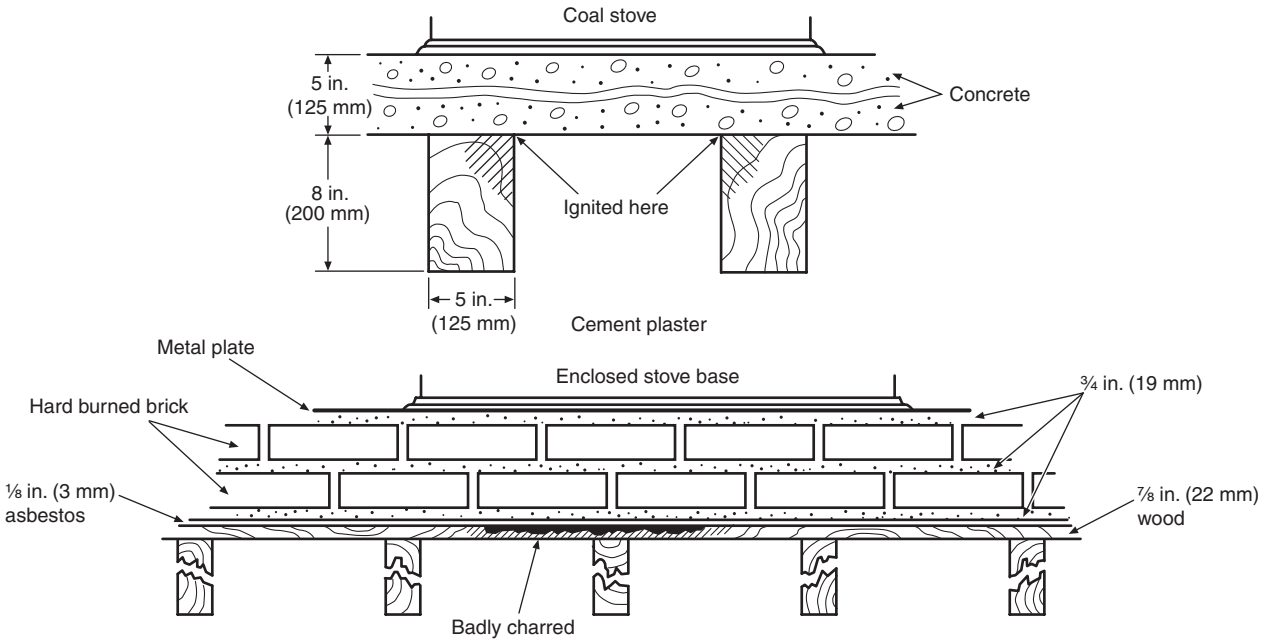


FIGURE 10.2.31 Typical Fires Due to Improperly Installed Heating Appliances

especially where masonry coverings are attached directly to the surface of the combustible material. Heat transfer to the combustible material is usually more efficient as the density of the covering material increases. Therefore, without an air space between the masonry and the combustibles, the heat transfer can actually increase, resulting in the ignition of the combustibles. However, since the masonry products do have a relatively large mass, it will take some time of operation of the appliance to transfer sufficient energy to ignite combustibles. This, however, is entirely dependent on the weight and dimensions of the masonry and the rate of heat transfer from the appliance. The same rationale would also apply to products other than masonry attached directly to the surface of combustibles.

Mountings

The limitations of masonry, concrete, metal, and other materials as insulating mediums apply particularly to the underside of stoves, heaters, boilers, furnaces, and other similar heat-producing appliances. Tables 10.2.8 and 10.2.9 list mountings for various classes of heat-producing appliances.

The testing laboratories indicate in their listings whether the appliances tested may be installed on combustible or noncombustible floors. In some cases, there is a statement on the appliance itself to the effect that it may be installed on a combustible floor. If no such indication appears, however, it is advisable to check the listing for the particular appliance.

Air for Combustion and Ventilation

In many locations, combustion-type heat-producing appliances have ample sources of air for efficient combustion in addition to the ventilation required to prevent undue temperature rises. In basements of dwellings, for example, sufficient air comes in through the cracks around doors and windows.

In relatively tight rooms, such as furnace and boiler rooms, a means to supply air for combustion and ventilation must be provided. Because there are so many variables involved, there is no universally accepted formula for calculating the size of openings necessary to provide adequate air for combustion and ventilation. For example, the tightness and size of the furnace or boiler room, and the operation of exhaust fans and other equipment, would affect the static air pressure in the building. Both NFPA 31 and NFPA 54, as well as other standards pertaining to heat-producing appliances, include specific recommendations on how to supply the air for combustion and ventilation. For certain laboratory-tested appliances, notably gas- and oil-burning appliances for installation in closets, the minimum size necessary to provide enough air for the operation of the unit and ventilation of the room or space is specified for an opening to the heater room or space.

In recent years there has been a clear trend toward tighter, more energy-efficient buildings, particularly houses. Such buildings have less ability to supply the necessary combustion air through natural infiltration. At the same time there has been an increase in the use of high-capacity exhaust and ventilation devices, such as attic fans and down-draft-powered cooking ranges. The operation of such devices tends to forcibly remove more air than can easily be replaced by infiltration. Such buildings are prone to depressurization, where the pressure inside the house, or portions of it, is significantly lower than the atmospheric pressure outside.

Depressurization can cause constant or intermittent spillage of flue gases from combustion appliances. If the drop in building pressure is greater than the draft created in the chimney or vent, flue gases and air will be drawn down through the venting system and into the building—a phenomenon called backdrafting. This has a serious negative effect on indoor air quality. The moisture produced by combustion will raise indoor humidity levels and promote the growth of molds and fungus. If combustion is not complete, carbon monoxide and other products may be introduced to the indoor environment and can become concentrated to dangerous levels.

Direct-vent, "sealed combustion" appliances are essentially immune to such problems, since they take combustion air directly from the outdoors and do not communicate with the indoor atmosphere. Appliances with powered exhausts are also less likely to suffer from backdrafting. For natural draft, conventionally vented appliances, methods of predicting and diagnosing the risk of backdrafting in any particular house are being developed and popularized. Codes are increasingly requiring positive provisions for makeup air in tight, mechanically ventilated houses, so that indoor pressure does not become exceedingly low.

Installation of a natural draft appliance should always include an empirical test of the sufficiency of draft and vent flow. Such tests should be conducted with other exhaust devices operating, including fans and other appliances, to simulate worst-case conditions under which the appliance must properly operate and be fully vented.

Clearances for Servicing

Clearances must also be provided for servicing and maintenance of equipment. Lack of proper servicing and good maintenance can result in fires. If lack of space around an appliance makes accessibility difficult, the appliance, or at least some parts of it, will be neglected. This same reasoning applies to appliances located in out-of-the-way places and places difficult to reach. Suspended furnaces and furnaces in attics and underfloor crawl spaces are typical examples of such installations.

CHIMNEY AND VENT CONNECTORS

Chimney and vent connectors are specifically the pipe or breeching used to connect fuel-burning appliances with the required chimney or vent, unless the chimney or vent is attached directly to the appliance. NFPA 211 includes requirements for chimney and vent connectors and should be consulted for information on materials to be used and the sizing and installation of connectors.

Chimney and vent connectors must be installed with adequate clearances to combustibles. Table 10.2.10 provides guidance for appropriate clearances. Table 10.2.11 shows how clearances can be reduced by installing protection between the connector and combustible material.

TABLE 10.2.8 Floor Mountings for Residential Nonsolid Fuel Heat-Producing Appliances
(See Table 10.2.9 for residential solid fuel appliances)

Type of Mounting	*Required for the Following Types of Heaters and Furnaces*
No Floor Protection:	
Combustible floors.[a]	Residential-type central furnaces so arranged that the fan chamber ccupies the entire area beneath the firing chamber and forms a well-ventilated air space of not less than 18 in. (460 mm) in height between the firing chamber and the floor, with at least one metal baffle between the firing chamber and the floor Low-heat appliances (see Table 10.2.5 for examples) in which flame and hot gases do not come in contact with the base, on legs that provide not less than 18 in. (460 mm) open space under the base of the appliance, with at least one sheet metal baffle between any burners and the floor Other appliances for which there is evidence that they are designed for safe operation when installed on combustible floors
Metal:	
Sheet metal not less than 24 gauge (0.024 in. [0.6 mm]) or other approved noncombustible material, laid over a combustible wood floor.[a]	Heating and cooking appliances set on legs or simulated legs that provide not less than 4 in. (100 mm) open space under the base Ordinary residential stoves with legs Residential ranges with legs Residential room heaters with legs Water heaters with legs Laundry stoves with legs Room heaters with legs[b]
Hollow Masonry:	
Hollow masonry not less than 4 in. (100 mm) in thickness laid with ends unsealed and joints matched in such a way as to provide free circulation of air through the masonry.	Downflow furnaces
Hollow Masonry and Metal:	
Hollow masonry not less than 4 in. (100 mm) in thickness covered with sheet metal not less than 24 gauge (0.024 in. [0.61 mm]), laid over a combustible floor. The masonry will be laid with ends unsealed and joints matched in such a way as to provide a free circulation of air from side to side through the masonry.	Heating furnaces and boilers in which flame and hot gases do not come in contact with the base Floor-mounted heating and cooking appliances Residential stoves without legs Residential ranges without legs Room heaters without legs Water heaters without legs Laundry stoves without legs Residential-type incinerators Restaurant ranges on 4 in. (100 mm) legs Other low-heat appliances on 4 in. (100 mm) legs Medium-heat appliances on legs which provide not less than 24 in. (600 mm) open space under the base
Two Courses Masonry and Plate:	
Two courses of 4 in. (100 mm) hollow clay tile covered with steel plate not less than 3⁄16 in. (5 mm) in thickness, laid over a combustible floor. The courses of tile will be laid at right angles with ends unsealed and joints matched in such a way as to provide a free circulation of air through the masonry courses.	Heating furnaces and boilers in which flame and hot gases come in contact with the base Restaurant ranges Other low-heat appliances
Fire-Resistive Floors Extending 6 in. (150 mm):	
Floors of fire-resistive construction with noncombustible flooring and surface finish and with no combustible material against the underside thereof, or on fire-resistive slabs or arches having no combustible material against the underside thereof. Such construction will extend not less than 6 in. (150 mm) beyond the appliance on all sides, and where solid fuel is used, it will extend not less than 18 in. (460 mm) at the front or side where ashes are removed.	Floor-mounted heating and cooking appliances Residential-type room heaters Residential-type water heaters

TABLE 10.2.8 Continued

Type of Mounting	*Required for the Following Types of Heaters and Furnaces*
Fire-Resistive Floors Extending 12 in. (300 mm):	
Floors of fire-resistive construction with noncombustible flooring and surface finish and with no combustible material against the underside thereof, or on fire-resistive slabs or arches having no combustible material against the underside thereof. Such construction will extend not less than 12 in. (300 mm) beyond the appliance on all sides, and where solid fuel is used, it will extend not less than 18 in. (460 mm) at the front or side where ashes are removed.	Heating furnaces or boilers Restaurant-type cooking appliances Residential-type incinerators. Other low-heat appliances.
Fire-Resistive Floors Extending 3 ft (0.9 m):	
Floors of fire-resistive construction with noncombustible flooring and surface finish and with no combustible material against the underside thereof, or on fire-resistive slabs or arches having no combustible material against the underside thereof. Such construction will extend not less than 3 ft (900 mm) beyond the appliance on all sides, and where solid fuel is used, it will extend not less than 8 ft (2.4 m) at the front or side where ashes are removed.	Medium-heat appliances and furnaces (See Table 10.2.7 for examples.)
Fire-Resistive Floors Extending 10 ft (3.1 m):	
Floors of fire-resistive construction with noncombustible flooring and surface finish and with no combustible material against the underside thereof. Such construction will extend not less than 10 ft (3.1 m) beyond the appliance on all sides, and where solid fuel is used, it will extend not less than 30 ft (9.3 m) at the front or side where hot products are removed.	High-heat appliances and furnaces (See Table 10.2.7 for examples.)

[a]If an appliance is mounted on a combustible floor, and solid fuel is used or the appliance is a domestic-type incinerator, a sheet of ¼ in. (6 mm) asbestos covered by sheet metal not less than 24 gauge (0.024 in. [0.61 mm]) will be required, extending at least 18 in. (460 mm) from the appliance on the front or side where ashes are removed. (The sheet of asbestos may be omitted where the protection required under the appliance is sheet metal only.) For residential-type incinerators, the protection must also extend at least 12 in. (300 mm) beyond all other sides. If the appliance is installed with clearance less than 6 in. (150 mm), the protection for the floor should be carried to the wall.

[b]Floor protection for radiating-type gas-burning room heaters that make use of metal, asbestos, or ceramic material to direct radiation to the front of the device should extend at least 36 in. (900 mm) in front when the heater is not of a type approved for installation on a combustible floor.

TABLE 10.2.9 Floor Mountings for Residential Solid Fuel-Burning Appliances

Kind of Appliance	*Allowed Mounting*
1. All forced air and gravity furnaces, steam and water boilers.	Floors of fire-resistive construction with noncombustible water heaters, fireplace flooring, and surface finish, or fire-resistive arches or slabs. These constructions must have no combustible material against the underside thereof. Such construction must extend not less than 18 in. (460 mm) beyond the appliance on all sides. These appliances must not be placed on combustible floors.
2. Residential type ranges, stoves, room heaters, and combination fireplace stove/ room heaters, having less than 2 in. (50 mm) of ventilated open space beneath the fire chamber or base of the unit.	
3. Residential-type ranges, water heaters, fireplace stoves, room heaters, and combination stove/room heaters having legs or pedestals providing 2 to 6 in. (50 to 150 mm) of ventilated open space beneath the fire chamber or base of the heater.	On combustible floors when such floors are protected by 4 in. (100 mm) of hollow masonry, laid to provide air circulation through the masonry layer. Such masonry must be covered with sheet metal. The required floor protection must extend not less than 18 in. (460 mm) on all sides of the appliance. On noncombustible floors, such floors must extend not less than 18 in. (460 mm) on all sides of the appliance.
4. Residential-type ranges, water heaters, fireplace stoves, room heaters, and combination fireplace stove/room heaters having legs or pedestals providing over 6 in. (150 mm) of ventilated open space beneath the fire chamber or base of the covered heater.	On combustible floors when such floors are protected by closely spaced masonry units of brick, concrete or stone, which provide a thickness of not less than 2 in. (51 mm). Such masonry must be covered by sheet metal. The required floor protection must extend not less than 18 in. (460 mm) on all sides of the appliance. On noncombustible floors, such floors must extend not less than 18 in. (460 mm) on all sides of the appliance.

TABLE 10.2.10 Chimney Connector and Vent Connector Clearances from Combustible Materials

Description of Appliance	Minimum Clearance[a] *in.*	*mm*
Residential-Type Appliances		
Single-Wall Metal Pipe Connectors

[a]These clearances apply, except if the listing of an appliance specifies a different clearance, in which case the listed clearance takes precedence.
[b]If listed Type L vent piping is used, the clearance shall be permitted to be in accordance with the vent listing.
[c]If listed Type B or Type L vent piping is used, the clearance shall be permitted to be in accordance with the appliance and vent listing.
[d]Clearances shall be based on good engineering practice and acceptable to the authority having jurisdiction. The clearances from connectors to combustible materials shall be permitted to be reduced, provided the combustible material is protected in accordance with Table 10.2.11.

Source: NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances.*

Connectors for residential-type appliances may pass through walls or partitions constructed of combustible material if the connector is either listed for wall pass-through or is routed through a device listed for wall pass-through. Connectors for residential-type appliances with inside diameters less than or equal to 10 in. (250 mm) may pass through walls or partitions constructed of combustible material to a masonry chimney if the connector system selected or fabricated is installed as illustrated in Table 10.2.12. Figures 10.2.32 and 10.2.33 illustrate two example installations in detail.

TABLE 10.2.11 Reduction of Connector Clearance with Specified Forms of Protection[a–h]

Clearance Reduction Applied to and Covering All Combustible Surfaces Within the Distance Specified as Required Clearance with No Protection (see Table 10.2.10)	Maximum Allowable Reduction in Clearance (%)		If the required clearance with no protection is 36 in. (914 mm), the clearances below are the minimum allowable clearances; for other required clearances with no protection, calculate minimum allowable clearance from maximum allowable reduction[f]			
			As Wall Protector		As Ceiling Protector	
	As Wall Protector (%)	*As Ceiling Protector (%)*	*in.*	*mm*	*in.*	*mm*
3½-in. (90-mm) thick masonry wall without ventilated air space	33	—	12	305	—	—
½-in. (13-mm) thick noncombustible insulation board over 1 in. (25 mm) glass fiber or mineral wool batts without ventilated air space	50	33	9	229	12	305
0.024 in. (0.61 mm) 24-gauge sheet metal over 1 in. (25 mm) glass fiber or mineral wool batts reinforced with wire, or equivalent, on rear face with ventilated air space	66	50	6	152	9	229
3½-in. (90-mm) thick masonry wall with ventilated air space	66	—	6	152	—	—
0.024 in. (0.61 mm) 24-gauge sheet metal with ventilated air space	66	50	6	152	9	229
½-in. (13-mm) thick noncombustible insulation board with ventilated air space	66	50	6	152	9	229
0.024 in. (0.61 mm) 24-gauge sheet metal with ventilated air space over 0.024 in. (0.61 mm), 24-gauge sheet metal with ventilated air space	66	50	6	152	9	229
1 in. (25 mm) glass fiber or mineral wool batts sandwiched between two sheets 0.024 in. (0.61 mm) 24-gauge sheet metal with ventilated air space	66	50	6	152	9	229

[a]Spacers and ties shall be of noncombustible material. No spacers or ties shall be used directly behind appliance or connector.
[b]With all clearance reduction systems using a ventilated air space, adequate air circulation must be provided. There shall be at least 1 in. (25 mm) between the clearance reduction system and combustible walls and ceilings for clearance reduction systems using a ventilated air space.
[c]Mineral wool batts (blanket or board) shall have a minimum density of 8 lb/ft^3 (128.7 kg/m^3) and have a minimum melting point of 1500°F (816°C).
[d]Insulation material used as part of clearance reduction system shall have a thermal conductivity of 1.0 (Btu·in.)/(ft^2·hr·°F) or less. Insulation board shall be formed of noncombustible material.
[e]If a single-wall connector passes through a masonry wall used as a wall shield, there shall be at least ½ in. (13 mm) of open, ventilated air space between the connector and the masonry.
[f]To calculate the minimum allowable clearance, the following formula can be used:
$C_{pr} = C_{un} \times (1 - R/100)$, where C_{pr} is the minimum allowable clearance, C_{un} is the required clearance with no protection, and R is the maximum allowable reduction in clearance.
[g]There shall be at least 1 in. (25 mm) between the connector and the protector. In no case shall the clearance between the connector and the wall surface be reduced below that allowed in the table.
[h]All clearances and thicknesses are minimum; larger clearances and thicknesses shall be permitted.
Source: NFPA 211, *Standards for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances*.

Appliances to Be Chimney or Vent Connected

All oil-fired appliances are chimney connected, except direct-fired heaters, listed kerosene stoves, and portable kerosene heaters. All solid-fuel appliances are chimney connected.

NFPA 54 is quite specific on the types of gas appliances that are required to be vented through vents or chimneys and those that are not so required. Generally, it is the larger types of heating appliances, for example, boilers and furnaces, that require venting, whereas smaller appliances, such as listed cooking stoves and hot plates, do not. However, if several smaller

TABLE 10.2.12 Connector Systems and Clearances from Combustible Walls for Residential Heating Appliances

	System	Clearance *in.*	*mm*
A.	Minimum 3.5-in. (90-mm) thick brick masonry wall framed into combustible wall with a minimum of 12 in. (305 mm) brick separation from clay liner to combustibles. Fire clay liner (ASTM C315, *Standard Specification for Clay Fire Linings,* 17 or equivalent) minimum ⅝ in. (16 mm) wall thickness, must run from outer surface of brick wall to, but not beyond, the inner surface of chimney flue liner and must be firmly cemented in place.	12	305
B.	Solid insulated listed factory-built chimney length of the same inside diameter as the chimney connector and having 1 in. (25 mm) or more of insulation with a minimum 9 in. (229 mm) air space between the outer wall of the chimney length and combustibles. The inner end of the chimney length must be flush with the inside of the masonry chimney flue and must be sealed to the flue and to the brick masonry penetration with non-water-soluble refractory cement. Supports must be securely fastened to wall surfaces on all sides. Fasteners between supports and the chimney length must not penetrate the chimney liner.	9	229
C.	Sheet steel chimney connector, minimum 24 gauge (0.024 in. [0.61 mm]) in thickness, with a ventilated thimble, minimum 24 gauge (0.024 in. [0.61 mm]) in thickness, having two 1 in. (25 mm) air channels, separated from combustibles by a minimum of 6 in. (152 mm) of glass fiber insulation. Opening must be covered and thimble supported with a sheet steel support, minimum 24 gauge (0.024 in. [0.61 mm]) in thickness. Support must be securely fastened to wall surfaces on all sides and must be sized to fit and hold chimney section. Fasteners used to secure chimney sections must not penetrate chimney flue liner.	6	152
D.	Solid insulated listed factory-built chimney length with an inside diameter 2 in. (51 mm) larger than the chimney connector and having 1 in. (25 mm) or more of insulation, serving as a pass-through for a single-wall sheet steel chimney connector of minimum 24 gauge (0.024 in. [0.61 mm]) thickness, with a minimum 2 in. (51 mm) air space between the outer wall of chimney section and combustibles. Minimum length of chimney section must be 12 in. (305 mm). Chimney section concentric with, and spaced 1 in. (25 mm) away from, connector by means of sheet steel support plates on both ends of chimney section. Opening must be covered and chimney section supported on both sides with sheet steel supports of minimum 24 gauge (0.024 in. [0.61 mm]) thickness. Supports must be securely fastened to wall surfaces on all sides and must be sized to fit and hold chimney section. Fasteners used to secure chimney sections must not penetrate chimney flue liner.	2	51

Additional requirements:

1. Insulation material used as part of wall pass-through system must be of noncombustible material and must have a thermal conductivity of 1.0 Btu·in./ft^2·°F (3.88 kg·cal/hr·°C) or less.
2. All clearances and thicknesses are minimums; larger clearances and thicknesses are acceptable.
3. Any material used to close up an opening for the connector must be of noncombustible material.
4. A connector to a masonry chimney, except for System B, must extend to in piece through the wall pass-through system and the chimney wall to the inner face of the flue liner, but not beyond.

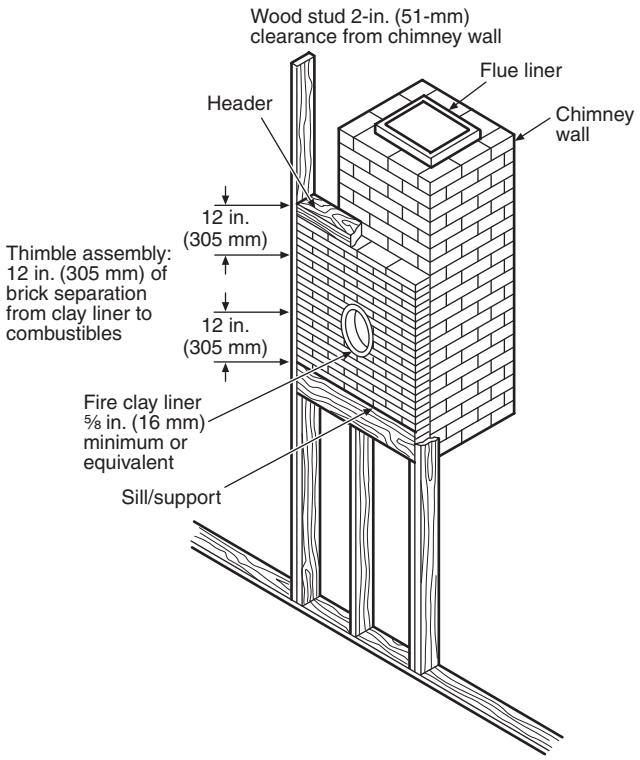

FIGURE 10.2.32 Detail of System A in Table 10.2.12

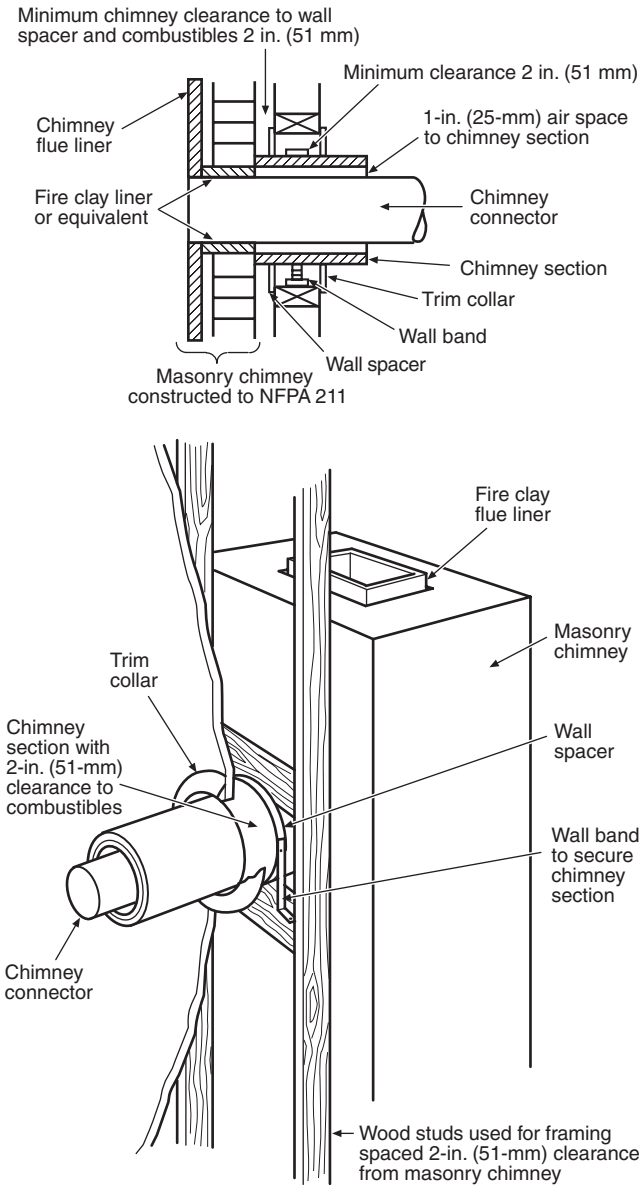

FIGURE 10.2.33 Detail of System D in Table 10.2.12

appliances that normally do not require venting are located within the same space or room, some might require venting if the aggregate input for all the appliances exceeds 20 Btu per hour per ft^3 (0.2 kW/m^3) of the space in which they are installed. NFPA 54 should be consulted for the specifics on the types of gas appliances requiring venting, the conditions under which vents may be omitted or required, and the type of chimney, gas vent, or venting system that can be used and its installation.

Listed unvented room heaters may be used, but care should be taken to follow the manufacturer's instructions. Such heaters are equipped with an oxygen depletion safety shutoff system designed to shut off the gas supply to the heater if the oxygen in the surrounding atmosphere is reduced below about 18 percent. Unvented room heaters are not to be used in institutions, convalescent homes, orphanages, and so on.

A change to the 1996 edition of the *National Fuel Gas Code* allowed listed unvented wall-mounted heaters to be used in bedrooms and bathrooms that meet the following limitations:

1. The installation of unvented space heaters in bedrooms and bathrooms must be approved by the authority having jurisdiction.
2. Heaters in bathrooms must have an input no greater than 6000 Btu/hr (1760 W/hr).
3. Heaters in bedrooms must have an input no greater than 10,000 Btu/hr (2930 W/hr).
4. The bedroom or bathroom must be an unconfined space as defined in the *National Fuel Gas Code,* which means that the room volume must be at least 50 ft^3 for each 1000 Btu/hr (4.8 m^3 per kw) of heater input.

This change was first made as a tentative interim amendment to the 1992 edition of the *National Fuel Gas Code* that was adopted in 1994. It resulted from problems in the southern United States where gas-fired unvented space heaters have a long history of use due to the moderate climate. Old heaters, many installed before 1940, though in need of repair, could not be repaired because parts were not available, nor could they be replaced due to the pre-1994 *National Fuel Gas Code* prohibition of unvented space heaters in bedrooms and bathrooms.

The change was made in the *National Fuel Gas Code* following the introduction of wall-mounted unvented heaters. One concern of the *National Fuel Gas Code* Committee regarding space heaters in bedrooms and bathrooms had been the lack of clearance to combustibles in these small rooms, specifically the possibility that the heaters would be used to dry towels and

clothing, which could create a fire problem. Wall-mounted heaters address this concern. Another concern of the committee regarding these and other space heaters was a means to ensure adequate air of combustion. As a result, the standard to which the heaters are listed requires the use of an oxygen depletion sensor.

Ventilating hoods and exhaust systems may be used to vent gas utilization equipment installed in commercial applications. They may also be used to vent industrial equipment, particularly when the process itself requires fume disposal. If industrial gas utilization equipment is located in a large and well-ventilated space, it may be operated by discharging the products of combustion directly into the atmosphere.

VENTS

Vents are laboratory-tested, factory-built units used to vent fuel-burning, heat-producing appliances. Specific types of vents have specific uses (Table 10.2.13).

Types of Vents

Type B Gas Vents. Type B vents are used to vent listed gas appliances that have draft hoods or are specifically listed to be used with Type B gas vents.

Type BW Gas Vents. Type BW vents are used with listed gas wall furnaces having capacities not greater than that of Type BW gas vents (Figure 10.2.34).

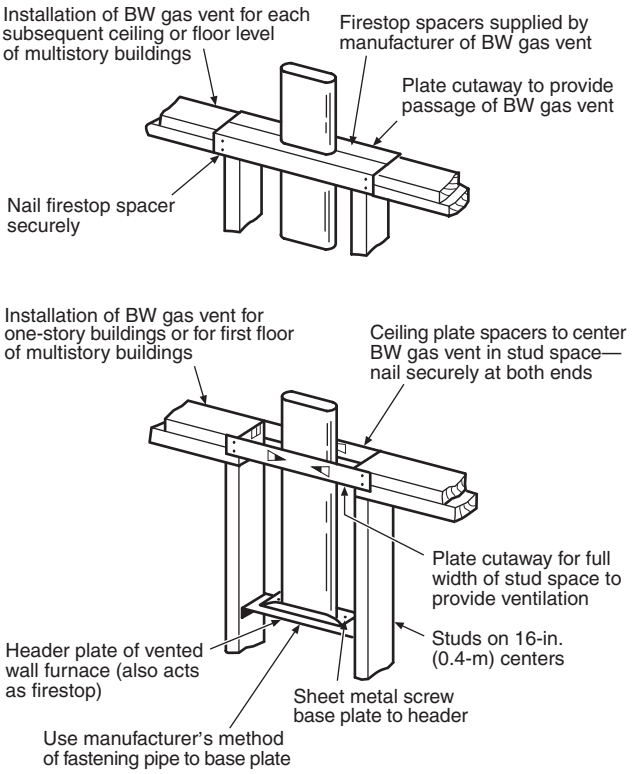

FIGURE 10.2.34 Installation of Type BW Gas Vents for Vented Wall Furnaces

TABLE 10.2.13 Vent Selection Chart

Heating boilers 5. Ranges 6. Built-in ovens 7. Vented wall furnaces listed for use with Type B vents 8. Room heaters 9. Water heaters 10. Horizontal furnaces 11. Unit heaters	Column II 1. Vented wall furnaces listed for use with Type BW vents only	Column III 1. Low-temperature flue gas appliances listed for use with Type L vents 2. Gas appliances shown in Column I	Column IV 1. Listed Category II, III, and IV gas appliances only	Column V 1. Listed pellet-burning appliances listed for use with pellet vents	Column VI 1. Incinerators used outdoors, such as in open sheds, breezeways, or carports 2. Gas appliances shown in Column I 3. Listed residential and low-heat gas appliances without draft hoods, and unlisted residential and low-heat gas appliances with or without draft hoods

Type L Vents. Type L vents are used to vent oil-burning appliances listed for use with Type L vents and gas appliances listed for use with Type B vents.

Special Gas Vents. Special vents are listed specifically for venting Category II, III, and IV gas appliances. Special gas vents must be specified by the appliance manufacturer.

Pellet Vents. Pellet vents are used for venting listed pellet fuel-burning appliances. They are similar in construction to Type L vents and may be additionally listed as such.

Single-Wall Metal Pipe. Single-wall metal pipe, constructed of galvanized sheet steel not lighter than No. 20 galvanized sheet gauge (0.020 in. [0.51 mm]) or other noncombustible corrosion-resistant material, may be used to vent residential-type and low-heat gas appliances equipped with draft hoods. They may also be used to vent incinerators used outdoors, such as in open sheds, breezeways, or carports (see Table 10.2.13). Single-wall metal pipe is not used with solid-fuel appliances, which require either masonry or factory-built chimneys.

Plastic Pipe. Unlisted PVC or other plastic pipe may be used to vent Category IV gas appliances, subject to the specifications and limitations in the appliance manufacturer's instructions.

New Considerations for Venting Gas Appliances

Prior to the 1980s most gas furnaces were of similar design. They typically included an atmospheric burner, supplemented by excess air introduced in and above the combustion zone. Flue gases passed though a clamshell heat exchanger into a draft hood incorporated into or directly attached to the outlet of the furnace. The draft hood allowed for the relief of backdrafts, which would otherwise interfere with combustion, and also allowed a significant amount of dilution air to mix with the flue gases. The flue gas/air mixture was then drawn up the chimney or vent by draft created by the buoyancy of warm gases. Gas furnaces of this design typically operated in the range of 65 to 75 percent annual fuel utilization efficiency (AFUE). Many furnaces manufactured prior to the 1980s remain in service.

During the 1970s and 1980s gas appliance manufacturers responded to both market and regulatory pressures by developing more efficient appliances. The National Appliance Energy Efficiency Act of 1987 (NAEEA) requires that all gas furnaces achieve a minimum AFUE of 78 percent. Most standard gas furnaces now fall in the range of 78 to 83 percent AFUE. Such furnaces are referred to as "mid-efficiency" appliances, to distinguish them from conventional "low-efficiency" designs.

In order to achieve these higher efficiencies, both on-cycle and off-cycle heat losses up the flue needed to be reduced. Conventional furnace design was altered in several ways:

1. The standing pilot was eliminated, replaced by some form of intermittent ignition device (IID).
2. In most designs the draft hood was eliminated, thus reducing on-cycle dilution air and the off-cycle loss of heated room air.
3. The draft hood was replaced by a small fan at the flue outlet of the appliance. This fan provides for a controlled flow of flue gases and excess air through the heat exchanger, and inhibits the flow of heat from the furnace into the flue during the off-cycle. Mid-efficiency furnaces of this design are known as "fan-assisted" furnaces.
4. In some designs the heat exchanger was made somewhat more efficient.

Another class of furnaces, that is, "high-efficiency" condensing furnaces, has evolved. These achieve efficiencies well above 90 percent. Such appliances contain a second heat exchanger that is designed to cool the flue gases below their dewpoint, thereby capturing the latent heat of the water vapor created by combustion. Because condensation takes place intentionally, within the appliance, these furnaces must be constructed of corrosion-resistant materials and designed for suitable disposal of the condensate.

Conventional appliance design (below 75 percent AFUE) allowed for simple and mostly trouble-free venting. Relatively high flue gas temperatures provided adequate draft in most chimney and vent configurations, whereas excess and dilution air helped control condensation by lowering the dewpoint temperature (the temperature below which moisture will condense on flue walls) of the flue gas mixture, and providing a drying flow of air during the off-cycle.

The mid-efficiency and high-efficiency designs create significantly different venting conditions and introduce new considerations in vent design and installation. Reduced loss of heat through the venting system and lower vent gas flow rate result in lower venting system temperatures, with a consequent reduction in available draft and in the surface temperature of venting system components.

Elimination of the draft hood and reduction of dilution air increases the humidity and dewpoint temperature of the vent gases, making them more prone to condensation in the venting system. Because they dry out more slowly, vent system components will be exposed to potentially corrosive condensate for longer periods of time.

Elimination of the standing pilot and off-cycle flow of room air inhibits the drying of vent system components during the off-cycle and lowers the standby temperature of the flue. The reduction in dilution air and use of fan assistance increases the maximum capacity of the venting system; a vent of a given size can handle more gas input to the appliance.

The presence of a fan at the outlet of the appliance increases the likelihood that the vent will become pressurized. If this is intended by the appliance design, the vent must be designed for positive pressure. If this is not intended, the vent must be sized and configured to prevent pressurization.

Vented Gas Appliance Categories

From the standpoint of the general type of venting system required for a gas appliance, the two key variables are (1) the pressure of the gases within the venting system and (2) the temperature of the vent gases. The vent pressure can either be positive (relative to the surrounding atmosphere) or nonpositive (neutral or negative). The temperature of the gases entering the

venting system can either be above or below a critical temperature that is likely to result in an excessive volume or duration of condensation in the vent.

The combination of these two variables creates a matrix of four possible appliance types, or categories, with respect to their venting needs. These vented gas appliance categories are defined in NFPA 54, as follows:

Category I. An appliance that operates with a nonpositive vent static pressure and with a vent gas temperature that avoids excessive condensate production in the vent.

Category II. An appliance that operates with a nonpositive vent static pressure and with a vent gas temperature that may cause excessive condensate production in the vent.

Category III. An appliance that operates a positive vent static pressure and with a vent gas temperature that avoids excessive condensate production in the vent.

Category IV. An appliance that operates with a positive vent static pressure and with a vent gas temperature that may cause excessive condensate production in the vent.

The category of a gas appliance can be determined only in the laboratory, using criteria from the appropriate ANSI appliance test standard. The vent pressure that is produced by the appliance is determined using a special test apparatus. The determination of whether the vent gas temperature will cause or avoid "excessive condensate production in the vent" is unique for each type of gas appliance and is based on an efficiency profile of the appliance type. It is not possible to reliably determine the category of an appliance through testing in the field.

Categorization criteria for every gas appliance type have been or are being developed. The category of an appliance is part of its certification and will be shown on the rating plate. There is no further need to evaluate the category in the field.

Both Category I and III appliances generally fall within the mid-efficiency range. Since both typically have a small fan at the outlet, the major difference between them is whether or not the fan is used to force vent gases through the vent, or simply to pull gases through the heat exchanger, delivering them at neutral pressure to the beginning of the vent. Category IV represents high-efficiency, condensing appliances. Category II appliances are problematic, since they need to operate under natural draft, but without sufficient vent gas temperature to produce much draft. There are few, if any, Category II appliances on the market.

The category of a gas appliance determines the general characteristics of the venting system that must be used. Category III and IV furnaces, which are designed to operate with positive vent gas pressure, must use a vent that can withstand the pressure and be sealed against leakage. Category I and II appliances are expected to be vented by natural draft and must use a vertical venting system sized and configured to develop sufficient draft.

Further, Category I and III appliances have relatively high vent gas temperatures. The vent may not need to withstand severe exposure to condensate but must be able to withstand relatively high temperatures. Category II and IV appliances need not withstand such high temperatures but must be corrosion resistant and designed to contain and dispose of condensate.

Venting Category I Appliances

Category I appliances and low-efficiency, uncategorized appliances are vented through "conventional" venting systems: mainly Type B vents and masonry chimneys. However, venting systems for mid-efficiency, fan-assisted appliances call for careful attention to sizing and factors of vent geometry. For instance, long connector runs between the appliance and vertical vent can cause excessive heat loss and unacceptable condensation. Masonry chimneys, due to their mass, heat up slowly and have limited use with mid-efficiency appliances. Frequently, masonry chimneys must be relined with a lightweight aluminum or stainless-steel liner, in order to provide adequate capacity and minimize condensation. The use of chimneys and vents on the exterior of the building is severely restricted or prohibited in most climate zones by NFPA 54.

Procedures for sizing venting systems for Category I appliances underwent significant changes in the 1990s. NFPA 54 has provided vent sizing tables since the 1950s. These tables were developed for draft-hood-equipped appliances operating in the low-efficiency range. Modern mid-efficiency appliances, without draft hoods, bring different conditions to the vent, which must be anticipated in the sizing regimen.

In-depth research into the venting needs of mid-efficiency appliances, much of it sponsored by the Gas Research Institute (GRI), led to the updating and expansion of the original NFPA 54 sizing tables. The original tables addressed only the *maximum* capacity of vents and chimneys, which corresponded to a minimum size that could be used for an appliance of a given input rate and a given vent geometry to prevent spillage. With the advent of fan-assisted appliances, the maximum capacity (or minimum size) also becomes important to prevent pressurization of the vent by the fan.

The new tables introduce the concept of a *minimum* vent capacity, which is the smallest appliance input rating that can be connected to a given vent. A vent connected to an appliance with an input lower than the vent's minimum capacity will warm up slowly, and condensation will continue until the vent wall is warmer than the dewpoint temperature of the vent gases. This longer "wet time," or exposure to condensate, may lead to corrosion and premature failure of the vent. The minimum capacities are designed to limit the wet time to acceptable levels. The concept of minimum vent capacity results in a maximum vent size that can be used for the given input rate and vent geometry.

For any proposed system, a chimney or vent size must be found that lies between the minimum and maximum. The new tables in NFPA 54 also add a number of conditions and adjustments to the former table values that may further restrict the applicability of a vent. Depending on the details of the system, the choice of acceptable sizes may be quite narrow, or even nonexistent. Combinations of appliance input and vent configuration that were, in the past, used routinely must now be carefully scrutinized and may not be acceptable for mid-efficiency, fan-assisted appliances.

Venting Category III Appliances

Like Category I appliances, Category III appliances are mid-efficiency appliances. However, they are designed to exhaust the products of combustion under positive pressure rather than natural draft. Since the "work" will be done by a fan, such systems can typically be vented horizontally through a sidewall. Thus, they avoid the need for a chimney or other vertical vent running up through, or beside, the building.

Vents for Category III appliances are not designed with reference to standard installation requirements and sizing tables found in codes. Instead, the materials, size, and installation guidelines for each appliance are found in the manufacturer's instructions. Such instructions must be adhered to in order to produce a proper installation.

Category III appliances have relatively high vent gas temperatures, which are under positive pressure within the vent. Therefore, the vent must be of a temperature-resistant material that can be constructed with sealed joints to prevent leakage. A new type of listed vent system, special gas vents, has been developed to meet these requirements (see Table 10.2.13). Such systems must comply with UL 1738, *Standard for Safety Venting Systems for Gas-Burning Appliances*. They are typically formed of a high-temperature plastic resin or stainless steel. Sections of pipe are joined together, using a manufacturer-specified sealant cement.

Since the vent will be subjected to elevated temperature, some degree of condensation, and mechanical stress induced by thermal expansion, it is extremely important that the vent be installed with care. Hangers and other securement of the pipe must be done according to instructions. The specific sealant required by the manufacturer must be used and joints fitted together according to the specified procedure. Some systems require condensate disposal systems and a specific pitch or rise back to, or away from, the appliance. Both appliance and vent manufacturer's instructions must be consulted and followed.

Venting Category IV Appliances

To obtain efficiencies approaching 90 percent or better, the flue gases from high-efficiency, Category IV appliances have been reduced to temperatures as low as 100°F (38°C). Because these temperatures are too low to allow atmospheric venting, mechanical venting is required to exhaust the flue gases under positive pressure. Furthermore, the temperature of the flue gases is low enough to cause condensation of the water vapor in flue gases. Thus, special treatment is needed to provide a venting system that will retain and dispose of the condensate and, in cases of mechanical venting, to prevent leakage of flue gases from the venting system.

Unlike Category I appliances, high-efficiency Category IV appliances do not use standardized, code-specified venting systems. Instead, the type of venting system to be used and any limitations on size and configuration must be specified explicitly in the appliance manufacturer's instructions. Such limitations include maximum length and number of turns in the vent. Typically, manufacturers' instructions specify the use of PVC (or other plastic pipe) or a high-alloy, corrosion-resistant type of stainless steel, such as AL29-4C. These can frequently be run horizontally through a side wall, with an appropriate termination. Many designs use a parallel pipe to bring in combustion air, creating a closed combustion, direct vent system.

Manufacturer's instructions will also specify the method to be used to dispose of condensate, as well as necessary clearances from the vent. The instructions must be followed exactly to ensure a safe and properly performing system.

Installation of Vents

Types B, BW, and L, and Special Gas Vents. Installations must be made in compliance with the terms of their laboratory listings and the manufacturers' instructions, making certain that the required clearances are maintained.

Single-Wall Metal Pipe. The use of single-wall metal pipe is restricted to runs directly from the space in which the gas appliance is located through the roof or exterior wall to the outside. The pipe is not to originate in any attic or concealed space and is not to pass through any attic or inside space, nor through any floor or ceiling. The minimum clearances from combustible material for single-wall metal pipe are as given for connectors in Table 10.2.10. In Figure 10.2.35, "A" equals the required clearance with no protections as specified in Table 10.2.10 and "B" equals the reduced clearance permitted by the types of protection specified in Table 10.2.11. The protection applied to construction using combustible material should extend far enough

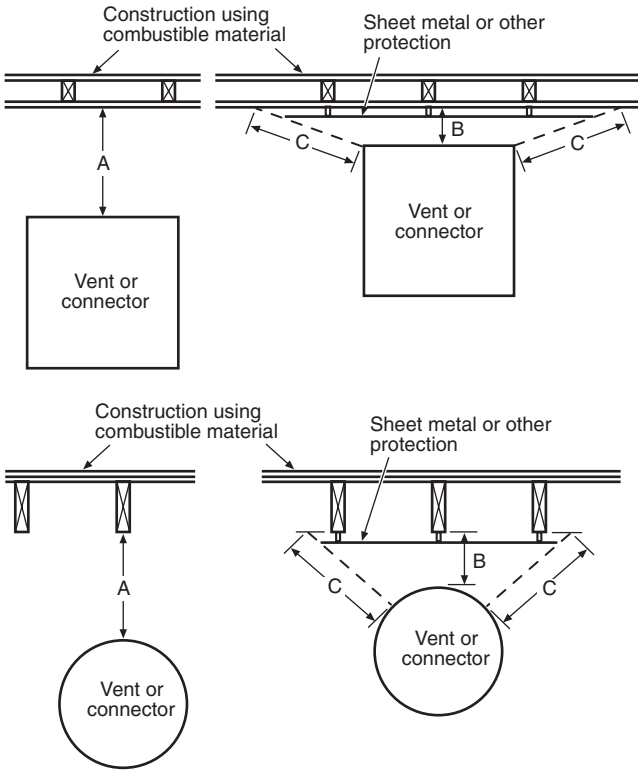

FIGURE 10.2.35 Extent of Protection Required to Reduce Clearances from Combustibles for Vents and Connectors

in each direction to make "C" equal to "A." These clearances may be reduced if appropriate protection is provided for combustible materials (see Table 10.2.11) Where a single-wall metal pipe passes through an exterior wall constructed of combustible material, or the pipe passes through a roof constructed of combustible material, it is protected at the point of passage as specified for connectors in Table 10.2.12. If the appliance the pipe serves is a gas appliance for use with a Type B gas vent, protection is by a noncombustible, nonventilating thimble not less than 4 in. (100 mm) larger in diameter than the pipe and extending not less than 18 in. (457 mm) above and 6 in. (152 mm) below the roof, with annular space open at the bottom and closed at the top.

Venting Capacities. The venting capacities of various sizes of Type B gas vents, chimneys, and single-wall metal pipe used for venting gas appliances are given in tables in NFPA 54. NFPA 54 also contains data that may be used to calculate the size of vents required under various circumstances and to establish configurations of venting arrangements. Approved engineering methods may also be used.

Firestopping. Vents that pass through floors of buildings requiring the protection of vertical openings are enclosed within walls having a fire-resistance rating of not less than 1 hour if the vents are in a building less than four stories in height, and not less than 2 hours if the vents are located in a building four stories or more in height.

Draft Hoods

A draft hood is a device built into an appliance, or made a part of the vent connector from an appliance. It is designed to (1) ensure the ready escape of the flue gases in the event of no draft, backdraft, or stoppage beyond the draft hood; (2) prevent a backdraft from entering the appliance; and (3) neutralize the effect of stack action of the chimney or gas vent upon the appliance operation.

Draft hoods are an important safety feature of gas appliances and are generally required on all vented appliances, except incinerators, dual-oven-type combination ranges, direct-vent appliances, and units designed for power burners or for forced venting by mechanical means. Many newer mid-efficiency appliances replace the draft hood with a fan at the appliance outlet. Such fans do not necessarily pressurize the vent, since they might be designed only to pull the gases through the heat exchanger and deliver them at neutral pressure to the beginning of a natural draft venting system.

CHIMNEYS

Chimneys are classified into three major types: (1) factory built, (2) masonry, and (3) unlisted metal (smokestacks). In addition to the major chimney classes, there are subclasses that involve type of building and surroundings. For example, small, well-insulated, factory-built chimneys may be installed at close clearances in residential frame construction, whereas larger chimneys for the same type of appliances are suitable mainly for noncombustible surroundings or in well-ventilated open-room use at much greater clearance to combustibles. Details of installation for chimneys, fireplaces, and vents are provided in NFPA 211.

Factory-Built Chimneys

A factory-built chimney is an assembly of manufactured components that form a completed chimney. Factory-built chimneys are tested for compliance with safety standards.[15–17]

Factory-built chimneys for use with residential-type appliances are tested fully enclosed to establish a minimum clearance to combustibles not greater than 2 in. (51 mm). The test is conducted using a flue gas generator that simulates an appliance steadily producing 1000°F (540°C) gases. A typical factory-built chimney for residential appliances is shown in Figure 10.2.36.

For building heating equipment (gases to 1000°F [540°C]), commercial ovens and furnaces (gases to 1400°F [760°C]), and medium-heat appliances (gases to 1800°F [980°C]), factory-built chimneys are available in sizes from 10 in. (250 mm) to several feet (1 ft equals 0.3 m) in diameter. These chimneys are tested for the appropriate temperature and are used mainly in noncombustible surroundings, although tested thimbles are available for penetration of combustible roofs. None of these are suitable for close clearance to combustible enclosures; however, this is seldom a problem in the usual large building of masonry or metal construction. A typical unenclosed type of large factory-built chimney for serving building boilers is shown in Figure 10.2.37.

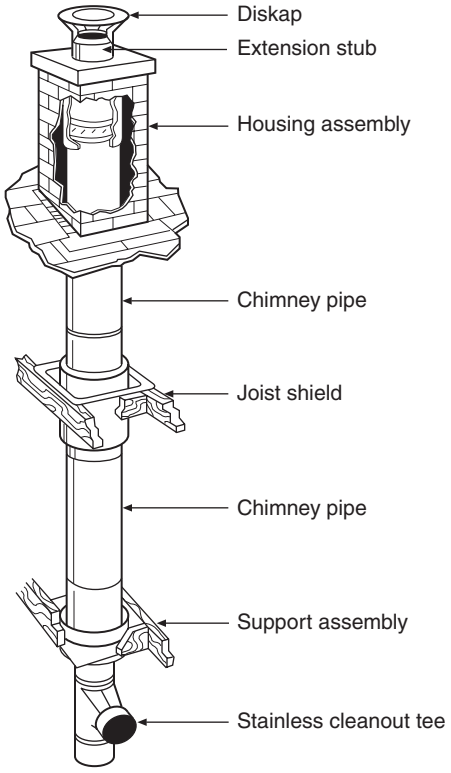

FIGURE 10.2.36 Typical Factory-Built Chimney

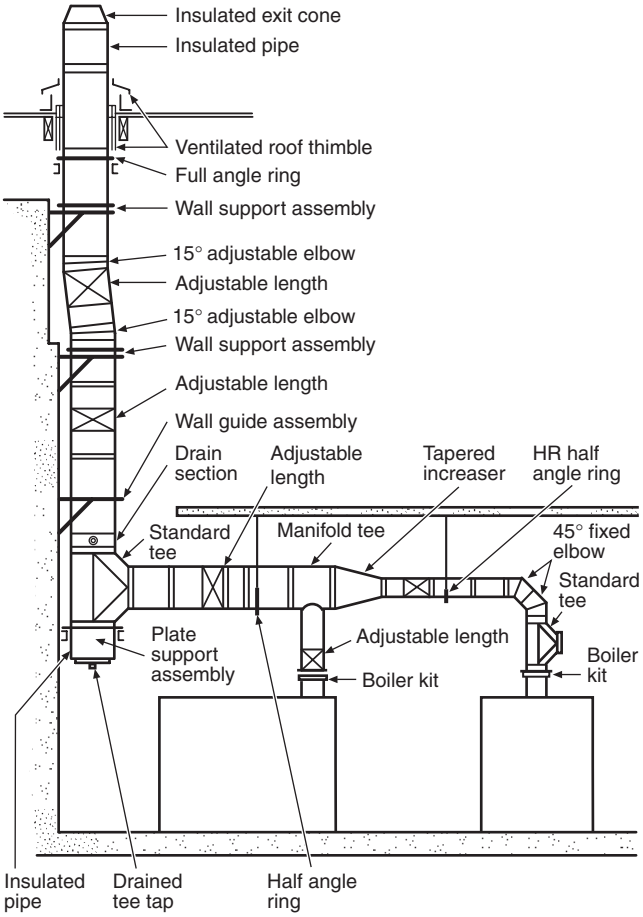

FIGURE 10.2.37 Typical Unenclosed Factory-Built Chimney for Serving Building Boilers

Current information on types, usage, and installation limitations of all UL-listed factory-built chimneys is given in the *UL Gas and Oil Equipment Directory,*[18] published annually with a supplement.

Masonry Chimneys

Field construction requirements for masonry chimneys are detailed in NFPA 211, as well as in building codes. Field-erected masonry chimneys, which are subject to the know-how and ability of available labor, are not tested, except perhaps for a smoke test. A minimum residential masonry chimney consists of a refractory fire clay tile liner and an air space of roughly ½ in. (13 mm) between the liner and brick, with all liner joints grouted both to prevent leakage and to center and support the tile liners (Figure 10.2.38). One course of common brick around the liner suffices for usual residential chimneys. For higher temperature classifications, firebrick is used as the liner, with additional courses of brick for larger size or greater strength and security. All chimneys should, of course, be supported by footings suitable for the chimney size and weight and be provided with cleanouts between the points of entry and the lowest chimney level.

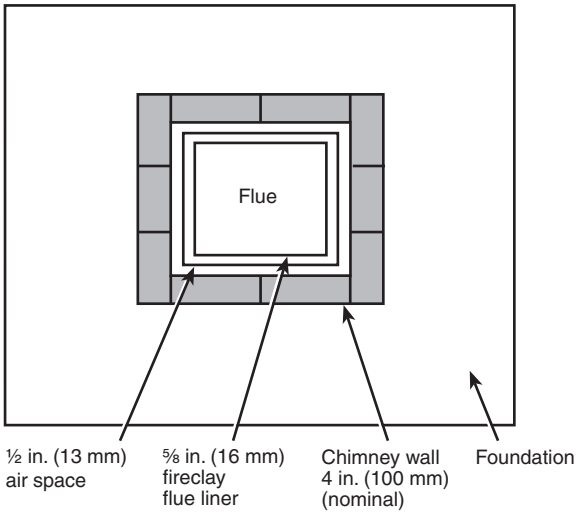

FIGURE 10.2.38 Minimum Residential Masonry Chimney

For residential and low-heat chimneys located entirely or partially inside the building, a minimum of 2 in. (51 mm) of air space is required between the chimney and surrounding combustibles. For residential and low-heat chimneys located entirely outside the building, a minimum of 1 in. (25 mm) clearance is required. For higher heat chimneys, larger clearances are appropriate. All clearances must consist of an air space. Solid material, including building insulation, whether noncombustible or not, must not be allowed to impinge into the required air space clearance.

As a general rule, the best and safest chimney operation and appliance control is obtained with only one appliance attached to a chimney flue. Two or three gas appliances, however, may be connected into a masonry chimney flue at one level of a building, provided that the connector size, its vertical rise, and chimney size and height are in accordance with tabulated capacity data in NFPA 54. The construction of masonry chimneys for open-front fireplaces is the same as for other residential appliances and is specified in NFPA 211.

Flue Liners for Masonry Chimneys. All masonry chimneys must have flue liners. The liner serves several functions that are essential for chimney safety:

1. The liner provides a smooth corrosion- and erosion-resistant surface that is conducive to the flow of flue gases and that protects the brick and mortar flue wall from direct exposure to combustion products.
2. The liner forms a sealed conduit that contains the products of combustion, including gases, moisture, heat, and solids such as soot and creosote, and conducts flue gases to the outside atmosphere.
3. The liner is an important element in the thermal performance of the chimney. The liner, with its surrounding air space, forms a thermal break between the warm flue gases and the chimney wall. This helps maintain the temperature of the gases for good draft and reduces temperatures on the exterior of the chimney wall.

Traditionally, the flue lining for residential and low-heat type chimneys has been a clay flue lining, which has been fired to produce a vitreous, relatively non-porous wall. Manufacturing specifications for clay flue linings are set in ASTM C315, *Standard Specification for Clay Flue Linings.*[19] The general requirements for clay flue linings and their installation are specified in NFPA 211. Clay linings should be installed with small joints struck smooth on the inside, bedded in a non-water-soluble refractory cement, such as a calcium aluminate mixture. All tile sections should be carefully aligned and should never be offset more than 30 degrees from the vertical. Liners should start from a point at least 8 in. (203 mm) below the lowest inlet, and extend continuously to a point at least 2 in. (51 mm) above the chimney crown (splay or wash).

Alternative Flue Lining Systems. A variety of alternative flue lining systems has been developed. These can be used either as the original liner in the chimney, in place of clay lining, or retrofitted into an existing chimney. Relining of chimneys is most often done when the original liner has become damaged or deteriorated or when a smaller flue is needed to serve a new connected appliance.

Although NFPA 211 does provide for the installation of unlisted linings, most alternative lining systems have been tested and listed to UL 1777, *Standard for Safety Chimney Liners.*[17] As with all listed systems, they should be used only for the intended purpose and installed in strict compliance with their manufacturer's instructions.

Most alternative linings fall into one of two types: (1) stainless steel and (2) cast-in-place cementitious mixtures. Stainless steel liners are usually made of a 300 series alloy and can be composed of rigid pipe sections or a continuous flexible tube that can be passed through chimney offsets. Stainless steel linings must be insulated, either with a ceramic blanket wrapped around the pipe before insertion, or with a backfill of a moist vermiculite/cement mixture, depending on the liner listing. Loose, unbound backfills are not permitted. Stainless steel lining systems come with a rain cap tested to exclude most precipitation, as well as other parts that must be used to form a complete listed system.

Cast-in-place liners are usually composed of a proprietary mixture of perlite or vermiculite, and Portland or other cement as a binder. One method involves insertion of a properly sized, sausage-shaped inflated bladder within the chimney, held off the walls by spacers. A very wet slurry of liner mix is then pumped around the tube and allowed to harden. After several days the bladder is deflated and removed, leaving a smooth, formed flue. In another method, a damp mixture is poured in the chimney while a bell-shaped slipform is pulled up, forcing the mixture against the chimney walls. With either method, a second coating of a glazing material may be applied to the flue to reduce moisture penetration.

Special versions of either stainless steel or cast-in-place liner systems can be designed and listed to obviate the need for air space clearances to combustibles normally required for masonry chimneys. These "zero-clearance" liners typically contain more insulating material or wall thickness to reduce the amount of heat reaching the outside of the chimney wall. They are useful for lining existing chimneys that were constructed without proper clearances. To be eligible for this application, the liner will be explicitly labeled for zero clearance and will have special installation requirements that must be followed.

Other specialized subsets of chimney liner systems are those designed only for use with a specific type or class of appliance. The primary example of this are liners for use with Category I gas appliances. Many such systems are made of aluminum, which would not be suitable for the temperatures produced by general residential appliances. They have been tested under the temperature conditions of UL 441, *Standard for Safety Gas Vents,*[20] for Type B gas vents, and can be used for the same applications. They are, however, still chimney liners listed under UL 1777 and must be installed under the conditions appropriate for chimney liners, according to their own manufacturer's instructions. NFPA 54 and NFPA 211 both require that a notice warning against connection of inappropriate appliances be posted near the chimney inlet.

Unlisted Metal Chimneys

Metal chimneys are suitable for all the classes of appliances but are not subjected to safety testing of any kind. They are distinct from factory-built chimneys, which also can be made of metal but are tested and listed assemblies. The major hazard with metal chimneys is inadequate clearance to combustibles where they penetrate ceilings and roofs. For chimneys serving residential-type or low-heat appliances, dimension "A" (Figure 10.2.39) should be at least 6 in. (150 mm). For chimneys serving medium-heat appliances, dimension "A" should be at least 18 in. (457 mm).

Metal chimneys may be of single-wall metal for low-temperature use, such as with gas appliances, or metal lined with firebrick or refractory mortar for medium- and high-heat service. They may be located inside or outside of buildings, but not inside or outside of one- and two-family dwellings or buildings of wood-frame construction. The conditions under which metal chimneys may be used are quite limited and are spelled out in detail in NFPA 211. The standard is also quite specific on acceptable materials of construction.

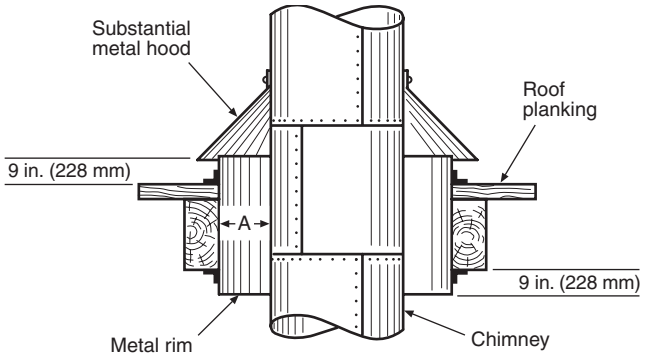

FIGURE 10.2.39 Arrangement of a Metal Chimney Through a Wood Roof

Regardless of permitted clearances, metal chimneys should not be enclosed with combustible construction. It is particularly important that the metal used be resistant to corrosion if the gases are 350°F (177°C) or below, because exposed outdoor portions of the chimney walls may be below the dew point. The resulting continuous condensation can lead to rapid corrosion and very short chimney life.

Chimney Functions

The purpose of a chimney is to create draft or negative pressure to provide combustion air for the fuel or fuel bed and to remove products of combustion from the appliance and building. For open fireplaces or for gas appliances having draft hoods, chimney draft has very little influence on the combustion process; the chimney serves only as a conduit for carrying away the products of combustion. For forced-draft or packaged boilers, the chimney might be under slight positive pressure and, again, serves only as a duct to carry away combustion products. The advantage of the slight positive pressure, commonly from 0.5 to 1.5 in. of water column (120 to 370 Pa), is that it permits use of much smaller chimneys and eliminates some concerns about the draft-producing ability or height of the chimney.

The technology of matching the size, height, and configuration of a chimney to the temperature, type, and quantity of fuel for its correct capacity is covered in the ASHRAE handbook and product directory.[21]

Height of Chimneys

A variety of factors determines the height of any chimney, including the type of appliance, need for draft, roof construction, and building height. The minimum height of a chimney (or gas vent) for gas appliances having draft hoods is based on the height specified in the applicable test standard for that appliance. For example, gas furnaces, water heaters, boilers, and room heaters must pass draft hood spillage tests with 5 ft (1.5 m) of chimney height measured from the draft hood to chimney outlet, while wall furnaces require a vent outlet at least 12 ft (3.7 m) above the floor.

In contrast to these low heights for draft hood appliances, some older types of solid fuel boilers require up to 50 or 70 ft (15 to 20 m) of chimney to produce the draft needed to overcome fuel bed and internal flow resistance and to develop rated heat output.

Residential oil furnaces and boilers with pressure atomizing burners are designed to function with negative outlet draft settings in the range of 0.04 to 0.06 in. of water column (10 to 15 Pa). Manufacturers of factory-built residential chimneys have prepared draft chimney height tables that allow for such factors as the number of connector elbows, fuel input rating, and outlet size, so that an adequate height can be selected.

Building or dwelling height and configuration also govern chimney height. The generally cited rule for minimum height of the chimney outlet is illustrated in Figure 10.2.40. The chimney

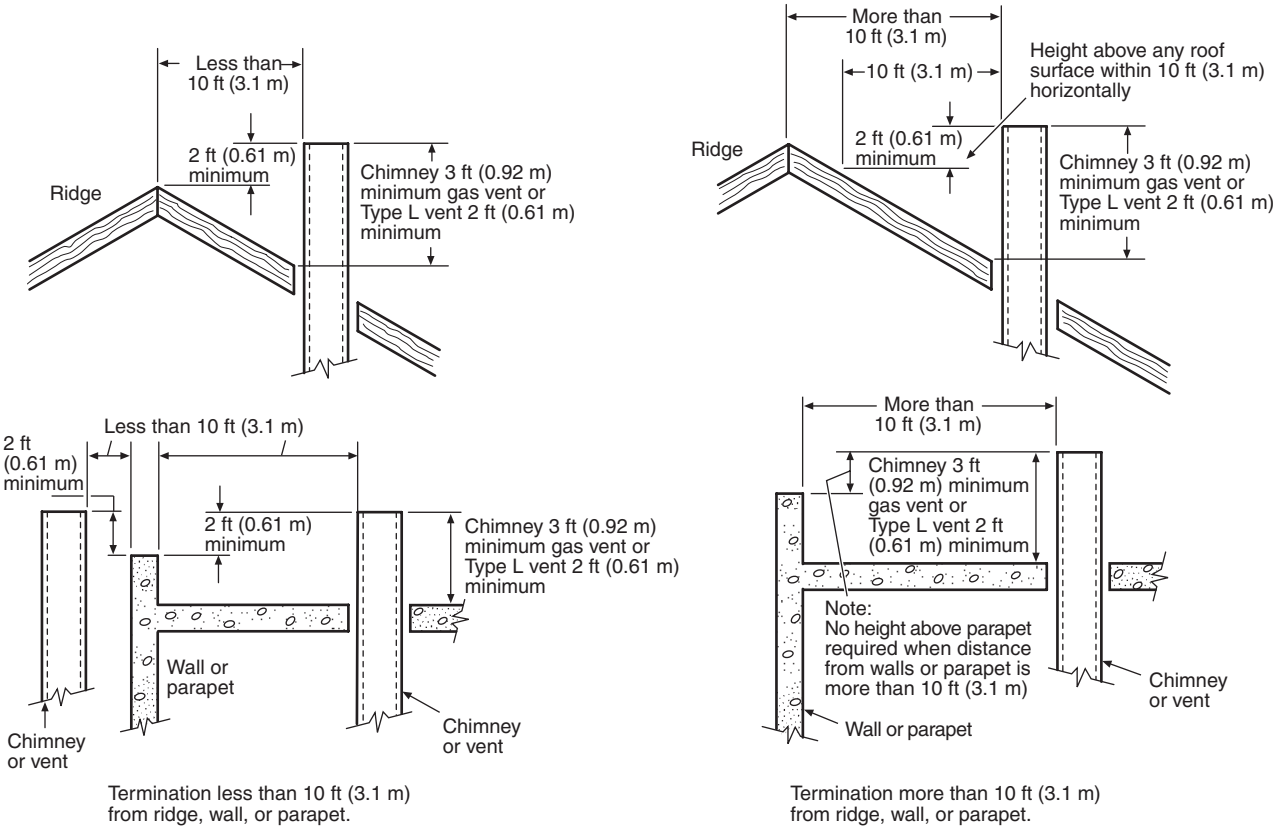

FIGURE 10.2.40 Termination of Vents and Chimneys Above Buildings

height selected must be adequate for proper appliance operation and for adequate chimney flow, as well as for proper height above the roof. Owing to the aerodynamic complexity of buildings, roofs, and chimneys, the dimensions suggested in Figure 10.2.39 sometimes are not adequate for efficient operation, which is attested to by the proliferation of special vent caps, chimney extensions, and other devices used in attempting to cure fireplace or draft problems.

Airflow over the roof must be visualized to analyze a structure for the correct chimney top location and to minimize backdrafts due to wind. Only the pressure or windward side of pitched roofs needs to be considered, because the flow moving up a building wall or toward the ridge separates from the downward side at the ridge or building edge and creates a zone of negative pressure, which circulates and eddies in this protected or cavity zone, as shown in Figure 10.2.41. The building may thus aid or impede chimney flow by using the wind to create a zone of negative or positive pressure at the chimney outlet.

Spark Arresters on Chimneys

Spark arresters are required on refuse burners or incinerators, but are desirable for all solid fuels. If sparks are expected from a fireplace or solid-fuel appliance, a chimney of any kind should have a spark screen and/or the roof surface material should be noncombustible. The usual recommendation for an arrester is for a wire mesh cloth or expanded metal having approximately ½-in. (13-mm) square openings. Smaller openings clog rapidly, whereas larger ones could allow passage of some sparks. Stainless-steel material is recommended, with galvanized steel hardware cloth a poor second choice because the coating soon burns off and frequent replacement is necessary. Factory-built chimney manufacturers offer a variety of chimney cap options with integral and accessory spark-arrester screens.

Selection of Chimneys

As an aid to selecting chimneys, heat-producing appliances have been graded by temperatures developed in the heating media or material being heated, and also by size. The grades of low-, medium-, and high-heat appliances can then be used to choose the chimney (Table 10.2.14). This selection method provides help if the appliance outlet gas temperature is consistent with its grade; however, the precepts of the grading system do not always hold true. With the availability of modern temperature instrumentation and controls and the need to conserve energy, the outlet flue gas temperature and other conditions can and should be known more precisely than heretofore for the vast majority of fuel-burning equipment. This information, which should be readily obtainable from equipment and appliance manufacturers, can offer a logical basis for chimney selection and for determining safe conditions of installation and use.

As an example of a grading inconsistency, a steam boiler operating at more than 50 psig (350 kPa) is classified in some codes as a medium-heat appliance. In selecting a chimney, it could be assumed that the outlet temperature was as high as 1500 to 1800°F (815 to 980°C). Modern multiple-pass boilers, however, operate at controlled outlet gas temperatures only 100 to 200°F (38 to 93°C) above steam temperature. Thus, the correct chimney for even a 150 psig (1000 kPa) steam boiler would be selected for an outlet gas temperature of 365.9°F + 200°F, or 565.9°F (185°C + 93°C, or 278°C). This is well below 600°F (316°C), one minimum temperature at which the medium heat grade begins. Thus, in this instance, neither the grade of appliance based on temperature of the process (2400°F [1300°C] gas in the flame) nor material (365.9°F [185°C] steam) provides a conclusive basis for selecting the boiler's chimney.

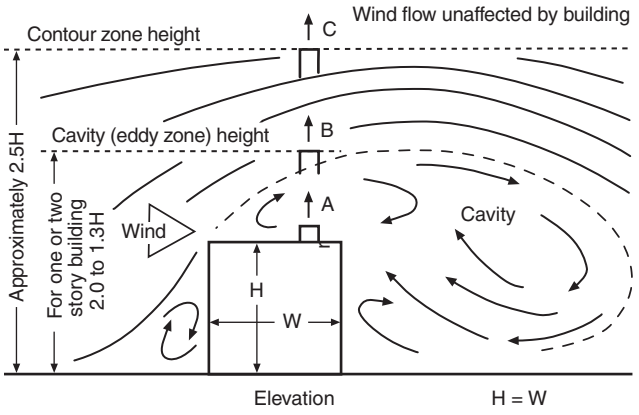

FIGURE 10.2.41 Eddy and Contour Zones Due to Airflow for One- or Two-Story Buildings and Their Effect on Chimney Gas Discharge

Chimney Selection Checklist

Selection of the correct chimney may be aided by the information in Table 10.2.14. (In those areas with adopted building codes, the code requirements take precedence over the generalities in the checklists; however, if special engineering is needed for a particular application, this approach should generally also meet the intent of any modern performance code.)

Hazards of Chimneys

For chimneys serving oil, wood, or coal appliances, fire may occur as a result of one or more of the following elements: (1) operator error or ignorance, (2) control failure, (3) improper installation, (4) use of a defective or unlisted appliance, (5) ignition of combustible soot or creosote deposits in the chimney, (6) serious cracks or internal collapse of the masonry, (7) defective construction, and (8) failure to secure joints of factory-built products.

Even masonry chimneys for gas appliances operating at very low temperatures have their problems. Condensation of flue product moisture could eventually disintegrate the mortar, leaving the chimney weak and easily toppled—a hazard to passersby.

In masonry chimneys, the following conditions can cause a fire in adjacent combustible materials:

1. Filling the space between the chimney and wood framing with insulation, or placing framing into or against the chimney wall. Note that a fill of even noncombustible insulation can be hazardous. Though the insulation itself might not ignite, it

interferes with the dissipation of heat away from the chimney and framing. Temperatures can build to the point where framing separated from the chimney by insulation is exposed to potential ignition. All clearances from chimneys must be maintained as an air space, without a fill of any kind.

2. Using a restrictive chimney cap in combination with cracks or failed mortar in a chimney, which could cause excessive leakage of hot gas at roof level, thus endangering rafters and roofing.

3. Prolonged overfiring, which may cause excessive heating on adjacent walls. At temperatures of 500°F (260°C) on the brick exterior surface, 2 in. (51 mm) clearance to nearby combustibles is of little protective value, particularly if there is little ventilation airflow.

4. Creosote or soot fires, insofar as masonry chimneys are susceptible to collecting creosote deposits. When thick or heavy enough, these deposits can burn long enough to cause outer chimney surface temperatures that can ignite the structure around them. Further, upward gas flow velocity might be sufficient to carry sparks up from the fire or burning creosote and to drop them on the roof. After a severe chimney fire, both the tile liner and bricks might have serious cracks due to thermal expansion.

Factory-built chimneys provide many opportunities for installation errors and shortcuts, which can lead to fire hazards. Among the potential installation errors and shortcuts are the following:

1. Installation of the chimney ceiling support above the ceiling framing. This necessitates passing the single-wall connector through ceiling framing at what could be dangerously close clearance; thus, the hazard might more properly be blamed on the connector.

2. Failure to secure joints or align gas-carrying parts. Many designs of factory-built chimneys allow very little tolerance for misalignment. Failure to make sure that the inner pipes of a multi-wall chimney are aligned and connected can allow flames to enter external passages reserved for cooling airflow.

3. Use of mismatched chimney parts. A given design or brand of chimney is intended to be assembled only with identical parts. There is no interchangeability and it is extremely bad practice to mix multiwall and insulation-filled chimney sections.

4. Failure to maintain proper air space clearances. As with masonry chimneys, close proximity of framing, or filling of the air space with insulation, can cause a fire hazard. Factory-built chimneys are listed for specific clearances, which are shown in the instructions and on labels. When properly used, the required manufacturer's support and spacing parts will enforce proper clearance.

The foregoing installation errors might cause fires at relatively low flue gas temperature; however, even a correctly assembled and installed chimney lacks the capability of repeatedly acting as a combustion chamber.

Chimney or Creosote Fires

The term *creosote* as applied to chimney systems refers to the tarry brown or hard black internal deposits produced by burning wood. Combustion of wood produces varying amounts of complex hydrocarbons that can condense and accumulate inside connector and chimney surfaces. These combustible deposits ignite when temperature is sufficiently high and will burn at temperatures in the range of 1200 to 2000°F (650 to 1100°C). The temperature and duration of the fire both depend on the accumulated thickness of creosote, chemical composition of the deposit, availability of oxygen, type of heating appliance, type of chimney, and so on.

In masonry chimneys, intense fires can cause cracking of tiles and brick masonry, as well as excessive heat transfer through chimney walls and hazardous overheated external surface temperatures. Clay flue liners are quite resistant to high temperatures, when applied gradually. However, chimney fires typically cause a very sudden rise in internal chimney temperature. This results in thermal shock as the hot inner surface of the liner expands against the cooler, inflexible outer portions. Longitudinal cracks in one or more liner sections are a frequent result of chimney fires. Such cracks can appear closed when the chimney is cool, but can open up to measurable dimensions when the chimney is heated by subsequent use.

The likelihood of fire spread to the adjacent structure is related to the duration of the chimney fire. Because of their mass, masonry chimneys produce significant thermal inertia. A short, though intense, chimney fire is less likely to overheat the chimney structure than a longer-lasting fire. It is therefore important that, after initial steps are taken to control a chimney fire, the fire department be called to make sure that it is completely extinguished.

In factory-built chimneys, as with masonry, the effect of chimney fires varies depending on attained temperature. Factory-built chimneys are tested with repeated application of flue gas temperatures up to 2100°F (1149°C) for periods of up to 30 minutes. They can, therefore, be expected to survive a chimney fire in usable condition. This, however, should never be simply assumed; chimney fires can exceed the test temperatures and differential heating of flue surfaces can create unmanageable stresses in the metal. It is not uncommon for the liner of a factory-built chimney to exhibit buckling after a fire. If the buckling is minor, such that flue gases or other combustion products cannot pass beyond the liner, the chimney can continue to be used. If buckling is more significant, the affected section, at minimum, should be replaced. In general, if the outer chimney is not discolored and remains shiny, it is unlikely that any building structural damage has occurred, since shiny surfaces are unlikely to radiate damaging amounts of heat if the chimney is installed at correct clearance.

Inspection after Chimney Fire. If it is suspected that a chimney fire has occurred, both masonry and factory-built chimneys should be thoroughly inspected. The flue surface, in particular, should be closely examined for cracks, holes, missing sections, or distortion. Unless the chimney is very short, such inspections should be done using closed-circuit video inspection equipment, which is the only practical way to view the inaccessible flue surface. The outer chimney surface should be examined as well, for cracks, smoke leaks, or major discoloration. Combustibles surrounding the chimney should be checked for evidence of charring and any insulation removed from required air space clearances. Damaged chimney caps and other appurtenances should be replaced. The chimney should be placed back in service only after any necessary repairs have been made.

Control of Chimney Fires. In wood-burning stoves and heaters having air dampers and doors, reducing the air supply by closing them is the best option to control chimney fires; then the combustion rate in the chimney depends on its air supply. When other appliances are connected to the chimney or a barometric damper is used for draft control, these can supply air and must also be closed to control a chimney fire. Flare-type chimney fire

extinguishers (similar to automotive safety flares) are available that, when activated and placed in the appliance, release a cloud of fire extinguishing agent into the chimney. For the agent to be effective, it must be retained in the chimney. Therefore, the stove should be closed to prevent the agent from being drawn quickly up and out of the chimney. Open-front fireplaces or fireplace stoves without doors may not accumulate creosote rapidly, but under fire conditions air control is difficult. The best policy with fireplaces is routine chimney inspection and mechanical cleaning (brushes and scraping).

Because of the possibility of fire spread to the building structure, occupants should, at minimum, be gathered and prepared to leave the building. The fire department should be immediately called, both as a precaution against fire spread and to ensure that the chimney fire is completely extinguished.

Maintenance and Inspection of Chimneys

To remain safe and effective, chimneys need periodic inspection and maintenance. NFPA 211 requires all chimneys (regardless of the fuel used in connected appliances) to be inspected at least once a year. Such inspections should include, at minimum, examination of the inner flue surface for the presence of combustible deposits and freedom from cracks, gaps, softening, or other damage or deterioration. The outer wall should be examined for missing bricks or mortar and evidence of leakage. Although clearances to the building structure are usually determined at the time of construction, inspection should verify that no insulation or loose combustible material has fallen into the required air space.

For chimneys serving solid-fuel equipment, cleaning of creosote and other combustible deposits from the flue is the most frequent maintenance activity. A common rule of thumb suggests that a buildup of ¼ in. (6.4 mm) in thickness indicates a need for cleaning. This might be most applicable to soft, powdery, or crusty deposits. Deposits of smooth, gummy, or hard tar-glaze, on the other hand, might contain significantly more potential energy, and can fuel a more intense and longer-lasting fire than less dense material. Therefore, when any thickness of tarry deposits is detected, immediate cleaning is in order.

Cleaning of loose deposits is usually done with a stiff wire brush, fitted to the flue dimensions and scrubbed up and down the chimney with rods. More resistant deposits require the use of a flat wire brush or specialized manual scrapers. There are various mechanical devices available that use rotating chains or brush heads to flail and chip hard creosote deposits on the flue walls. In extreme cases, there are chemical treatments that can soften or loosen deposits. Mechanical and chemical cleaning methods should be used only by trained professional chimney service specialists.

NFPA 211 also includes requirements for corrective action when inspection shows that the chimney is no longer suitable for the intended application. Any damage or deterioration, from whatever cause, that impairs the ability of the chimney to conduct the products of combustion directly to the outdoors, while protecting the structure and occupants from heat, leakage, or spillage, is cause for repair or replacement of the chimney. Specifically, with respect to flue lining, NFPA 211 requires repair, replacement, or relining if the lining has "softened, cracked, or otherwise deteriorated such that it no longer has the continued ability to contain the products of combustion, that is, heat moisture and flue gases."

FIREPLACES AND FIREPLACE STOVES

Fireplaces of masonry or factory-built construction are primarily open fire-chamber appliances with no controls on the air supply to the fire. These require a properly sized chimney to carry out the smoke and combustion gases. Fireplace stoves are free-standing, factory-built appliances operating with an open front, but, if these have doors, they may also operate as stoves or heaters with controlled combustion air. The addition of glass doors to a masonry fireplace, or the installation of a closed-front fireplace insert, will transform its combustion characteristics to that of a heater.

Special techniques are required for connection of a heating appliance to a fireplace. The appliance must be directly connected to masonry fireplace flues with a suitable connector extending through the damper and smoke chamber. Appliances must not be inserted in, or connected to, factory-built fireplaces unless the appliance is listed for that fireplace, and then only in strict accordance with manufacturer's instructions.

Masonry Fireplaces

Field-constructed masonry fireplaces must conform to building codes or provisions of applicable standards (e.g., NFPA 211) to ensure safe operation. They may be served by a masonry residential chimney or may use a factory-built chimney with a suitable factory-furnished transition between smoke chamber and chimney. Prefabricated designs of masonry fireplaces and masonry fireplace chimney combinations are available in some localities. When a lining of low-duty firebrick is provided, masonry fireplaces require at least 8 in. (203 mm) of brick thickness or equivalent for the back and sides, with 2 in. (51 mm) clearance to combustibles at the sides and 4 in. (102 mm) minimum clearance from the back. When the lining described above is not used, the thickness of the masonry at the back and sides should not be less than 12 in. (305 mm). The entire fireplace must be supported on a noncombustible footing, with structural floor framing well away from direct heat conduction from the fire zone or external hearth (Figure 10.2.42).

Hearth extensions of approved noncombustible material must be provided for all fireplaces. The hearths must extend at least 16 in. (406 mm) in front and 8 in. (203 mm) beyond the sides of fireplaces with an opening of less than 6 ft^2 (0.56 m^2). If the opening is 6 ft^2 (0.56 m^2) or larger, the hearth must extend at least 20 in. (508 mm) to the front and 12 in. (305 mm) to the sides.

Masonry fireplaces may be built around steel fireplace units or heat circulating forms incorporating an air chamber. A total thickness at back and sides of not less than 8 in. (203 mm) must be provided, of which not less than 4 in. (102 mm) is solid masonry. The same clearances to surrounding combustibles apply to fireplaces with circulators.

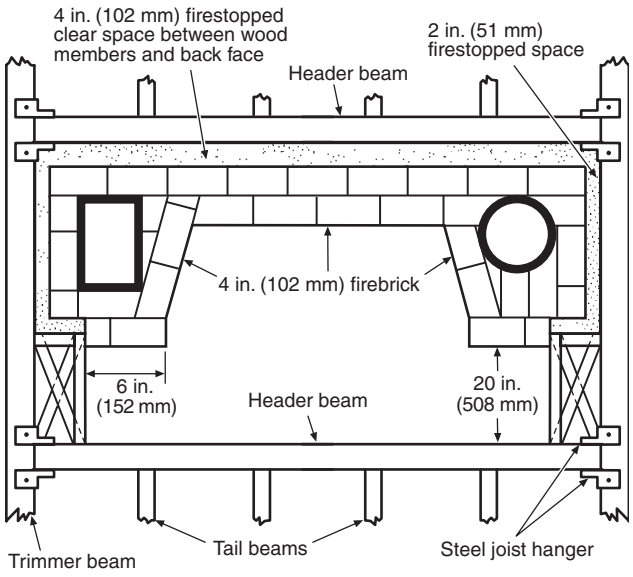

FIGURE 10.2.42 Floor Framing Around a Fireplace, When the Fireplace Opening Is 6 ft^2 (0.56 m^2) or Larger

Factory-Built Fireplaces

Factory-built fireplaces are mainly of metal construction using multiple air spaces, refractory hearths and liners, and insulation to obtain the required level of safety. Factory-built fireplaces are tested and listed to ANSI/UL 127, *Standard for Safety Factory-Built Fireplaces*.[22] Each fireplace must be installed with the specific chimney and other parts called for by the manufacturer's instructions and the terms of its listing.

Combustion Air Inlets

Some fireplaces incorporate a duct to bring combustion air directly to the fire chamber from the outdoors. This theoretically reduces the consumption of room air and minimizes the possibility of excessive depressurization of the house. Because such ducts communicate with the combustion zone, care must be taken to ensure that they do not create a hazard. Building fires can occur if combustion products, such as embers, have entered the duct in proximity to combustible construction.

NFPA 211 does not allow combustion air ducts to terminate within the fire chamber of a fireplace unless the device is listed for such an application. Otherwise, the duct must terminate outside the fireplace; if within 6 in. (152 mm) of the opening, they must be equipped with a guard to prevent the entry of embers, ashes, flame, and so on. The duct itself must be made of 26-gauge galvanized steel or equivalent, and must maintain a 1 in. (25.4 mm) clearance to combustibles.

Factory-built fireplaces may use combustion air ducts that are incorporated into the original design of the listed fireplace, and, if optional, must be a listed accessory to the particular fireplace. They will be accompanied by specific installation instructions and must be installed accordingly.

No combustion air duct should draw air from an attic, basement, garage, or other interior space, or an area where combustible vapors might be present. Any duct that connects directly to the fire chamber should not extend vertically above the fireplace, to avoid the possibility of the duct acting like a chimney and drawing in combustion products.

Chimney Sizes for Fireplaces

For masonry fireplaces, the correct size and height of chimney will ensure that all smoke, fire, and gas goes up the chimney. Although imprecise, there are several rules of thumb for sizing fireplace flues. For very short chimneys (less than about 15 ft [4.6 m]), the actual cross-sectional area of the flue should be at least one-eighth of the area of the frontal opening of the fireplace. For chimneys of normal height, rectangular flues should be at least one-tenth of the fireplace opening; round flues should be at least one-twelfth of the opening. The nominal size of tile liner must be carefully checked to ensure that the internal cross-section area is adequate. In addition, the area of opening through the damper throat must be approximately twice the required flue area or greater, or it may reduce flow and possibly cause smoking.

For factory-built fireplaces, the chimney and, therefore, the flue size, is an integral part of the appliance design. Only the chimney specified or supplied by the fireplace manufacturer should be used. There are also factory-built fireplaces made of masonry material that are assembled on site from precast components. Some of these come with an integral chimney, whereas others specify a particular size chimney of conventional construction. Some of these fireplaces use advanced principles of airflow through the fireplace and can use unconventionally small flue sizes; ratios of fireplace opening area to flue area of 20:1 are possible with some designs.

Charts are available for factory-built and masonry chimneys in the ASHRAE handbook and product directory[21] and in manufacturers' literature that indicate the correct chimney size and height in relation to frontal opening, based on an average room air velocity of not less than 0.8 ft/sec (0.24 m/sec) into the opening. This minimum velocity rule is valid for a wide variety of open fire chamber combustion systems, including masonry fireplaces as well as combination room heaters and fireplace stoves.

Factory-Built Fireplace Stoves

These free-standing units are usually of metal or combination metal and refractory construction and may require a specific type of chimney and special connectors, or may be connected to any acceptable chimney by conventional means. Fireplace stoves are tested and listed (see ANSI/UL 737, *Standard for Safety Fireplace Stoves*),[23] but if the stove has doors it becomes a combination fireplace and room heater, and to be listed for operation with doors closed it must also comply with ANSI/UL 1482, *Solid Fuel Type Room Heaters*.[24]

Investigation of many combination fireplace stove heater designs has demonstrated the validity of the geometrical relationship between heater size and required clearance. Simply

stated, larger units may require greater than standard clearance. To be sure of correct installation, the manufacturer's installation instructions for listed stoves and heaters should be scrupulously observed. These instructions have been reviewed for consistency with test results and are as essential to the safety of an installation as are the design features of the stove.

Although untested fireplace stoves and related heaters can be installed and operated safely, they are seldom accompanied by carefully written instructions. Many imitations of listed designs can be found that are sold through retail outlets having little interest in the final installation. The lack of clear instructions and warnings poses many hazards to the consumer.

Hazards of Fireplaces and Their Chimneys

Open fireplaces, transferring heat primarily by radiation from the fire, can create several kinds of hazards:

1. Ignition by radiation of furnishings or walls located too close to the fire.

2. Ignition of furnishings or carpeting by sparks or from logs rolling out of the fire. For large, high fireplaces having a high fuel capacity, the 20 in. (508 mm) hearth width requirement may be grossly inadequate.

3. Ignition of combustible structural materials by excessive heat conducted through hearth or fireplace walls, which can make prolonged overfiring of a masonry fireplace dangerous.

4. Escape of gases from the opening into a construction gap between the fireplace shell and the front facing wall. This is a common installation fault with factory-built fireplaces, since a smoking unit—one with insufficient chimney flow—allows very hot gas to escape into this area.

5. Sparks and embers falling onto a combustible floor between the fireplace and its hearth extension. This can be prevented by placing the masonry or factory-furnished hearth extension flush against the front of the fireplace, or by using a sheet of metal at the floor surface under the joint between the fireplace and its hearth.

6. Burning highly combustible solid materials, such as a dried Christmas tree and wrappings. The high gas temperatures resulting may ignite creosote deposits, or cause damage to the masonry. The high rate of burning may cause the flames, heat, and smoke to billow out of the fireplace opening, possibly igniting nearby combustibles.

7. Use of any flammable liquid to start or rekindle a fire, or in any room with or near an open fire.

8. Failure to clean the chimney whenever creosote deposits build up to dangerous thickness. A layer of creosote 1⁄16 in. (1.6 mm) thick in an 8-in. (200-mm) size chimney 15 ft (4.6 m) high contains as much as 122,000 Btu (128 MJ) of fuel. If this burns off in 15 min, the resulting temperature could reach 1700°F (930°C) at a heat release rate as high as 488,000 Btu per hour (140 kW).

9. Use of an incorrect or mismatched chimney. For safe operation, many types of factory-built fireplaces require a chimney that interconnects with its air passages. Failure to connect the fireplace to this specific chimney could be extremely dangerous and clearly violates installation requirements and the listing.

10. Failure to install firestopping around chimneys, which might be termed an indirect installation hazard. This will not start a fire, but, if one starts elsewhere, the lack of firestopping may cause severe losses. Because of the numerous possibilities for operator or construction errors in the vicinity of the fireplace itself, every precaution should be taken to prevent rapid involvement of the entire structure in case of fire. Many modern single and multiple residences of frame construction use a chase or vertical enclosure, inside or external to the dwelling, containing one or more fireplace chimneys. The absence of floors or other internal framing makes it easy to install all the chimneys, but also provides an ideal passage for rapid vertical spread of flame to upper levels and the roof. The shape and size of firestopping for this sort of installation cannot readily be anticipated by the fireplace manufacturer, but carefully fitted sheet metal or lath and plaster may limit the spread and allow time for effective fire fighting.

SUMMARY

Heating systems and appliances are frequent causes of fire because they operate at high temperatures and sometimes can involve hazards such as combustible mixtures and fuels. There are many different components involved in a heating system, including various types of fuel, heating applications, firing methods, distribution systems, storage, vents, chimneys, and fireplaces. Each type of fuel and heating system component is associated with potential fire hazards. Proper installation, operation, and maintenance in accordance with the fire codes are the keys to fire safety and prevention.

Key Terms

accessibility, building transportation system, dumbwaiter, elevator, elevator car, escalator, hoistway, machine room, moving walk

Building transportation systems are mechanical/electrical systems that transport people or materials vertically or horizontally in a building. They provide conveyance for building occupants or selective, noncontinuous movement of materials. Unlike materials-handling systems, they are not part of a manufacturing process and are not designed to continuously move material.

Because of their impact on fire safety, building transportation systems must be considered during the design stage and should be integrated with the total building fire protection system. Hazards associated with these systems must be included in any prefire planning and fire protection survey.

Building transportation systems, such as elevators and escalators, make high-rise buildings feasible. Today, accessibility requirements mandate elevators in most buildings with two or more stories. Although it is unrealistic for multistory buildings to function without elevators, elevator hoistways can contribute to the spread of smoke and/or fire. On the other hand, an elevator is a necessary tool for fire-fighting operations in high-rise buildings.

The discussion of elevators, dumbwaiters, escalators, and moving walks in this chapter is intended to complement NFPA *101®*, *Life Safety Code®*, and *NFPA 5000®*, *Building Construction and Safety Code®*, which requires elevators and escalators to be installed in accordance with ASME A17.1, *Safety Code for Elevators and Escalators.*[1] U.S. building codes also refer to ASME A17.1.

In Canada the *Safety Code for Elevators,* CSA B44,[2] applies in lieu of ASME A17.1. The ASME A17 and CSA B44 Elevator Safety Codes are essentially fully harmonized. In April 2007 the *Safety Code for Elevators and Escalators,* ASME A17.1/CSA B44-2007, was published as the successor to ASME A17.1 and CSA B44. The model building code in Canada is the National Building Code of Canada (NBCC).

This chapter examines the various building transportation systems—elevators, escalators, dumbwaiters, and moving walks—that transport people or materials vertically or horizontally in a building.

The following chapters are pertinent to the subject matter of this chapter and should be reviewed for a more comprehensive view of fire problems associated with building transportation systems: Section 18, Chapter 1, "Confinement of Fire in Buildings"; Chapter 3, "Smoke Movement in Buildings"; and Chapter 4, "Venting Practices." See also Section 8, Chapter 3, "Materials-Handling Equipment," for other-than-freight elevators and dumbwaiters.

CODE REQUIREMENTS

Requirements for the installation of equipment for elevators, dumbwaiters, escalators, and moving walks appear in ASME A17.1/CSA B44. Current ASME A17.1/CSA B44 code requirements provide a framework for standards of safety for products whose technologies have become state-of-the-art and commonplace. In a progressive elevator industry, designs and products emerge that are not specifically covered in ASME A17.1/CSA B44. Since code requirements cannot anticipate future

Edward A. Donoghue, CPCA, is president of Edward A. Donoghue Associates, Inc., code and safety consultants, Salem, New York.

development and innovation in the elevator industry, ASME A17.1/CSA B44 is written to reflect state-of-the-art technologies following its introduction.

With new materials and processes in mechanical, structural, electronic, and optics areas, in addition to analytical capabilities now available, the need for flexibility to introduce products resulting from maturing technical developments is heightened. The ASME A17 and CSA B44 committees have responded to this need with the new ASME A17.7/CSA B44.7, *Performance-Based Safety Code for Elevators and Escalators.*[3] ASME A17.7/CSA B44.7 requires compliance with ISO-based Global Essential Safety Requirements (GESRs). Design compliance with GESRs is evaluated to ensure that the hazards have been addressed and mitigated using a risk assessment (RA) process. Finally the design along with the RA documentation is presented to an Accredited Elevator/Escalator Conformity Organization (AECO) to review and evaluate for compliance with ASME A17.7/CSA B44.7. Once the AECO is satisfied a certificate of compliance will be issued. The process is outlined in Figure 10.3.1.

ELEVATORS

An elevator is defined as a hoisting and lowering mechanism equipped with a car that moves within guides and serves two or more landings.[1] The two major elevator types, classified by their driving means, are electric and hydraulic.

Types of Elevators

Electric Elevators. An electric elevator's power source is an electric motor. The most common electric elevator is the electric traction elevator that employs a grooved traction drive sheave, over which pass suspension ropes that are attached to the car and counterweight (Figure 10.3.2). This arrangement is very simple and safe, allowing its use in buildings of any height. An inherent safety feature is traction loss when the car or counterweight is at its travel limit. The car or counterweight cannot be pulled into the overhead structure, provided proper traction ratios are provided.

Another, older type of electric elevator is the winding drum machine elevator. In this arrangement, suspension ropes are attached to, and wind onto, a winding drum. Counterweight ropes also may be fastened to, and wind onto, the drum. Winding drum machines typically have no counterweights, but older designs may have a car counterweight and/or a drum counterweight. It is possible for either the elevator car or counterweight to be pulled dangerously into the overhead structure.

Hydraulic Elevators. Hydraulic elevators are powered by liquid under pressure, in a hydraulic jack (Figure 10.3.3). The rise, or travel, of a direct plunger hydraulic elevator is limited to the length of its piston, usually six floors or less.

Another type of hydraulic elevator is the roped hydraulic elevator. This elevator type has its plunger, or piston, connected to the car with wire ropes or indirectly coupled to the car by wire ropes and sheaves.

Classification of Elevators by Use. Elevators are classified according to use as either passenger or freight elevators. A passenger elevator's primary use is to carry persons other than an operator and persons necessary for loading and unloading. A freight elevator is used primarily for carrying freight; only the operator and persons who unload and load the freight are permitted to ride, unless the elevator has been designed to comply with the provision in ASME A17.1/CSA B44 as a freight elevator permitted to carry passengers. Freight elevators will have a sign advising who is permitted to ride. A service elevator is officially classified as a passenger elevator that is designed to carry freight.

Construction

Hoistway Construction. Elevators travel in a vertical space or opening, called a hoistway or shaft, that extends from the pit floor of a building to the floor, or roof, above. ASME A17.1/CSA B44 requires that hoistway construction conform to the applicable building code or, in the absence of local code, to provisions of one of the model building codes.

Although elevators made high-rise buildings practical, they also created new, complex, potentially dangerous fire safety challenges. Hot smoke and gases from fire, if allowed to accumulate at the top of the elevator hoistway, can result in mushroom fires on upper floors served by the elevator. This occurs because an enclosed elevator hoistway acts as a chimney or flue due to stack effect. This generally results in the movement of smoke and combustion products from lower to upper building levels.

The stack effect may also adversely affect elevator door closing, even under normal conditions. ASME A17.1/CSA B44 specifies the maximum door closing force and kinetic energy for safe automatic door closing. Pressure differentials must be taken into account to safely regulate door closing operations.

All model building codes require venting of elevator hoistways. Most require venting of the hoistway for elevators serving three or more stories. Some local codes permit venting through the machine room, with mechanical or natural venting from the machine room to the outside. This practice may result in premature loss of elevator service in a fire emergency due to elevated machine room temperatures and/or smoke damage to the control system. Most codes restrict the size of the opening in machine room floors. For fully sprinklered buildings that have no sleeping rooms, some codes allow sprinklers in the hoistways in lieu of hoistway venting.

Some local codes require pressurization of the hoistway to a specified minimum positive pressure above the pressure of the elevator lobby. When a pressurized hoistway is provided, it should contain a vent that opens automatically in case of power failure. A manual means should also be provided to vent smoke that penetrates the hoistway. Due to numerous variances and rapid developments in this area, local code requirements should be checked.

When designing a hoistway pressurization system the following issues need to be taken into consideration. The kinetic energy and closing forces on elevator doors are regulated by ASME A17.1/CSA B44, *Safety Code for Elevators and Escalators.* The limitations on the maximum kinetic energy and door

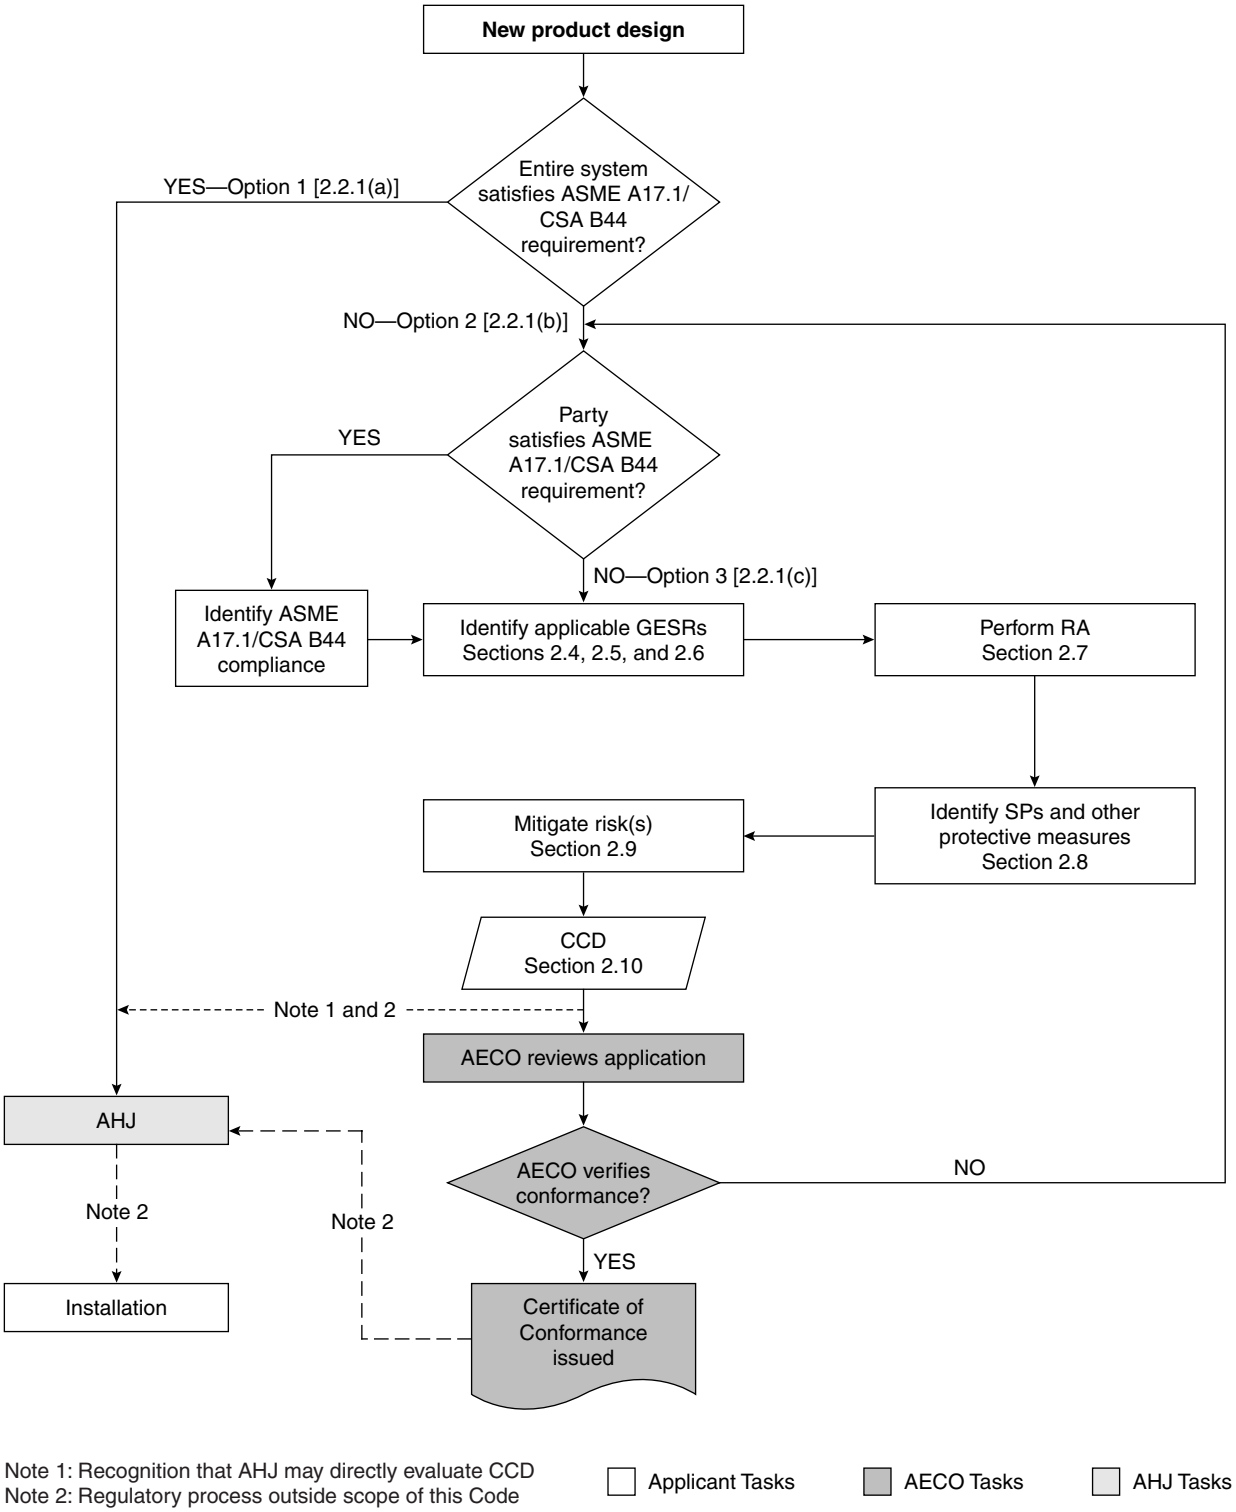

FIGURE 10.3.1 Elevator/Escalator ASME A17.7/CSA B44.7 Design Compliance Process (Source: Reprinted from ASME A17.7/CSA B44.7-2007 by permission of the American Society of Mechanical Engineers. All rights reserved.)

closing forces are critical to ensure the safety of passengers entering and exiting elevator cars. Excessive pressurization will lead to jamming of the elevator doors due to the high pressures. A pressure of 0.35 in H_2O (8.7 Pa) will produce lateral force on each panel of a landing door of about 28 lb (12.7 kg) on a 44 in. (1117.6 mm) door. This force will also be in the opposite direction of the normal forces to which the door panel is normally subject. In all likelihood open elevator doors will not be able

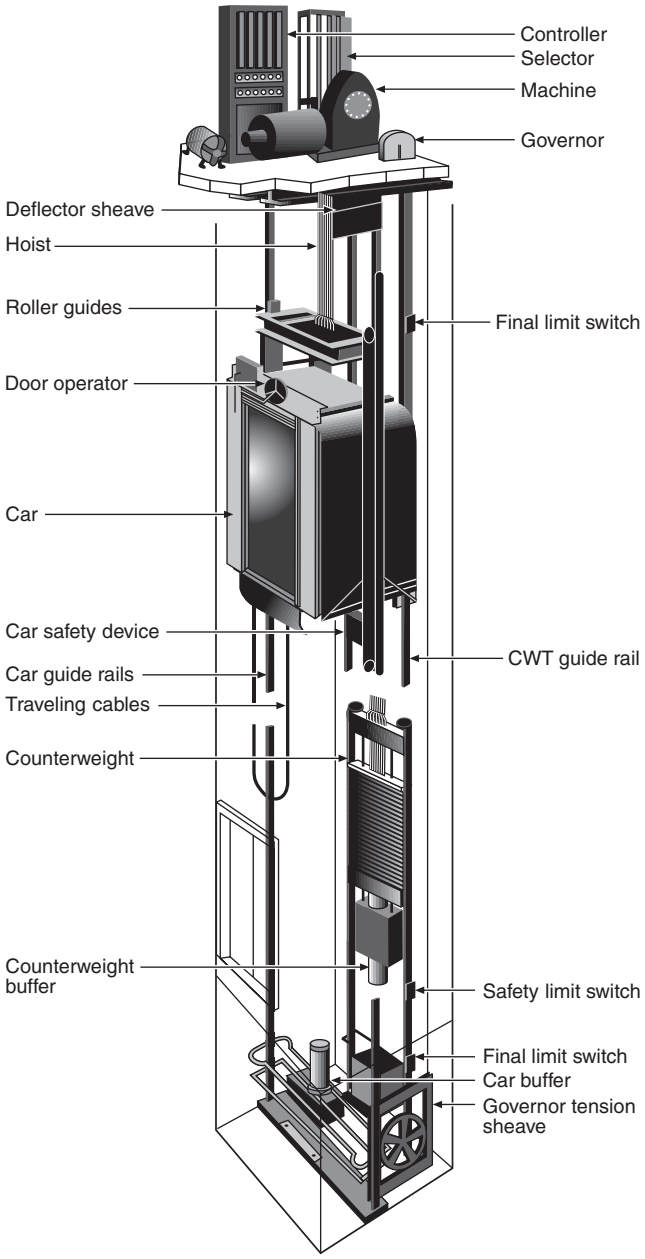

FIGURE 10.3.2 Electric Traction Elevator (Source: National Elevator Industry, Inc.)

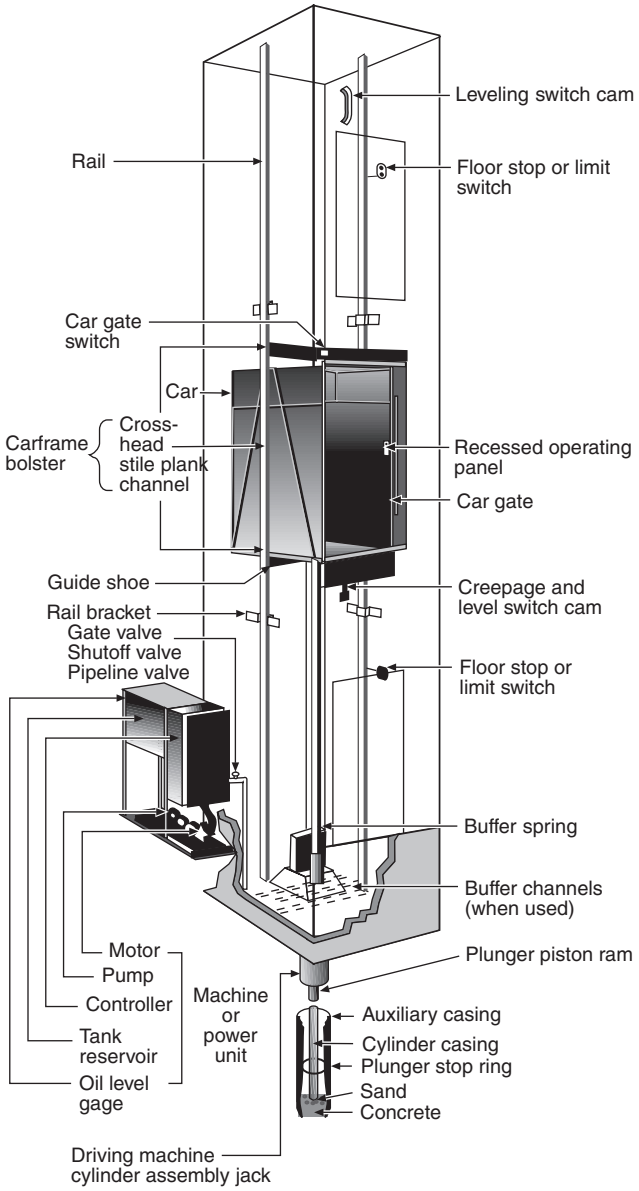

FIGURE 10.3.3 Direct Plunger Hydraulic Elevator (Source: National Elevator Industry, Inc.)

to power close once pressurization is activated. The following scenarios are typical of some of the conditions that could be encountered:

- Elevators operating on normal service; pressurization activated due to fire in building; Phase I not activated by smoke detector in elevator lobby, machine room, or hoistway; elevators doors open to accept or discharge passengers; elevator doors unable to overcome pressure and close; elevator service in building is lost one car at a time.
- Elevator operating on normal service; pressurization activated due to fire in building; Phase I activated by smoke detector in elevator lobby, machine room, or hoistway or by Phase I key switch; elevators at landings with open doors not able to overcome pressure and close doors; cars do not return on Phase I to designated landing; arriving fire fighters will not find all elevators at designated landing and lose valuable time searching for cars not recalled on Phase I to designated landing. (Phase operations are discussed later in this chapter.)
- Elevators at designated landing that have returned on Phase I; arriving fire fighter activates Phase II; doors not able to overcome pressure and close; fire fighters lose use of elevators.

Elevator hoistway enclosure walls are normally fire partitions with a fire resistance rating of 2 hours. Some situations require no fire resistance rating. For example, an elevator that

serves only open balconies without penetrating separate fire-resistant areas of a building does not require a fire-resistant hoistway. In other cases, the fire resistance rating may be required on only one or two walls. An example is an observation elevator that permits exterior viewing by passengers, where entrances to the elevator penetrate fire-resistant walls.

The maximum number of elevators permitted in a single hoistway is controlled by building code requirements, which are intended to limit the potential of a fire knocking out all elevator service in a structure. For buildings with three or fewer elevators, codes generally permit all elevators to be in the same hoistway enclosure. Four elevators require at least two separate hoistway enclosures, and, where there are more than four elevators, no more than four can be enclosed in the same hoistway enclosure.

Hoistway Entrances. If the hoistway wall is load bearing, it can support the hoistway entrance operating mechanisms and locking devices. If the walls are not load bearing, other building structures must support the hoistway entrance operating mechanisms and locking devices. Elevator entrance frames are not designed to carry the weight of the wall above, so a lintel must be provided.

Elevator hoistway entrance assemblies customarily have been rated at 1½ hours, but they may be rated at 1 hour or ¾ hour. A labeled entrance ensures that the hoistway entrance door assembly can meet the fire safety requirements specified by building codes and NFPA 80, *Standard for Fire Doors and Other Opening Protectives.* The label is visible from the hoistway. Arrangements must be made with the elevator company so the label can be safely seen from the top of the car.

In masonry construction, passenger elevator doors typically overlap the wall by ¾ in. (19 mm). When this requirement is met, the frames, if supplied, are not required to be labeled. Masonry-type walls generally consist of brick, concrete block, or reinforced concrete construction. All three materials are fire resistant.

Drywall Enclosure Construction. Drywall construction largely supplanted masonry construction as the most prevalent hoistway construction used today throughout North America. Early elevator entrance installations in drywall were similar to masonry installations. However, some design changes were made to ensure the integrity of the interface between the entrance assembly and the drywall construction. Brackets were placed within the frame of the entrance assembly to accept "J" struts furnished by the drywall contractor.

The "J" strut is vitally important in ensuring a proper entrance frame drywall interface. Drywall frames must be labeled unless the door panel overlaps the wall by ¾ in. (19 mm), an atypical condition. There is no difference in the door panels. Figure 10.3.4 shows a cutaway view of a drywall entrance assembly interface.

The drywall entrance assembly is critical to the fire performance of masonry and drywall elevator door entrances. The entrance frame assembly, including the frame, door panels, hardware, and so on, is labeled as part of the drywall entrance enclosure. Prior to the use of drywall for hoistway enclosures, the entrance frame was only decorative and not part of the labeled entrance assembly (see the ASME A17.1/CSA B44 handbook for more information).[4]

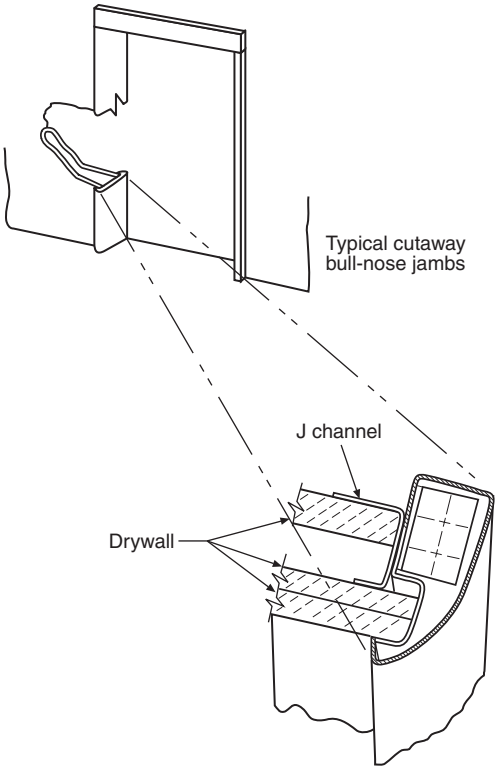

FIGURE 10.3.4 Interface Between Drywall Construction and Bull-Nose Doorjamb of an Elevator Entrance

Drywall construction with stone veneers is available but has not been investigated by testing laboratories under fire conditions; therefore, the performance of such construction cannot be accurately predicted. Engineering judgment can be applied when comparing stone-faced drywalls with solid masonry walls. In drywall construction, the application of the facing material could affect the interface between the door and steel frame.

Entrance Fire Test and Marking. ASME A17.1/CSA B44 requires entrances installed in fire-resistive enclosures to be subjected to type test specified in NFPA 252, *Standard Methods of Fire Tests of Door Assemblies,* or UL 10B.[5] In Canada, NBCC requires entrances installed in fire-resistive enclosures to be subjected to the standard fire exposure test described in CAN-S104.

The classification marking, or label, on passenger elevator door panels covers the design and construction of the door panels only. In addition to the door panels, when the panel does not overlap the wall ¾ in. (19 mm), the fire door frames and transom, if provided, must be labeled.

Hardware also must be labeled for a completely listed entrance assembly. Passenger elevator door hardware consists of a header; track hangers; pendant bolts; floor sill with guides, sill support plates, and brackets; retaining angles; and closure assemblies. Each component must be labeled individually. For

hardware packaged and shipped as a single unit, ASME A17.1/CSA B44 permits one label for all components. ASME A17.1 also permits a single label for the entire entrance when it is shipped as a single package and duplicates the tested assembly. Typically freight entrances and dumbwaiter entrances are provided with a single label.

Door Gasketing Materials. Listing agencies have classified gasketing materials for use on elevator fire door and frame assemblies. Individual gasketing materials are investigated for use on particular frame or door types and for specific fire duration periods. The basic standards used to investigate gasketing materials are Underwriters Laboratories Inc.'s *Fire Test of Door Assemblies* (UL 10B)[5] and *Standard for Air Leakage Tests of Door Assemblies* (UL 1784).[6] However, the tests do not evaluate the potential adverse effect on door operation.

Fire departments consider in-car elevator operation crucial in a high-rise fire. A question arises: Does gasket material affect elevator door operation? The kinetic energy and door-closing forces of power-operated doors are regulated for passenger safety by ASME A17.1/CSA B44. When the doors are almost closed, the closing speed must be reduced. Friction from the gasket material may prevent complete closure, immobilizing the elevator and exposing the elevator hoistway to smoke, hot gases, and fire. Another question is what effect this seal will have on doors designed to close automatically if the car leaves the landing zone for any reason.[7] ASME A17.1/CSA B44 requirements address the safety needs of passengers, including fire fighters, when gasketing is provided on elevator entrances.

Although enclosing elevator lobbies with smoke and draft control doors is perhaps not as aesthetic as the architect and building owner would like, it is the most practical substitute for gasketing elevator entrances, as a means of controlling the movement of smoke into the elevator hoistway. An enclosed lobby also could serve as an area of rescue assistance for the disabled in a fire and as a safe staging area for fire fighting.

Machine Room Construction. Most building codes require machine room enclosures to be constructed of equally fire-resistant material as that provided for the hoistway enclosure. When a non-fire-resistant hoistway is constructed for an electric or hydraulic elevator and when the building code permits, the machine room enclosure must be of noncombustible material extending to a height of not less than 6 ft (1.83 m). Machine rooms access doors are to be kept closed and locked, and entry is required by ASME A17.1/CSA B44 to be restricted to authorized personnel familiar with the precautions that are necessary around moving elevator machinery. Machine room floors should be kept free of oil and grease. Material not necessary for the maintenance or operation of the elevator should not be stored in the machine room. Flammable liquids with flashpoints of less than 110°F (43°C) should not be kept in the machine room. ASME A17.1/CSA B44 requires an extinguisher for use on Class A, B, and C fires in all machine rooms; the extinguisher should be conveniently located near the access door.

ASME A17.1/CSA B44 requires elevator machinery to be in a room that contains only elevator equipment. Machine rooms that are not located at the top of hoistways should not contain equipment inessential to the operation of the elevator, because a fire that starts in a basement machine room has a clear unobstructed path to the hoistway. Previously, ASME A17.1/CSA B44 permitted a machine room located above the hoistway to contain other equipment essential to building operation, provided the elevator equipment was separated from the other equipment by a metal grill or solid partition at least 6 ft (1.83 m) high.

The ambient temperature and humidity in the elevator machine room is critical, especially for modern solid state controls. ASME A17.1/CSA B44 requires that machine room temperature be maintained in the range the equipment manufacturer specifies. ASME A17.1/CSA B44 requires that the temperature and humidity range be permanently posted in the machine room. Loss of elevator service in a fire emergency may result if the elevator machine room HVAC is shut down.

Sprinklers in Hoistways and Machine Rooms. NFPA 13, *Standard for the Installation of Sprinkler Systems,* outlines provisions for sprinklers installed in elevator hoistways and machine rooms. ASME A17.1 does not require sprinklers, but, when installed, sprinklers must meet NFPA 13. CSA B44, likewise, does not require sprinklers, but, when installed, sprinklers must meet NBCC requirements. Before considering the installation of sprinklers in spaces containing elevator control equipment, certain potential problems should be analyzed. One should consider whether any water discharge on the control equipment may adversely affect the elevator's safe operation. Water has been known to short safety circuits and allow an elevator to run with an open car or hoistway door. In addition, wet brakes may be unable to stop and hold an elevator.

ASME A17.1/CSA B44 requires that, when a sprinkler in the machine room or hoistway when the sprinkler is more than 2 ft (610 mm) above the pit floor is discharged, the main line power source to the elevator be disconnected. *NFPA 72®, National Fire Alarm Code®,* contains details on how to implement this requirement. In a fire, the sequence of events would probably be as follows:

1. A smoke detector in the machine room, hoistway, or elevator lobby recalls the elevator.
2. The main line power automatically disconnects.
3. The sprinkler discharges.

Even if the smoke detector is not activated or if all elevators have not been returned to the lobby, stopping the car and containing the passengers is considered safer than allowing operation to continue with the sprinkler discharging. Fire fighters should be aware that, if fire is in the elevator machine room, the elevators with machinery in that room will not be available for their use.[8]

There have been numerous requests for delaying the removal of power from the elevator and sprinkler activation to allow for the completion of Phase I recall, or for the elevator to stop at the next available floor and open its doors. This is not practical if either the elevator control system is involved in the fire or the ambient temperature in the machine room is significantly above the design tolerance for the equipment. ASME A17.1/CSA B44 recognizes delaying the disconnecting of power and activation of a sprinkler provided it is accomplished independent of the elevator control system.

NFPA 13 requires sprinklers at both the top and the bottom of the shaft. The sprinklers may be omitted when the elevator shaft is enclosed with noncombustible materials and combustible hydraulic fluids are not present in the shaft. A potential problem is the interpretation of this provision relative to an electric traction elevator installation with oil buffers. In addition, sprinklers may be omitted from the top of noncombustible elevator hoistways of passenger elevators complying with ASME A17.1/CSA B44.

Elevator Car Construction. ASME A17.1/CSA B44 requires that all material exposed to the car interior and the hoistway be metal or glass, or have a flame spread rating of 0 to 75 and smoke development rating of 0 to 450. Materials must be tested in their end use configuration. Padded protective linings for temporary use in passenger cars during freight handling also must meet these criteria.

The smoke development rating for materials in cars is equal to NFPA *101,* requirements for an exit passageway in a fire-resistant building. Smoke development characteristics of materials may be more crucial than flame spread, as passengers in a confined enclosure box may not be able to escape rapidly. In Canadian jurisdictions enforcing NBCC, where the elevator is designated as a fire fighter elevator, the flame spread rating for walls and ceilings is 0 to 25 and for floors 0 to 300. The smoke development rating for walls and ceilings is 0 to 100 and for floors 0 to 300.

Napped, tufted, woven, looped, and similar materials must be subjected to a vertical burn test in their end use configuration, as specified by ASME A17.1/CSA B44. This test is based on applicable portions of FAA Regulation 25.853, in addition to the flame spread and smoke development test NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Materials.* Such material, located on elevator car walls, can be easy to ignite inadvertently. Tufted material, such as carpeting, may accumulate dust, which could increase the possibility of ignition and flame spread.

Floor covering, underlayment, and adhesive are required to have a critical radiant flux of not less than 0.45 W/cm^2, as measured by NFPA 253, *Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source.* The level of critical radiant flux acceptable for floor systems in elevator cars is based on the assumption that occupants of an elevator may not be able to escape rapidly. The flux level equals the requirements for health care facilities.

Handrails, operating devices, ventilating devices, signal fixtures, audio and visual communications devices, and their housings are not required to meet any of these criteria because they are deemed to contribute little to fire load in relation to overall elevator car assembly.

Accessibility Considerations. Two national standards address accessibility requirements for elevators: (1) ADAAG, *Americans with Disabilities Act Accessibility Guidelines,*[9] and (2) ICC/ANSI A117.1, *American National Standard for Accessibility.*[10] Both standards require all passenger elevators to be made accessible to the disabled. ADAAG will most likely be replaced with ADA/ABAAG, *Americans with Disabilities Act/Architectural Barriers Act Accessibility Guidelines,*[11] over the next few years. Planned and practiced procedures are needed to evacuate the disabled in a fire. Additional information on accessibility requirements for elevators can be found in *ADA and Building Transportation.*[12] In Canada, accessibility requirements can be found in the NBCC and ASME A17.1/CSA B44 Appendix E.[3]

Emergency Lighting, Alarm, and Communications. ASME A17.1/CSA B44 requires emergency lighting on all elevators. The power source must originate on the elevator to ensure that passengers are not thrust into total darkness if building power fails. The building emergency power source is not a recognized alternative to this requirement, because this source generally would not respond to a branch circuit failure and usually is activated only on loss of the building power supply. Moreover, it would rely on the elevator's traveling cables to supply lighting power, which would be useless if the lighting problem were in the traveling cables.

Major changes have been made recently in ASME A17.1/CSA B44 regarding emergency alarms and communications. The code requires a means for all passengers, both able-bodied and disabled, to communicate in an emergency. Requirements were prepared to address the following reported deficiencies with the prior code requirements:

1. Reports of passengers being trapped overnight or on weekends and holidays
2. Alarm bells being ignored
3. Alarm bells not working
4. No one accepting responsibility or accountability for providing assistance
5. Deficiencies with new technology being utilized

The ASME A17.1/CSA B44 code requires the call be directed 24/7 to authorized personnel (trained) who are responsible for taking appropriate action. The location and elevator number are also required to be automatically transmitted at the time of the call.

In addition to these requirements, the model building codes require all elevators in high-rise buildings to have a fire department communication system from the elevator lobby, car, and machine rooms to the building's central control station.

Electrical Requirements. ASME A17.1/CSA B44 requires electrical wiring for elevators, escalators, moving walks, and dumbwaiters to conform to NFPA 70, *National Electrical Code®,* or in Canada CSA C22.1, *Canadian Electrical Code.* Electrical equipment must be certified and labeled as complying with CSA B44.1/ASME A17.5.[13]

Elevators in Fire Emergencies

High-rise buildings present new and different problems to fire suppression forces, including elevator use during emergencies. Elevators are unsafe in a fire for several reasons:

1. Persons may push a corridor button and wait for an elevator that may never respond, losing valuable escape time.
2. Elevators do not prioritize car and corridor calls, and one of the calls may be at the fire floor.

3. Elevators cannot start until the car and hoistway doors close, and panic could lead to elevator overcrowding and door blockage, which would thus prevent closing.
4. Power can fail at any time during a fire, thus leading to entrapment.

The elevator can be delivered to the fire floor when the following occurs:

1. An elevator passenger presses the car button for the fire floor
2. One or both of the corridor call buttons is pushed on the fire floor
3. Heat melts or deforms the corridor push button or its wiring at the fire floor
4. The elevator functions normally at the fire floor, as in high or low call reversal

ASME A17.1/CSA B44 recognizes all these unsafe conditions and mandates Fire Fighters' Emergency Operation on all new elevators. *NFPA 72* contains requirements for the automatic fire alarm system and initiating devices that provide the signal to the elevator control system for initiation of Phase I operation. The provision that allows fire-fighting personnel to operate the elevator from within the car, or emergency in-car operation, is commonly referred to as Phase II.

Phase I Operations. Phase I is the automatic or manual return, or recall, of elevators to a designated level or alternate level. Phase I also ensures that an elevator is not available to the general public during a fire. If the fire is in the designated level elevator lobby, the elevator will be recalled to an alternate level.

Designated level is defined as the main floor or other floor that best serves the needs of emergency personnel for fire-fighting or rescue purposes. Emergency personnel can use a three-position—on, off, reset—key-operated switch in the designated-level lobby to control each group of elevators. Another two-position—on, off—key-operated switch may be provided in the building's central control station. In the on position, the switch instructs all controlled elevators to return nonstop to the recall floor. All registered calls will be canceled. An ascending elevator will stop and reverse direction, without opening its doors.

Hoistway doors on the recall floor should remain open. On arrival, fire fighters have little time to learn whether the elevators are present. Open hoistway doors will reveal those elevators that have been recalled, as well as those that need to be located to ensure that no passengers are trapped. To help emergency personnel locate errant elevators, hall position indicators are required to remain operative during emergencies.

The open hoistway door at the designated level will admit air to the hoistway. If the fire is on a floor below the neutral pressure plane, the additional air will reduce the amount of smoke that can enter the hoistway from the fire floor, a beneficial side effect. If the fire is above the neutral pressure plane, flow of air from the hoistway to the floor will increase, which is also beneficial.

Visual and audible signals alert passengers in an automatically operated elevator to an emergency and can help minimize any apprehension that the passengers have as the elevator returns to the recall floor. In an attendant-operated elevator, this signal alerts the attendant to the emergency so that he or she can return the car immediately to the recall floor.

Elevator recall systems combine a key-operated switch with an automatic fire alarm system, using smoke detectors at each floor lobby. Elevator recall by the smoke detector is the same as placing the key switch in the on position. The only difference is that the smoke detector at the designated level will recall the elevator to an alternative level. If the automatic recall sent the elevator to the alternative level, the key switch will override the designated level smoke detector and recall the elevator to the designated level. The key switch will not recall an elevator to the alternative level.

To advise the public that elevators may not be available during a fire, a pictograph should be posted above all elevator hall call buttons.[1] Some jurisdictions may require different wording and pictographs, but the message is similar.

Phase II Operations. Phase II fire fighters' operation benefits fire fighters who must have the elevators for their own use. It is standard operating procedure in high-rise structures for fire fighters to use elevators not only to carry equipment for fire-fighting or evacuation purposes, but also to deliver fire personnel to nonfire floors.

The current ASME A17.1/CSA B44 calls for Phase II operation on all new elevators. The rule considers the need for fire fighters to evacuate disabled persons during an emergency. This code has also standardized operation procedures, regardless of the elevator manufacturer.

The switch keys required for Phase I and Phase II operation must be the same to ensure a speedy response to an emergency. Operating procedures must be incorporated with, or adjacent to, the Phase I and Phase II key-operated switches to provide emergency personnel quick access to instructions during an emergency. Fire fighters should also be aware that when the visual signal required by ASME A17.1/CSA B44 is flashing, it signals an impending problem and continued use of the elevator is not advised.

ASME A17.1/CSA B44 does not require standby power for elevators. This requirement is found normally in the building code. However, the safety code does require that elevator operation be the same when standby power is supplied as it is when normal power is supplied. ASME A17.1/CSA B44 does require that a manual selection switch be provided for fire fighters to select the car(s) to which standby power is to be directed.

Use of Elevators in a Fire. As a result of the September 11, 2001, attacks on the World Trade Center, code provisions for emergency egress from tall buildings are being reexamined. There is renewed interest in the use of elevators for both occupant egress and fire fighter access. Therefore a Workshop on the Use of Elevators in Fires and Other Emergencies was held in Atlanta, Georgia, March 2–4, 2004. This workshop was co-sponsored by American Society of Mechanical Engineers (ASME International), National Institute of Standards and Technology (NIST), International Code Council (ICC), National Fire

Protection Association (NFPA), U.S. Access Board, and the International Association of Fire Fighters (IAFF).

The workshop focused on the two following general topics:

1. Use of elevators for egress
2. Use of elevators by fire fighters

The workshop consisted of plenary sessions during which selected papers were presented, as well as Breakout Sessions for attendees to brainstorm various ideas and develop recommendations. The recommendations have been forward to numerous code and standards writing organizations.

The ASME A17 committee has also organized two task groups with participation from the groups mentioned above to evaluate and prepare code requirements, if appropriate. The task groups are currently developing hazard analyses for their assigned topics. Once the hazard analyses are completed and risks identified, code proposals will be developed and submitted to the applicable codes and standards-writing organizations.

Evacuation from a Stalled Elevator. ASME A17.1/CSA B44 requires a written elevator evacuation plan. Trained elevator personnel should perform any evacuation of passengers from a stalled elevator car. Their expertise ensures that evacuation is carried out in a manner that is safe for both the passengers and the rescue party. However, waiting for trained elevator personnel may be impossible in a life-threatening emergency. Under such conditions, passenger evacuation must be performed by carefully selected and trained personnel. Planned and practiced procedures are needed to ensure the safety of rescued passengers and members of the rescue party. Any rescue party should be cautioned never to try to move an elevator from the machine room. Only trained elevator personnel should attempt this. ASME A17.4, *Guide for Emergency Personnel,*[14] details procedures to follow in performing a safe evacuation.

DUMBWAITERS

A *dumbwaiter* is a hoisting and lowering mechanism, used exclusively for carrying materials, with a limited size car that moves in guides in a substantially vertical direction. Dumbwaiters must conform to requirements of ASME A17.1/CSA B44. A dumbwaiter is actually a small elevator used for a variety of purposes, such as mail distribution in office buildings; distribution of medication, food, and supplies in hospitals; and the moving of books from floor to floor in a library. A dumbwaiter can be loaded and unloaded manually or automatically at the floor or at a counter. Dumbwaiter car size is restricted to discourage riding. When dumbwaiters penetrate fire-resistant floors, their hoistway construction is critical. Requirements for a dumbwaiter hoistway are the same as those for an elevator. The section on elevator hoistway construction earlier in this chapter details fire-resistant hoistway enclosures and entrances.

ESCALATORS

The escalator is another type of vertical people mover. An *escalator* may be defined as a power-driven, inclined, continuous stairway used for raising or lowering passengers. In the early days, escalators were found principally in department stores and in bus and airline terminals. Today, they are common in office buildings, hospitals, banks, sports arenas, and other locations where many people must be moved quickly from one floor to another.

Fire Protection of Escalators

NFPA *101* requires that escalator floor openings be enclosed or protected like other vertical openings. In completely sprinklered buildings, escalators need not be enclosed if they are protected by alternative means.

The sprinkler draft curtain method is detailed in NFPA 13 and consists of surrounding the escalator opening with an 18-in. (457-mm) deep draft stop located on the underside of the floor to which the escalator ascends. A row of automatic sprinklers located outside the draft stop surrounds the escalator well. Figure 10.3.5 shows a typical installation. Two methods recognized in previous editions of NFPA *101* and found in existing buildings are the sprinkler vent method and the spray nozzle method.

Sprinkler Vent Method. An automatic fire or smoke detection system, an automatic exhaust system, and an automatic water curtain are combined in the sprinkler vent method. When a detector senses a fire, the automatic damper opens, thereby venting smoke and gases. Replacement air is drawn through the outdoor air intake above the escalator opening. To control smoke, an exhaust rate of about 60 air changes per hour is required. The sprinkler curtain provides a thermal barrier. The system needs to be carefully designed so that both sprinklers and vents are effective. For more information, see Section 18, Chapter 4, "Venting Practices." Figure 10.3.6 shows a typical installation.

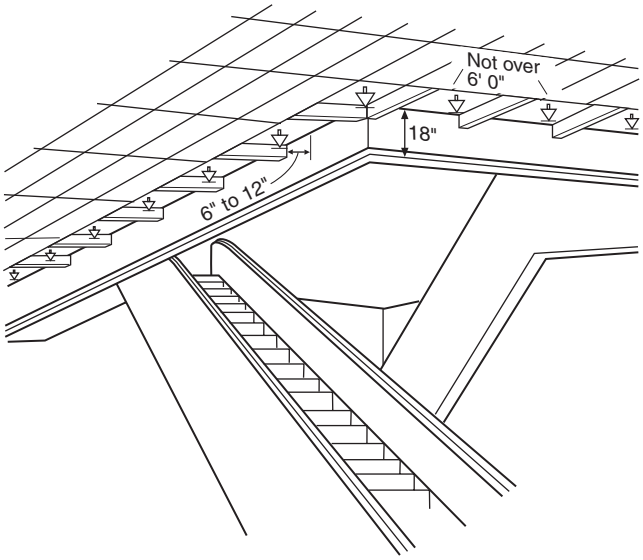

FIGURE 10.3.5 Sprinklers Around an Escalator

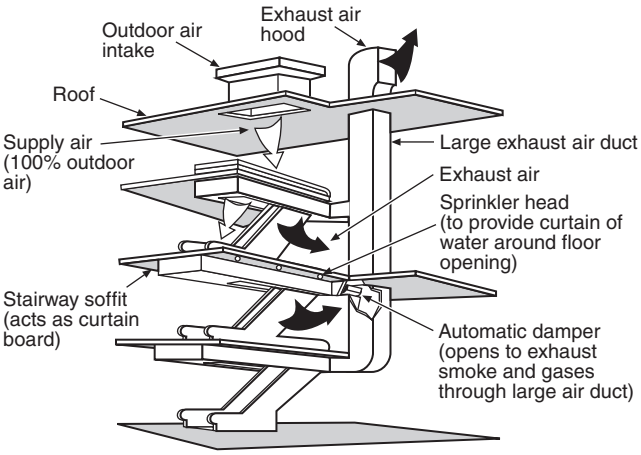

FIGURE 10.3.6 Sprinkler Vent Method Installation

Spray Nozzle Method. The spray nozzle method combines an automatic fire or smoke detection system and a system of high-velocity water spray nozzles. There must be enough spray nozzles with discharge angles such that the escalator opening between the top of the wellway housing and the treadway will be completely filled with a dense water spray when the system operates.

Escalator Enclosures

The two methods of enclosing the escalator opening used in both new and existing buildings are the rolling shutter method and the partial enclosure method.

Rolling Shutter Method. In the rolling shutter method, escalators above the street floor may be protected by automatic self-closing rolling shutters that completely enclose the top of the escalator wellway. To avoid injury, the escalator must stop automatically before the shutter begins to close. The shutter should close slowly and have a pressure-sensitive leading edge that will stop the shutter on contact. Figure 10.3.7 shows a typical rolling shutter escalator installation.

Rolling steel shutters are not recommended at the tops of escalators below street floors, even though the stairways are not required exits under the provisions of NFPA *101*. In an emergency, persons seeking egress from basements served by escalators could be trapped by a closed rolling shutter at street level, even though approved means of egress are available to them.

Partial Enclosure Method. Two fire-rated enclosures, one for the down escalator and one for the up escalator, can prevent the spread of smoke and fire. Automatic fire doors release when fire is detected. The door(s) must signal the escalator when they are not in the full open position and the escalator must then stop automatically. The enclosure should have a fire-resistant rating equal to that of the floor/ceiling assemblies, and there should be no unprotected escalator penetration of more than two

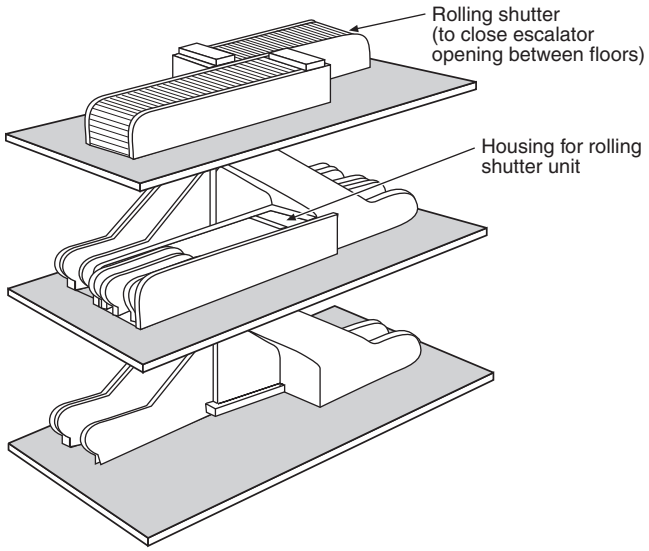

FIGURE 10.3.7 Rolling Shutter Escalator Installation

floors. Figure 10.3.8 shows a typical partial enclosure escalator installation.

Escalators in Fire Emergencies

In new buildings, escalators cannot be used as part of the means of egress. Modern escalator design requires the removal of steps for normal maintenance, thus rendering the escalator unusable. A stopped escalator also presents a tripping hazard, due to the nonuniform riser height of the first and last few steps. In some existing buildings, escalators are part of the means of egress. These escalators should be arranged to operate only in the direction of egress, or they should be stopped during a fire. Where the evacuation plan calls for escalator use, efficient crowd control is required to avoid serious crowding and potential panic. NFPA *101* requires the openings for existing escalators used as required exits to be enclosed in the same manner as exit stairs.

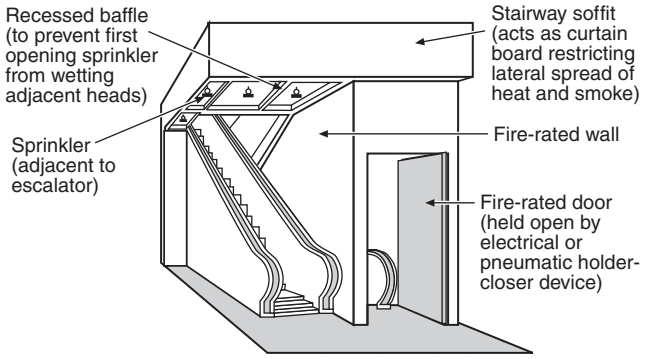

FIGURE 10.3.8 Partial Enclosure Escalator Installation

Another important factor in escalator fire prevention is keeping truss and machine areas free from oil, grease, and dust. A periodic cleaning schedule should be implemented.

MOVING WALKS

A *moving walk* is a moving device on which passengers stand or walk. Its passenger-carrying surface remains parallel to its direction of motion and is uninterrupted. Moving walks may be installed at an incline between two floors. The same fire prevention features described for escalators apply to moving walks. Some moving walks use a combustible belt, essentially the same as a large conveyor belt. This belt has the potential to spread a fire by itself. All moving walks can carry burning items along their lengths.

TESTS AND INSPECTIONS

At minimum, existing elevators and escalators should be required to conform to the requirements of ASME A17.3, *Safety Code for Existing Elevators and Escalators.*[15] NFPA *101* requires existing equipment to conform to this code. Existing installations that do not meet this code must be upgraded. When an existing installation is upgraded, at a minimum it must comply with ASME A17.1/CSA B44, Section 8.7. Existing installations required to meet more stringent requirements must continue to meet those requirements.

Elevators, dumbwaiters, escalators, moving walks, and other passenger conveyance equipment that are required to conform to the requirements of ASME A17.1/CSA B44 must be tested and inspected periodically. ASME A17.2, *Guide for Inspection of Elevators, Escalators, and Moving Walks*[16] should be used as a guide for these inspections. The quality of inspections depends upon the inspector's competence. ASME QEI-1, *Standard for the Qualifications of Elevator Inspectors,*[17] establishes uniform criteria for this purpose and serves as a standard for the expertise necessary to perform inspections.

SUMMARY

This chapter is not intended to be a complete, authoritative explanation of building transportations systems, but rather an overview of the fire protection issues normally associated with building transportation. Additional information on building transportation equipment can be found in the ASME A17.1/CSA B44 *Handbook on Safety Code for Elevators and Escalators.* Over the next few years, the technology and state of the art will advance rapidly. Machine room-less elevator equipment will become common for low- and mid-rise elevator application. New material will replace the steel hoisting ropes on electric elevators, and the control systems will become more advanced, using smart logic to anticipate user demands. The ASME A17.1/CSA B44 elevator code is already being revised to address the safe application of new technology.

Chapter 4

Air-Conditioning and Ventilating Systems

William A. Webb

Chapter Contents

System Types and Operation
Location of Equipment
Fresh Air Intakes
Air Cooling and Heating Equipment
Air Filters and Cleaners
Air Distribution
Restricting Spread of Smoke and Fire
Fans and Controls
Unit Air Conditioners
Maintenance
Energy Conservation

Key Terms

air-conditioning or comfort-cooling equipment, air distribution system, air intake, duct, fire confinement, fire damper, HVAC, plenum, smoke control, smoke damper

The term *air conditioning* has been defined by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) as "the process of treating air to simultaneously control its temperature, humidity, cleanliness, and distribution to meet the comfort requirements of the occupants of the conditioned space." Air-conditioning and ventilating systems, except for self-contained units, invariably involve the use of ducts for air distribution. The ducts, in turn, present the possibility of spreading fire, fire gases, and smoke throughout the building or area served. This and other potential hazards of air conditioning and ventilating systems are the subjects of this chapter.

Installation and protection of air heating systems are discussed in Section 10, Chapter 2, "Heating Systems and Appliances." Fire confinement, smoke movement, and venting practices are addressed in Section 18, Chapter 1, "Confinement of Fire in Buildings"; Section 18, Chapter 3, "Smoke Movement in Buildings"; and Section 18, Chapter 4, "Venting Practices."

Details on safeguarding against these hazards are presented in NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems.* See also the *ASHRAE Handbook 2004 Systems and Equipment* from the American Society of Heating, Refrigeration, and Air Conditioning Engineers, Inc.

SYSTEM TYPES AND OPERATION

The several types of air-conditioning systems include (1) systems in which air is filtered or washed, cooled and dehumidified in summer, and heated and humidified in winter; (2) systems in which air is filtered, cooled, and dehumidified; and (3) systems in which air is filtered, heated, and humidified. Figure 10.4.1 depicts a typical arrangement of the various components of a central air-conditioning system. A ventilating system simply supplies or removes air by natural or mechanical means to or from a space. The air may or may not be conditioned.

Referring to the typical system depicted in Figure 10.4.1, a fresh air intake duct connects directly to the system's return duct. From this point, the mixture of fresh and recirculated air passes through the air-conditioning equipment. The air is subjected to several operations in this equipment, including filtration or cleaning, heating or cooling, and humidification. The conditioned air is then circulated throughout the area served via the duct system (Figure 10.4.2). Those systems that do not recirculate any air take all of their makeup air directly from the outside. A building may contain more than one system, not necessarily of the same type.

LOCATION OF EQUIPMENT

Fans, heaters, filters, and associated equipment that make up a central system air-conditioning unit are preferably located in a room separated from the rest of the building area by walls, floor, and

William A. Webb, P.E., is a project manager at Schirmer Corporation in Deerfield, Illinois. He is a former chairman of the NFPA Air-Conditioning Committee and a current member of the NFPA Committees on Fire Tests and Building Systems.

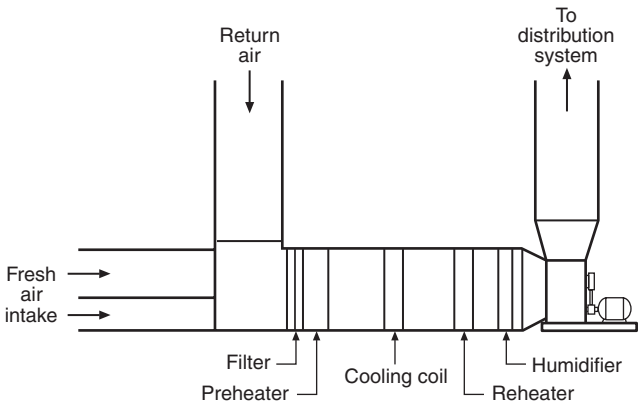

FIGURE 10.4.1 Typical Arrangement of Component Parts of a Central Air-Conditioning System

floor-ceiling assembly providing a minimum 1-hour fire resistance rating. This arrangement prevents a fire involving the equipment from immediately spreading to adjacent areas of the building. Such an arrangement also prevents access to the equipment by unauthorized persons. Ideally, service rooms housing air-conditioning equipment are protected by automatic sprinklers. At minimum, smoke detectors should be provided and arranged to initiate an alarm and shut down the air-conditioning system. No combustible storage should be allowed in the equipment room.

FRESH AIR INTAKES

The location selected for the fresh air intakes of a system is critical because fire, fire gases, or smoke originating outside the building can easily be drawn in through these intakes and spread throughout the building. Where such a hazard may exist, protection can be provided by the installation at the intakes of fire dampers or smoke dampers that are controlled by fire and smoke detectors.

When considering the location of exterior fresh air intakes, thought must be given to the possibility of sparks or other products of combustion from an exposed fire chimney or incinerator stack being drawn into the system. Consideration should not be limited to adjacent buildings or combustible storage. The possibility of fire from a different section of the same building or an adjoining building exposing the intakes is a factor that must also be considered. Since smoke usually rises, the lower the intakes are installed, the less the possibility of drawing in smoke.

All air intakes must be provided with screens of corrosion-resistant material to prevent material from entering the system. Mesh size is limited to ¼ to ½ in. (6 to 13 mm) for residential occupancies and ½ to 1 in. (13 to 25 mm) for other occupancies. Proper maintenance includes periodic removal of any accumulated rubbish or other waste from the immediate vicinity of the intakes. Some fresh air intakes are fitted with a filter that is subject to the same hazards mentioned later in this chapter, under "Air Filters and Cleaners." These filters should be protected and maintained accordingly.

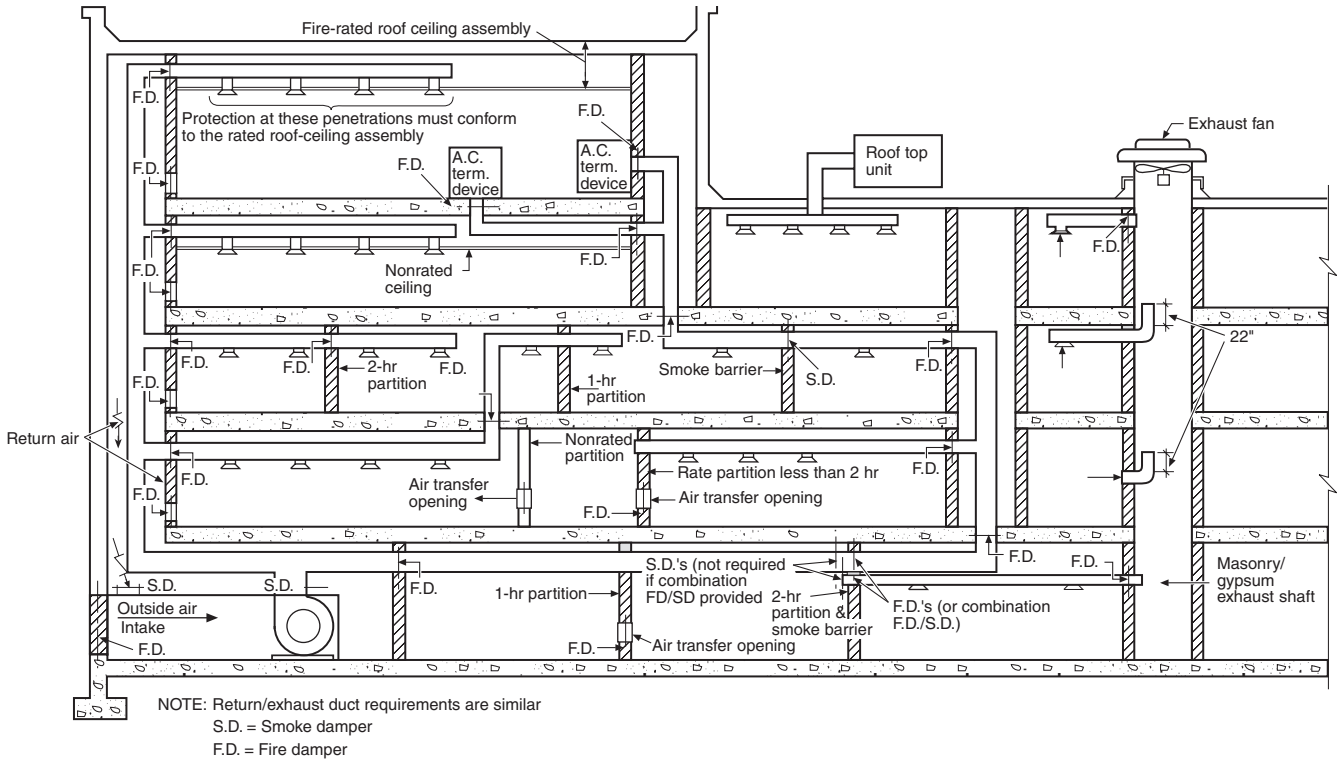

FIGURE 10.4.2 Typical Building Duct Installation Illustrating Required Protection of Walls, Ceilings, Floors, and Shafts

AIR COOLING AND HEATING EQUIPMENT

Air cooling equipment presents two basic classes of hazards: (1) those of the electrical equipment and (2) those of the particular refrigerant used. It is important that the cooling equipment be properly installed and maintained. Installation of all electrical equipment should follow both the manufacturer's recommendations and NFPA 70, *National Electrical Code®*.

One of the problems associated with refrigeration units is the explosion hazard due to overpressurization of the refrigerant. Proper safety controls can mitigate this problem.

As a result of the Montreal Protocol and the ban on some ozone-depleting refrigerants, the industry is actively seeking to develop acceptable substitutes.

At present, an array of candidate refrigerants are being used by manufacturers. The properties of candidate substitute refrigerants are being thoroughly tested. However, some appear to have flammability, explosive, and toxicity characteristics that have not been adequately addressed. In addition, there are requirements for maintenance personnel to capture and reprocess ozone-depleting refrigerants. Venting to the atmosphere is no longer permissible. Properties of refrigerants can be found in the ASHRAE *Safety Code for Mechanical Refrigeration.*[1]

AIR FILTERS AND CLEANERS

The types of air filters and cleaners used in air-conditioning and ventilating systems fall into three general categories: (1) fibrous media unit filters, (2) renewable media filters, and (3) electronic air cleaners. The first two are true filters; the last is a static precipitator. Air filters and cleaners pose a potential hazard due to their function of removing entrained dust and other particulate matter from the air stream. This material builds up on the filter media or precipitator collection plates and, if ignited, may burn, potentially producing large volumes of smoke. The smoke and other combustion gases can be circulated throughout the building by the air handling system, thus posing a direct threat to life safety. Not to be overlooked is the possibility that a filter medium may be coated with a combustible adhesive or may itself be combustible.

Underwriters Laboratories Inc. (UL) lists two classes of filter media:[2]

Class 1. Filters that, when clean, do not contribute fuel when attacked by flame and emit only negligible amounts of smoke

Class 2. Filters that, when clean, burn moderately when attacked by flame, emit moderate amounts of smoke, or both

Both of these classes include renewable (washable and reusable) media and replaceable (disposable) media.

Class 1 filter media are preferred, particularly for systems serving places of assembly, such as theaters, auditoriums, and department stores. Class 1 filter media are also the obvious choice for systems serving occupancies whose contents are easily susceptible to smoke damage. However, any filter media, if not cleaned or replaced regularly, may become hazardous due to accumulation of combustible dust and so forth. Appendix B of NFPA 90A contains recommendations for cleaning filters.

Fibrous Media Unit Filters

Fibrous media unit filters are placed into the air stream and remain there until the pressure drop across the filter reaches some critical point due to the buildup of entrained material. At this point, the filter is either removed, cleaned, and reinstalled, or simply discarded and replaced with a new filter. Fibrous media unit filters are of either the viscous-impingement type or the dry-media type.

The viscous-impingement type of filter is characterized by flat or pleated panels of relatively coarse fiber mats. Porosity of the panel is high. The fibers are coated with an adhesive that traps any material entrained in the air stream. The mats are ½ to 4 in. (13 to 102 mm) thick, 1 and 2 in. (25 and 51 mm) being most common. This type of filter is most effective when air velocity ranges from 400 to 700 ft/min (122 to 213 m/min). Most of these unit filters are ready for replacement when the pressure drop reaches ½ in. of water (124 Pa). The renewable panels must be washed with steam or a hot detergent solution, then recoated with fresh adhesive.

Dry media unit filters are flat or pleated panels of relatively fine fibers, usually ½ to 2 in. (13 to 51 mm) thick. As their name implies, these filters have no adhesive coating. Porosity is not as great as for the viscous-impingement-type filter; hence, particulate removal is greater, depending on fiber size and porosity. These filters are most effective with an air velocity of 90 to 500 ft/min (27 to 152 m/min). Pressure drop may reach as much as 2 in. of water (500 Pa) before replacement is necessary. Disposable dry fibrous media unit filters, particularly of the deep-pleated design, are fast becoming the standard for large central air-conditioning systems. The dry media classification of air filters also includes membrane and high-efficiency types, which are used to ultraclean air for clean rooms and similar areas.

Renewable Media Filters

Renewable media air filters can more accurately be termed *moving curtain* air filters, since they operate in exactly such a fashion. The medium, whether viscous coated or dry, is supplied on a large roll and extends across the air stream. Either a timer, light-sensitive device, or pressure switch may be used to activate a motor drive, which feeds fresh media across the air stream and winds the dirty media onto a takeup spool. Generally, controls are provided that de-energize the drive motor when the media supply is almost exhausted, thus preventing the media from being completely wound onto the takeup spool. A signal indicates that a fresh roll is needed. Operating velocities range from 200 to 500 ft/min (70 to 152 m/min), with the dry media types requiring the lower velocities. Filter thickness varies from ½ to 2½ in. (13 to 63 mm).

Electronic Air Cleaners

Electronic air cleaners use the principle of electrostatic precipitation to remove entrained dust and particulate matter. There are several types of electronic air cleaners, but their basic operation

is similar. Entrained particles in the air stream pass through intense, nonuniform electrostatic fields and, due to electric polarization, are collected either on a filter or on charged plates. In some units, equipment is provided to preionize the particulate matter.

Special Industrial Filters and Air Cleaners

Many industrial applications of air cleaning involve more than the usual filtering and cleaning methods previously cited. Exhaust systems for flammable vapors, dusts, and other materials in suspension require equipment for recovering the suspended material.

Air cleaning to limit contamination and pollution is of interest to industry and public health authorities. Whatever the reason for specialized air cleaning and whatever the type of equipment used, the selection and protection of the equipment are of concern as the fire hazards are similar to more common types of air cleaning equipment.

One current industrial application of air filtering is in clean rooms where high-efficiency particulate air (HEPA) filters are used to filter the atmosphere. These filters must pass an operational efficiency test of 99.97 percent efficiency with 0.3 micron particles. The filters are tested and labeled by UL in accordance with UL 586, *Standard for Safety High-Efficiency, Particulate, Air Filter Units.*[3]

Protection for Air Filters and Cleaners

Fire in the filters or air cleaning equipment can release copious quantities of smoke or fire gases that can be distributed by the air handling equipment throughout the area served. Adequate protection to minimize the possibility of such an occurrence must be designed into and around the air-conditioning system.

Some method is necessary to prevent smoke and fire gases from being distributed by the main supply fan to all areas served by the system. To accomplish this, detectors (either heat or smoke, depending on the size of the system) are located in the main supply duct, downstream of the filters or air cleaner, to sense smoke or particles of combustion. The detectors are interlocked so as to shut down the entire air-conditioning system upon activation. The detectors also control the operation of smoke dampers located in the main supply and return ducts, thus isolating the entire air-conditioning section of the system.

With specific regard to viscous impingement filters, the adhesive used should have a flashpoint of not less than 325°F (163°C) via the Pensky-Martens closed tester.[4] Also, combustible adhesives should be stored in a safe location, remote from the equipment room housing the air-conditioning equipment.

Fire protection should include facilities for manual fire fighting, usually portable fire extinguishers. Fans, motors, pumps, control circuits, and so on all point to the need for extinguishers suitable for electrical (Class C) fires; however, dry chemical (Class B) extinguishers would be more suitable for use on filters, especially the viscous-impingement type, because the chemical powder would readily adhere to the coated media.

The operational voltage and amperage of electronic air cleaners is lethal; therefore, interlocks should be provided on every access door and panel so that the equipment is immediately shut down if any one of them is opened. An alarm should also be incorporated into this safety interlock circuit.

AIR DISTRIBUTION

Air is distributed in air-conditioning and ventilating systems by ducts and plenums. Ducts are to an air-conditioning or ventilating system what pipes are to a water system—a means of distribution. The space between the ceiling and floor or roof slab is often used as a means to collect and return air. In some cases a raised floor is used to distribute supply air. Both of these arrangements are plenums and are a means to reduce distribution ductwork.

In fire situations, the air distribution system may transport deadly smoke and products of combustion instead of breathable air. If proper design and installation precautions are not taken, smoke, fire gases, heat, and even flame can spread throughout the area served by the duct system. Exit corridors used as plenums, lack of smoke detection activated control equipment in the system, and lack of required fire and smoke dampers in appropriate walls, ceilings, or partitions can lead to tragic situations.

Ducts

Construction. Ducts may be fabricated of metal, masonry, or other noncombustible material. The thickness of materials used in metal ducts of various sizes and methods of bracing, reinforcing, and hanging are covered in the duct manuals of the Sheet Metal and Air Conditioning Contractors' National Association, Inc. (SMACNA).[5] SMACNA also publishes manuals on the installation of glass fiber ducts.

UL tests and lists duct materials in accordance with UL 181A, *Standard for Safety Air Ducts and Air Connectors*[6] and UL 181B, *Standard for Safety Closure Systems for Use with Flexible Air Ducts and Air Connectors.*[7] These standards set limits on such characteristics as flame spread and flame penetration. Materials are classified as follows:

Class 0. Air ducts and connectors having surface burning characteristics of zero

Class 1. Air ducts and connectors having a flame spread rating of not over 25, without evidence of continued progressive combustion, and a smoke developed rating of not over 50

Class 2. Air ducts and connectors having a flame spread rating of not over 50, without evidence of continued progressive combustion, and a smoke developed rating of not over 50 for the inside surface and not over 100 for the outside surface

In addition to the above, Class 0 and Class 1 materials must pass a 30-minute flame penetration test, and Class 2 materials must pass a 15-minute flame penetration test.

NFPA 90A gives other mandatory provisions for duct linings and coverings, duct tapes, and bands. It also places limitations on the use of flexible duct connectors that must pass through walls, partitions, floors, or ceilings intended to afford fire resistance or smoke control.

NFPA 90A has a provision that gypsumboard may be used for negative pressure or return air ducts and for shafts subject to specific conditions. Gypsumboard shafts must be constructed in accordance with the Gypsum Association *Fire-Resistance Design Manual,*[8] must be constructed airtight, and must be designed to handle structural and air pressure loadings.

Installation. By their very nature, ducts provide a means for transferring heat, fire gases, and flame, thus resulting in the spread of fire from one area to another. In addition, at some point, a duct probably will pass through a wall, partition, floor, or ceiling that is designed specifically to provide fire resistance. Literally, a hole has been poked through a fire-rated design. The duct is intended to fill the opening. If the installation has been made without proper firestopping, safeguards will not have been accomplished. Also, under severe fire exposure, the duct may eventually collapse, creating an opening in the fire barrier. Fire dampers provide a method of protecting such penetrations.

In the gauges commonly used, some sheet metal ducts, if properly hung and adequately firestopped, may protect an opening in a building construction assembly for up to 1 hour. Therefore, ducts passing through fire barriers having a rating of up to 1 hour of fire resistance may present no extraordinary hazard. If the wall, partition, ceiling, or floor is required to have a fire-resistance rating of more than 1 hour, a fire damper is required to protect the opening. Where it is necessary for a duct to pierce a fire barrier, an automatic closing fire damper or fire door assembly should be installed at the wall opening. NFPA 90A provides comprehensive recommendations and requirements for location of fire dampers in rated assemblies.

Plenums

A plenum is a compartment or chamber to which one or more air ducts are connected and that forms part of the air distribution system. It can be used to supply air to the occupied area or it can be used to return or exhaust air from the occupied area.

A raised floor plenum is the space between the top of the finished floor and the underside of a raised floor when it is used as part of an air distribution system. It can be used to supply air to the occupied area or to return or exhaust air from the occupied area.

NFPA 90A describes limitations on the materials used to construct plenums as well as materials that may be used within a plenum. In each case the limitations are intended to restrict the combustibility of the materials in the plenum to reduce fire and smoke spread through the air distribution system.

Corridor Air Systems

Egress corridors in occupancies where people will reside should not be used as a component of the air distribution system in order to avoid a fire in one area spreading smoke through the corridor to another area in which occupants may be sleeping. There are exceptions in NFPA 90A that allow the corridor to supply air to ancillary spaces such as toilet rooms. Another exception recognizes that there may be some air movement between the corridor and adjacent spaces. The exception allows air movement where the door clearances on the egress corridor do not exceed the clearances for fire doors contained in NFPA 80, *Standard for Fire Doors and Other Opening Protectives.* Egress corridors that are part of an engineered smoke control system may be used to distribute air to achieve the smoke control objective. Detention facilities that have open grates have an exception.

RESTRICTING SPREAD OF SMOKE AND FIRE

As previously mentioned, NFPA 90A provides details of how HVAC systems are to be designed to safeguard against spreading fire, fire gases, and smoke throughout the building or area served. To achieve this objective, the HVAC system can be shut down and the fire area isolated or compartmented. Another approach is to allow fans to continue to run, using the air duct system for emergency smoke control. NFPA *101®*, *Life Safety Code®*, recognizes both approaches. NFPA 92A, *Standard for Smoke-Control Systems Utilizing Barriers and Pressure Differences;* NFPA 92B, *Standard for Smoke Management Systems in Malls, Atria, and Large Spaces;* and the ASHRAE manual *Design of Smoke Management Systems*[9] provide guidelines for smoke control system and smoke management system design.

Fire Dampers

Fire dampers and ceiling dampers are tested and listed for use in air-conditioning and ventilating ducts by UL in accordance with UL 555, *Standard for Safety Fire Dampers,*[10] and UL 555C, *Standard for Safety Ceiling Dampers.*[11] These dampers include single-blade, multiblade (Figure 10.4.3), and interlocking-blade

FIGURE 10.4.3 Typical Multi-Blade Fire Damper (Source: Courtesy of Ruskin Air and Sound Control)

FIGURE 10.4.4 Typical Static Fire Damper (Source: Courtesy of Ruskin Air and Sound Control)

(Figure 10.4.4) types, all actuated by fusible links. Most fire dampers are designed for vertical installation, although some can be installed horizontally as well.

Dampers are required to close against the maximum calculated airflow of that portion of the air duct system in which they are installed. Those that are intended to close under airflow are labeled for use in Dynamic Systems; those that are intended to close after airflow has stopped by automatically shutting down the fan or airflow in the event of a fire are labeled for use in Static Systems.

UL labels dampers for dynamic systems at 1000 ft/min (5 m/sec) intervals starting at 2000 ft/min (10 m/sec). Damper installation details are covered in manufacturers' installation instructions and in the SMACNA damper guide.[12]

Smoke Dampers

Smoke dampers (Figure 10.4.5) are required in air-conditioning or ventilating ducts that pass through required smoke barrier partitions. NFPA 90A requires smoke dampers to operate automatically on detection of smoke and must function so that smoke movement through the duct is halted. Basically, they simply interrupt airflow through the duct. NFPA 90A permits the use of fire dampers for smoke control purposes. Obviously, a combination fire and smoke damper must meet the requirements for both. Smoke dampers are tested and classified by UL in accordance with UL 555S, *Standard for Safety Smoke Dampers.*[13]

Damper Operators

Smoke dampers, combination fire and smoke dampers, and reopenable fire dampers are installed with damper operators to provide automatic operators. Operators can be electric or pneumatic. Damper operators used in smoke control applications are provided factory installed by the damper manufacturers as a means to establish that the combination of damper and operator perform properly.

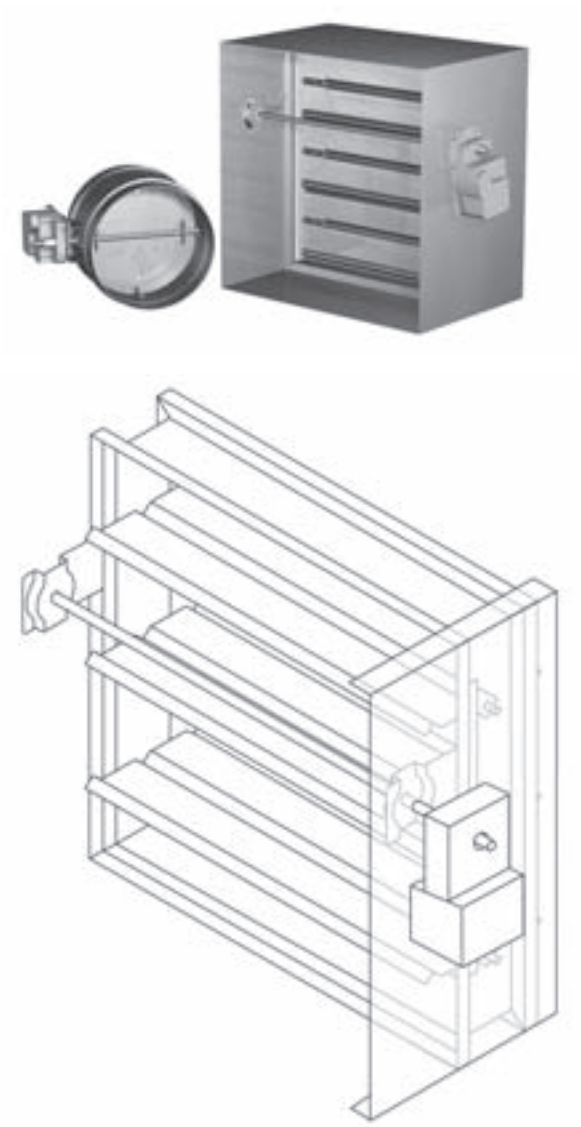

FIGURE 10.4.5 Smoke Dampers (Source: Courtesy of Greenheck Fan Corp.)

Smoke Detectors

Smoke detectors must be installed in all air-conditioning or ventilating systems of over 15,000 ft^3/min (425 m^3/min) capacity. Further, smoke detectors for use in ducts must include features in their design specifically for this purpose. Smoke detectors may shut down the air-conditioning or ventilating system, sound alarms, operate smoke control dampers, activate fire suppression equipment, or initiate active smoke control functions. Detectors with adjustable sensitivity are preferred in order to minimize false alarms due to incidental dust or other particulate matter.

These smoke detectors are located in the main supply ducts, downstream of air filters or air cleaners, and in the main return

ducts prior to exhausting from the building or joining the fresh air intake ducts. Smoke detectors at these locations are primarily intended to prevent smoke circulation throughout the entire area served by shutting down the air handling system. Also they prevent circulation of smoke from a fire in the air filters, air cleaners, belts, and motors. Due to dilution effects of air picked up from various branch return ducts, these smoke detectors cannot be expected to reliably provide "early warning" smoke detection. For this reason, additional smoke detectors may be provided, for example, in the main branch return duct from each floor or major area division. Such detectors could also be tied into a zoned fire alarm system; however, such an arrangement is not a substitute for a smoke detection system for building protection. For guidance on smoke detector location, see *NFPA 72®, National Fire Alarm Code®*.

FANS AND CONTROLS

It is attractive to use the air-conditioning or ventilating system for smoke control and smoke removal in case of fire. Tests have demonstrated the effectiveness of pressurizing emergency exit stairwells and elevator shafts to prevent smoke migration from the fire floor to other parts of a building during evacuation.[14,15]

The fan unit on an air-conditioning system should not in itself present undue hazard if properly installed and firmly supported on a rigid foundation. It should also be readily accessible for cleaning, servicing, and lubrication. Fans should be provided with excess vibration switches and wired to sound an alarm and initiate system shutdown when bearing failure is imminent.

Fan motors installed inside ducts or plenums need protective devices to cut off power before temperatures reach a point that smoke may be generated. Most fractional horsepower motors have over-temperature protective devices. Thermal overload relays are recommended for fan motors of one horsepower or larger.

Electric wiring to all components should follow NFPA 70. All electrical equipment should be listed by a qualified electrical testing laboratory. Wiring installed in ducts, plenums, and other spaces used for environmental air should meet the requirements of NFPA 262, *Standard Method of Test for Flame Travel and Smoke of Wires and Cables for Use in Air-Handling Spaces.*

All air-conditioning or ventilating systems need manual shutoffs for use in case of fire or other emergency. This shutoff should be well identified and located where it is readily accessible, such as near building exits. In systems of 2000 to 15,000 ft^3/min (57 to 425 m^3/min) capacity, it is good practice to provide automatic shutoff controls triggered by thermostatic devices in the same locations as recommended for smoke detectors. A setting of 136°F (58°C) for the thermostatic device in the return air stream and a setting of 50°F (10°C) above maximum operational temperature for the device in the supply stream are recommended.

UNIT AIR CONDITIONERS

The term *unit air conditioner* may include any factory-produced unit serving one room or area. Such units do not involve the hazard of spreading fire from floor to floor or area to area as do ducted systems. However, if improperly designed, installed, or maintained, they may involve the other hazards associated with larger systems. For example, any window-sill-type unit can overheat through failure of its thermal relay. This could lead to ignition of wire insulation or filter media, and the fire could spread to curtains or the wood sash of the window. Defective wiring could lead to the same condition. A common problem involving these units is that they are too frequently plugged into outlets on branch circuits not designed to carry the design load or on an already overloaded circuit. This practice directly violates principles of NFPA 70.

MAINTENANCE

Maintenance and cleaning are of utmost importance to safe operation of any air-conditioning or ventilating system. Filters must be changed or cleaned as frequently as necessary. Ducts, particularly on the return side of the system, must be cleaned out periodically to prevent hazardous accumulations of combustible dust and lint. Evidence of any defect of wiring or electrical equipment must be checked out immediately and corrected. Repairs on ducts or equipment casings that require welding or cutting should be protected by complete shutdown of the system and thorough cleaning of the area. If possible, the duct section to be repaired should be isolated from the rest of the system.

Proper maintenance includes periodic testing of all fire protection devices, including fire suppression equipment, smoke control and fire dampers, fire detectors and alarms, and even vibration switches on fans. A regular testing program should be established. For fire dampers, such testing should include removing fusible links, operating the damper, and lubricating parts as necessary. If such testing is outside the function of regular maintenance staff, it should be contracted to an outside agency.

ENERGY CONSERVATION

Energy conservation practices require a careful evaluation of the design and control of HVAC systems. To reduce electrical costs, fans are turned off during various portions of the day and during unoccupied hours. Without airflow, the duct fire and smoke detectors may not detect fire and thereby will not provide the protection that may be assumed as inherent in HVAC systems. The use of variable volume air systems is increasing as these systems have an overall lower energy use than most other systems. The variation in duct airflow in such systems can create a problem with the sensitivity of the duct-mounted detectors and cause false readings and alarms. Fan cycling and variable volume systems can also cause variations in air pressure relationships of the occupied spaces. An area may have a positive pressure relationship to another area when the fans are operating in one mode, and when the fans are cycled a completely different relationship can occur, which can affect the performance of detection and control systems and calls for careful design evaluation.

SUMMARY

The ducts used in air-conditioning and ventilating systems present the possibility of spreading fire, fire gases, and smoke

throughout a building. For that reason, the location of equipment and the fresh air intakes, the types of air filters and cleaners, the system of ducts and plenums, and the use of fire and smoke dampers are crucial in limiting and containing a fire. Just as critical are the choices of type of equipment, proper maintenance of that equipment, and energy conservation measures.

Chapter 5

Ventilation of Commercial Cooking Operations

David P. Demers

Chapter Contents

Ventilation
Components
Fire Concerns with System Operation Design
Fire Concerns with System Component Design
Fire Concerns with System Maintenance

Key Terms

cooking appliance (floor-mounted restaurant type), duct, duct system, exhaust system, grease, grease duct, grease filter, grease removal devices, hood, makeup air, replacement air, restaurant, ventilation (mechanical), ventilation (natural)

Fires in commercial cooking establishments are a serious concern. Many commercial cooking operations are part of assembly, educational, and health care occupancies where a fire could create a significant exposure to life safety. In the case of an institutional occupancy, the inability to provide meals on a continuing basis could result in a major relocation of facility occupants.

Fires in commercial cooking equipment, such as fires in cooking equipment in U.S. homes, have a relatively high frequency but a relatively low average severity. For example, there were nearly 5000 cooking equipment fires reported to U.S. local fire departments per year in 1994–2005 in eating and drinking establishments, with associated losses of $42 million per year. This represented 44 percent of reported fires but only 23 percent of associated direct property damage. In every property type, cooking equipment fires account for a much larger share of fires and injuries than of direct losses or deaths.

The reasons for the relatively high frequency are straightforward. An ignition source is usually available from the cooking operation itself, the fuel load can be significant due to the buildup of grease and cooking residue, the air supply is designed to be effective, and mitigation efforts require significant inspection and maintenance.

The reasons for low average severity are also straightforward. Cooking equipment fires typically occur while an awake, unimpaired adult is nearby, if not continuously focused on the cooking activity. Such fires usually begin with a small initial fuel source, in a location where quick response is not blocked.

One of the factors in severe fires is early spread into the ventilation equipment. Ventilation of commercial cooking operations is the subject of this chapter.

Ventilation and fire control for commercial cooking operations must be considered as a major building "system" with several components. Each of those components must be properly addressed for the fire safety system to be effective. The components include the following:

- Hood(s)
- Grease removal devices
- Exhaust duct system
- Air movement system
- Auxiliary equipment
- Fire-extinguishing equipment
- Operating procedures
- Inspection, cleaning, and maintenance procedures
- Training of facility management and employees

There are unique requirements for recirculating systems downdraft and solid fuel cooking operations. Large-scale cooking operations for the food service and supply industry also have special considerations.

David P. Demers, P.E., is president of Demers Associates, Inc., a fire protection engineering consulting firm based in Lunenburg, Massachusetts, and the deputy chief of the Lunenburg Fire Department. He is the former chair and a current member of NFPA's Technical Committee on Venting Systems for Cooking Appliances.

This chapter discusses those aspects of ventilation and fire protection systems in commercial food establishments that can have an effect on a fire relative to its initiation, spread, containment, and suppression. It also provides definitions, an overview of typical ventilation systems and their components, and a breakdown of the factors that can cause problems due to poor design or maintenance.

Information relating to this subject can be found in Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems"; and Section 18, Chapter 4, "Venting Practices."

The referenced NFPA standards apply to both commercial cooking and industrial cooking establishments such as bakeries.

VENTILATION

Ventilation is the replacement of stale, noxious, or contaminated air with clean—or at least cleaner—air. The moving of the air may replace the original air with new outside air, or it may clean and recirculate the original air. The temperature of outside replacement air is usually controlled. Common ventilation processes include heating and air conditioning by forced air, exhaust systems of all types, and air distribution and transfer systems.

Natural Ventilation

Natural or gravity ventilation is accomplished without mechanical assistance and can be provided by openings to the outside, draft stacks, and pressure differentials due to height or temperature. Natural draft exhaust systems are not specifically addressed in this chapter, although brick ovens and open barbecue pits are used for commercial cooking. These systems rely almost totally on natural draft. A natural draft makeup/supply system could be merely a screened open door or window to the outside. This chapter also does not address such exterior openings, except that if the openings are closed, makeup air is not available, and the exhaust system will not work properly. If a strong wind is blowing in through the opening, the draft could also cause the exhaust system not to work. Either condition can cause grease to build up on the surfaces of the room and thus increase the potential hazard and spread of a fire.

Mechanical Ventilation

Mechanical ventilation is accomplished with fans to create the pressure differentials necessary to produce the desired flows of air. Mechanical ventilation systems are specifically addressed in this chapter.

Exhaust

Exhaust is the ventilation process that draws noxious air-entrained particulates and vapors from a cooking operation, collects them in a hood, and contains them in a duct for transport to the outside or to equipment that cleans the air before discharging it to the outside or returning it to the area of origin. In a closed area, such as a kitchen, exhaust cannot operate at the flows required without having an equal supply of makeup air available. In the context of this chapter, exhaust primarily applies to the commercial cooking exhaust systems that are designed to capture, contain, and remove from the kitchen the effluents of the cooking operations. Other exhaust systems in a commercial cooking establishment can be for removal of heat and fumes from restrooms, dishwashers, and refrigeration condensers.

Makeup Air/Replacement Air

Makeup air and *replacement air* are the terms commonly used to refer to the air that has to be brought into a space to limit pressure gradients so the exhaust process can operate as designed. This air may be brought directly into a space via ducts or indirectly via openings from adjacent areas. The quantity of makeup air must be of a sufficient flow rate to allow the exhaust system to operate within its pressure differential design parameters yet not be so great as to create a positive pressure within the cooking area. A slight negative pressure in a commercial kitchen is usually desirable to reduce cooking odor migration to other spaces.

COMPONENTS

Exhaust Systems

An exhaust system consists of the hood over the cooking appliance(s), the ductwork connecting the hood to the exhaust fan, the exhaust fan itself, and all grease filtration devices and other effluent control devices within the system (Figure 10.5.1). The concept of the exhaust system is that the system will capture all the cooking effluent within the hood, contain it there until it is removed by the duct and fan system, and transport it through the duct system to the outside. Within the system, the effluent is treated for removal of effluent contaminants (grease, gases, odors). In some newer systems (designated recirculating units) for commercial cooking, the effluent contaminants are considered removed to such a thorough degree that the final air is able to be returned to the same space as the cooking operation instead of having to be discharged outside.

Hoods

Canopy Hoods. A canopy hood is one whose lower edges overhang the outer edges of the cooking appliance by a minimum of 6 in. (152 mm) on all sides of the cooking appliance that are not closed off between the cooking surface and the lower edge of the hood. If at least the rear side of the hood is closed off to the cooking appliance by a wall or panel, it is then called a wall canopy (Figure 10.5.2). If no side of the hood is closed off to the cooking appliance, it is called an island canopy (Figure 10.5.3). Very often, island canopy hoods are double wide when installed over two rows of cooking appliances that are back to back. Canopy hoods are required to be at a minimum of 6.5 ft (2 m) above the floor to prevent most people from hitting their heads on them. Such height above the cooking surface generally requires that canopy hoods operate at high levels of exhaust.

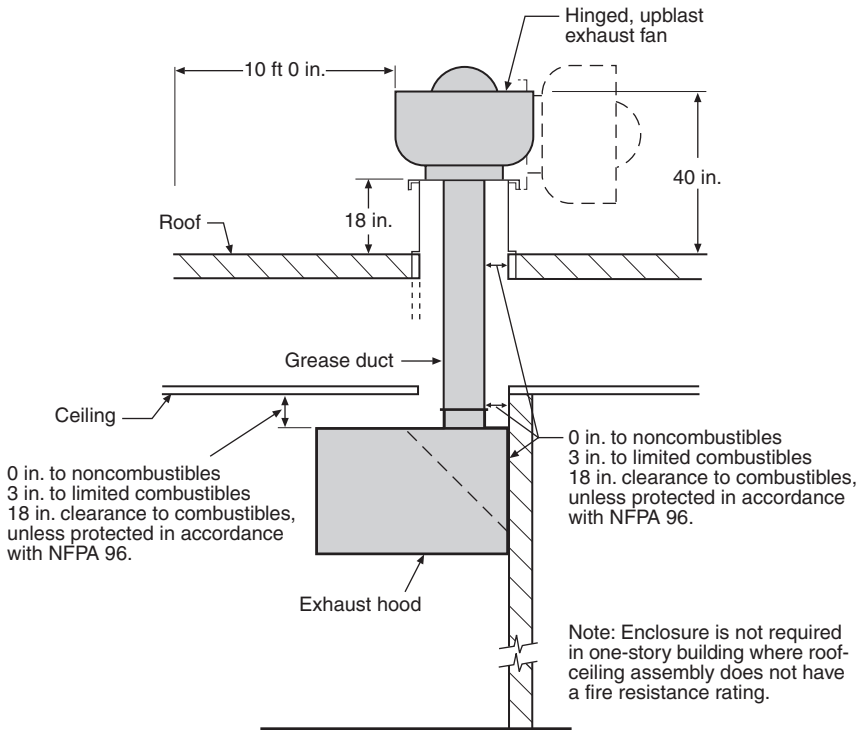

FIGURE 10.5.1 Typical Cooking Exhaust System

Noncanopy Hood. Noncanopy hoods come in many styles. They are noncanopy in that they do not meet the overhang and minimum height above the floor requirements of the canopy hoods. Noncanopy is a poor definition, since it defines what they are not, rather than what they are. They have many different names, such as backshelf, high-sidewall, eyebrow, cap, and high-velocity. In general, they are mounted much closer to the cooking surface and are usually required to have the front lower lip no more than 3 ft (0.9 m) above the cooking surface. This style is especially true of the backshelf, high-sidewall, and

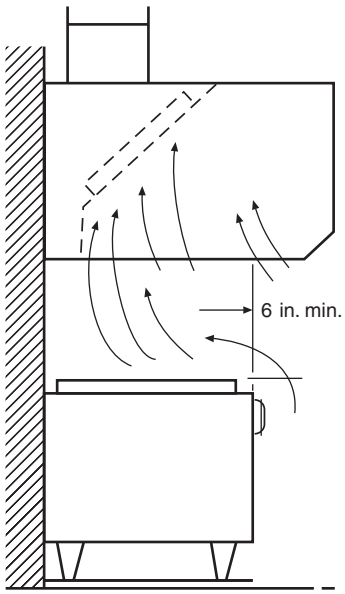

FIGURE 10.5.2 Wall Canopy Hood

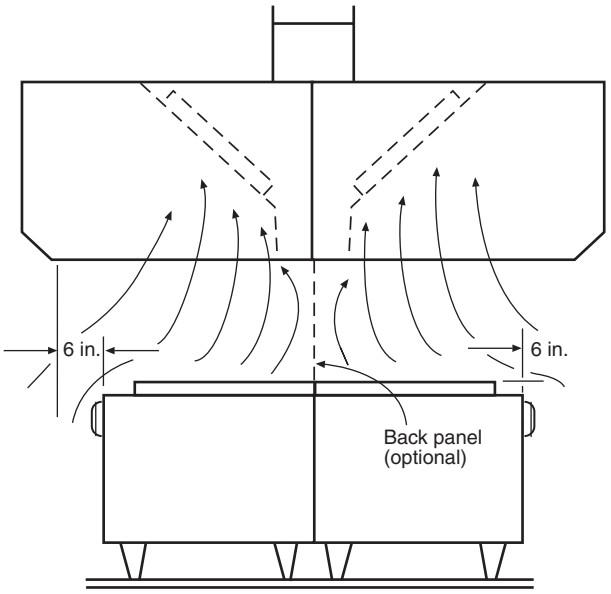

FIGURE 10.5.3 Island Canopy Hood

high-velocity hoods, which are primarily the same style hood with different names (Figure 10.5.4). Since noncanopy hoods are so low, they almost always have a setback from the front of the cooking appliance; that is, the front lower lip of the hood is behind the front edge of the cooking surface to minimize the possibility of hitting one's head when bending over the cooking appliance. If there is a conveyor chain or other feeding/retrieval device at either end of the cooking appliance, it generally is not covered by any portion of the hood, though local codes may alter this.

Two variations of a canopy hood are the cap hood and the eyebrow hood. They are generally mounted on or just above taller cooking appliances, such as multideck ovens and broilers. The cap hood looks somewhat like a baseball cap, with the main part of the cap (the hood) over the cooking appliance to gather heat, and the smaller bill part in front of the appliance to gather heat and effluent from the front when the doors are opened (Figure 10.5.5). The eyebrow hood is equivalent to the bill part of a cap hood but is just the portion that is over the front of the cooking appliance (Figure 10.5.6). Both hood styles are also used over chain broilers, grills, and dishwashers. Canopy hoods, at times, are also used in every application where noncanopy hoods are used. New styles of commercial cooking such as self-contained broilers and grills and downdraft appliances have required more performance-related requirements to address the ever present fire hazard. All of the systems will still require fire suppression.

Exhaust Ductwork

Single Exhaust Duct System. A single exhaust duct is one that serves one exhaust hood only. It will typically be of the same cross section from one end to the other and have one single fire suppression system for the entire exhaust system, including the appliances, hood, and all ductwork.

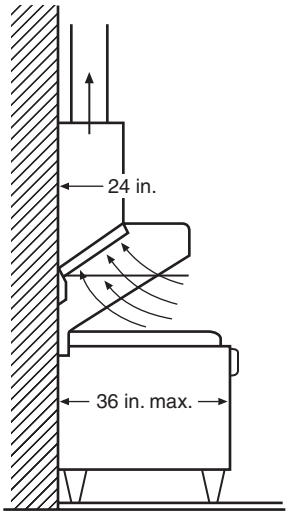

FIGURE 10.5.4 Noncanopy Backshelf Hood

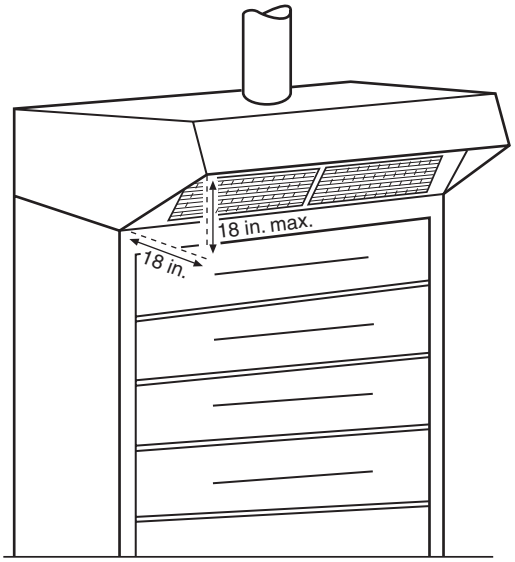

FIGURE 10.5.5 Cap Exhaust Hood

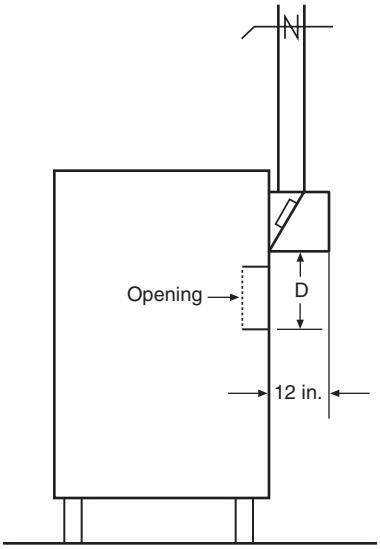

FIGURE 10.5.6 Eyebrow Exhaust Hood

Manifold Exhaust Duct System. A manifold exhaust duct system serves more than one exhaust hood. The cross section is at its smallest as it leaves each single hood and increases in cross section as it joins with another branch duct, thereby forming a common duct, and increases further in cross section as each additional branch duct enters the common duct (Figure 10.5.7). Manifold exhaust duct systems typically have separate fire suppression systems for each exhaust hood and its appliances and also for each branch duct. All the individual suppression systems will operate simultaneously for the protection of the common duct. However, there may be separate suppression systems for the branch ducts or for all or portions of the common exhaust

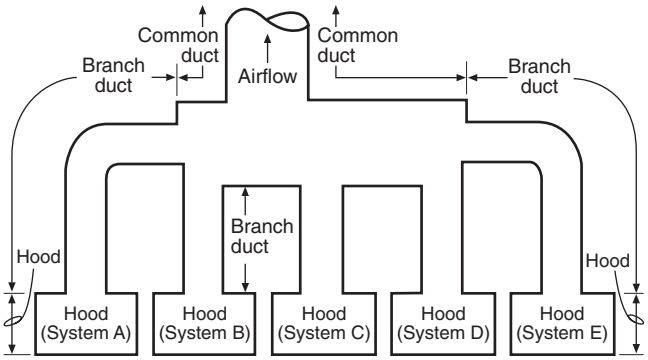

FIGURE 10.5.7 Manifold Exhaust Duct System

duct. In those cases, there are multiple ways to actuate the individual systems and provide for shutdown of the individual appliances. For more information, see NFPA 17, *Standard for Dry Chemical Extinguishing Systems;* NFPA 17A, *Standard for Wet Chemical Extinguishing Systems;* and NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations.*

Exhaust Fans

Connections of fans to ductwork are required to be liquidtight at all temperatures. It is common practice for standard ventilation systems to have flexible connections to limit vibrations and sound transmission of operating fans; however, such flexible connections are not permitted on cooking ventilation systems.

Upblast Fan. An upblast fan is one that terminates an exhaust duct system (Figure 10.5.8). It is located on the roof, sitting on a curb, with the inlet at its base and the discharge at its top pointing upward. For grease exhaust applications, it is required to be listed for the application. It is also required by NFPA 96 to be restrained and hinged to tilt back for easy and direct access to the exhaust duct for inspection and cleaning. Typically, it will operate only on single exhaust duct systems or small manifold exhaust duct systems, not operating much over 1.5 in. of water column static pressure (373 Pa).

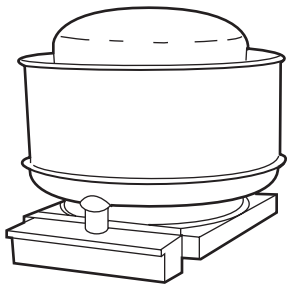

FIGURE 10.5.8 Upblast Exhaust Fan

Utility Fan. A utility fan is one that typically sits on the roof at the termination of the exhaust duct system, but it may also be found inside the building above the kitchen, with discharge ductwork leading it to the outside of the building. When installed on the roof, it sits beside the curb, with the duct coming out of the curb and leading into one side of the fan. The fan discharge is out of an opening that is perpendicular to the inlet and able to rotate the inlet so it can discharge to either side or up or down (Figure 10.5.9). The discharge is sometimes ducted to get it more than 10 ft (3.1 m) away from any fresh air inlet or put in a box to separate much of the grease from the air. It is capable of operating on both large single and manifold duct systems with high static pressure.

In-Line Fan. An in-line fan is almost always found inside the building at the same level as the kitchen but in a back room. It is typically round in shape like a large duct section, with the inlet duct connection at one end, and the outlet duct connection at the opposite end (Figure 10.5.10). The vane-axial fan blade

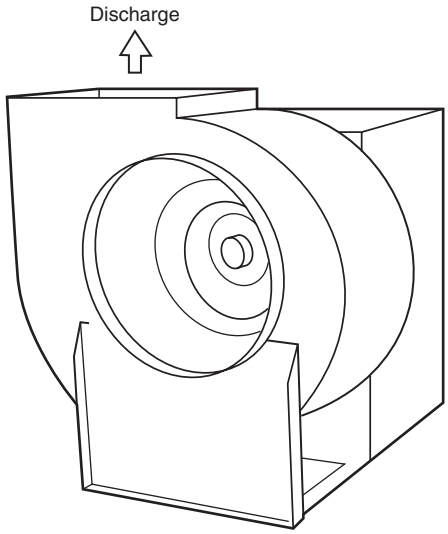

FIGURE 10.5.9 Utility Exhaust Fan

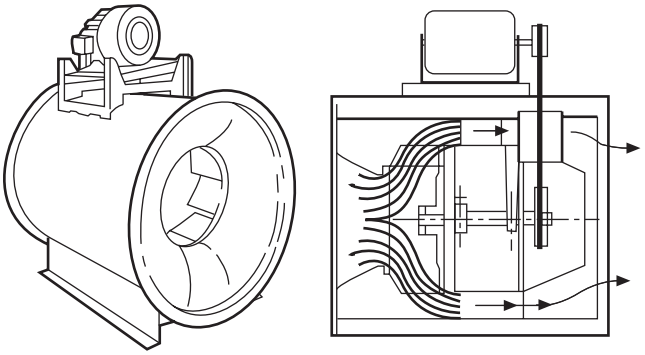

FIGURE 10.5.10 In-Line Exhaust Fan

is located in the center so the whole fan is "in line" with the ductwork, and thus its name. It must be flanged and bolted to the ductwork at each end, in order that it can be removed for service. In some rare cases, only the fan and motor section are flanged and bolted. In either case, in-line fans are more difficult to service and are typically used only where other types of fans are not practical. Flexible connectors are not allowed on this type of fan.

Makeup Air System

The makeup air system contains all the components (fans, ducts, registers, etc.) that provide for the delivery of the outside makeup air to the vicinity of the exhaust hood.

Integral Makeup Air. Integral makeup air is the method of delivering a portion of the outside makeup air directly to a separate chamber of the exhaust hood (Figure 10.5.11). Within the hood, the makeup air is introduced through registers or slots into the inside of the hood (short circuit), downward out the front lower edge of the hood (air curtain), or horizontally out the front of the hood (face discharge), or in multiple combinations of these. The makeup air may be provided without tempering of the short circuit and air curtain air flows. Hoods without tempered makeup air can be subject to performance variations, as the seasonal changes bring a change to the temperature and density of the makeup air. This method provides only a portion of the makeup air required with the rest supplied from other sources.

Nonintegral Makeup Air. Nonintegral makeup air is the method of delivering the makeup air to the kitchen space or adjoining area(s) through ducts and registers (Figure 10.5.12). Such air is always tempered in all but the mildest of climates.

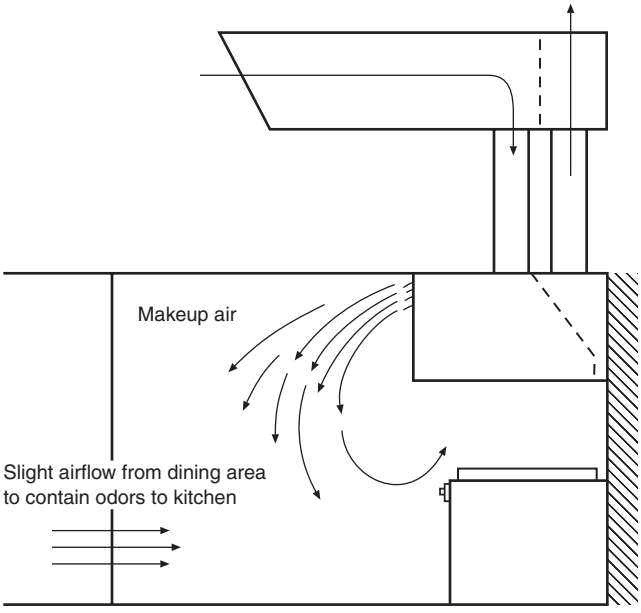

FIGURE 10.5.11 Integral Makeup Air Hood

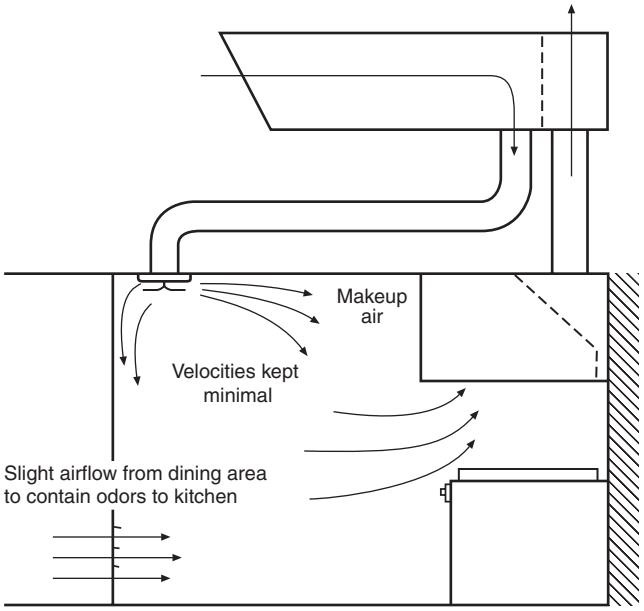

FIGURE 10.5.12 Nonintegral "Standard" Makeup Air Hood

Controls

Control circuits may be manual or automatic. Automatic control circuits are called interlock control circuits. Interlocks provide for safe cooking operation by ensuring that:

1. Cooking cannot operate unless the fire suppression system is armed
2. Cooking cannot operate unless the exhaust fan and makeup air fans are on
3. Cooking is shut down in the event of operation of the fire suppression system

Only the last of these is required by codes, but all are recommended and often put into practice.

Operating Controls/Interlocks. Operating systems use many types of controls. Among them are controls that operate cooking appliances and exhaust system components, and safety controls that are built into the cooking appliances and exhaust system components to control or shut down the components or system under emergency conditions. Many restaurants still operate with manual controls, but it is safer to have interlocked control systems. A typical operating interlock control system will not allow cooking to operate unless the exhaust is operating, and will not allow the exhaust to operate unless the makeup air is also operating. A wide variety of controls exist that may be optionally included with these, but most often the control systems are quite simple and use few of the optional controls. These extra controls may be as complicated as controls that regulate the appliance and room temperatures during high- and low-volume periods, the amount of fresh and exhaust air, and the economizer performance of the heating, ventilating, and air conditioning (HVAC) equipment. With some gas stoves and

ovens and with solid-fuel cooking there are often a number of manual controls.

Fire Controls/Interlocks. There are fire detectors to sense a fire and initiate action by the suppression system, and there is a minimum interlock consisting of a switch to shut off the fuel to the cooking appliance in the event of the suppression system operation (Figures 10.5.13). There should be additional controls to sound a local fire alarm, to sound a central alarm in a larger building, or even to notify a local fire department. There is always a manual means of operating the built-in fire suppression system (Figure 10.5.14).

FIRE CONCERNS WITH SYSTEM OPERATION DESIGN

Ventilation Flows

Exhaust. Exhaust flows must be adequate to capture and contain the effluents of the cooking process. If so, they are also adequate to capture and contain the small or short-term fire. But this does not mean they will be adequate to capture and contain the effluents of a serious and longer-term grease fire. The expansion of vapors due to the higher temperature fires will ultimately exceed the capacity of the hood if the fire burns long enough and the fire will escape from the hood.

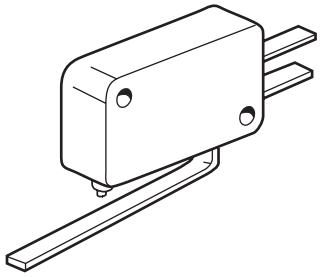

FIGURE 10.5.13 Fire System Interlock Switch

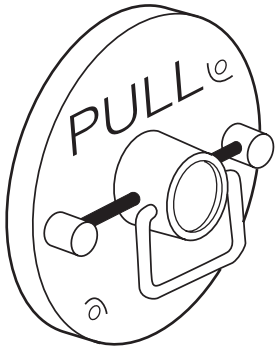

FIGURE 10.5.14 Fire System Manual Pull

Makeup/Replacement Air. The makeup/replacement air is critical to provide proper airflow.

Controls

Operating Controls. If there is no interlock between the cooking appliances, exhaust, and makeup air, or if the interlock fails, it increases the chance of noncontainment of the cooking effluent and increases the potential hazard in the event of a fire. Failed thermostats and high-limit temperature controls that can no longer shut off the cooking appliance cause fires every year in cooking appliances due to appliance overheating and autoignition of the oil or shortening in the cooking process. The same scenario occurs on manually controlled cooking equipment when pots of oil are left unattended and overheat to the point of autoignition. Where no interlock exists between the exhaust fan and cooking appliance, or if it fails, a fire can start in the hood, especially over gas-operated appliances, due to the flue gases overheating grease buildup in the hood to the point of autoignition.

Fire Interlock. The most serious fire interlock failures are the ones that fail to permit the suppression system to operate. These include grease-plugged detector line elbows that do not permit the cable to move, detector links that are too grease coated and insulated to respond in time to the fire, or detector links that are held closed with a wire from some previous maintenance operation. Another serious fire interlock failure is one that will not shut down the fuel that heats the appliance due to a failed interlock switch or a jammed mechanical gas valve. Other potential failures include defective switches or open wires in alarm circuits. These situations are the basis for the required 6-month control inspection.

FIRE CONCERNS WITH SYSTEM COMPONENT DESIGN

Exhaust Hoods

The three primary fire concerns with the exhaust hood are that it is (1) able to extract and drain the maximum amount of grease possible from the effluent to minimize any subsequent fire, (2) able to contain a fire within itself should one occur, and (3) protected from adjacent combustible surfaces so that it will not ignite them by radiant effect. In order to do so, the hood must be of adequate size and operate at adequate airflow and have a reasonably efficient filtration system, that it be of such structure to stay intact during a fire so that the fire cannot escape, and that it be installed in such a way as to provide protection between itself and adjacent combustibles so that it cannot radiate heat sufficient to ignite them.

Filters

Hoods may contain removable baffle filters, or they may have larger filtration baffles that may be removable in cassette form, or filters may be built in (Figure 10.5.15). The removable filtration devices must be removed from the hood to be cleaned. The

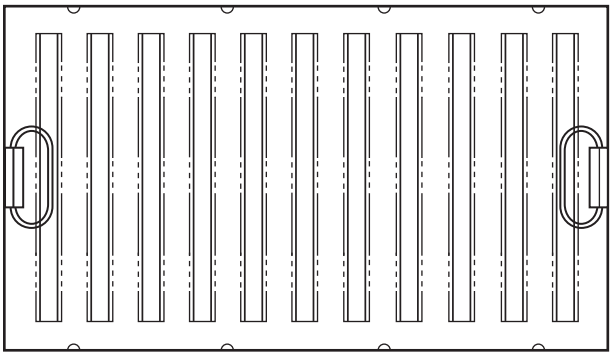

FIGURE 10.5.15 Grease Filter

built-in units are cleaned in place with a detergent and water wash system. It is very important for fire safety that all filtration devices be cleaned at least once a day. Further, while dirty filters are being cleaned, removable devices must have replacement units installed at all times when the appliances are still turned on. Operating the exhaust with filters removed will put much more grease into the hood and duct systems. It will also lower the static pressure so much that it will dramatically increase the amount of air being exhausted and unbalance the system. In the case of manifold exhaust systems, removing filters from one hood will increase the exhaust at that hood but dramatically lower it at all the other hoods connected to that manifold system. As a result, the other hoods will leak grease vapors into the space, which defeats the purpose of the hoods and increases the fire hazard potential. Filters in the hood must be tightfitting on all four sides in order to preclude any grease or fire bypassing them.

Exhaust Ducts

There are two essential requirements for exhaust ducts, relative to fire protection. The first is that the duct must be so solidly welded or assembled (listed ducts only) from one end to the other so that a fire within a duct cannot escape through the duct wall to a hidden combustible area. The second is that there must be adequate clearance or protection around the ductwork so that the radiant heat due to a fire will not be able to ignite any combustible products that may be close to the duct. This requirement prevents the duct from causing a fire to start in combustible concealed spaces of a building.

Duct integrity and construction are critical for containment of grease and any fires that may occur. All seams, joints, penetrations, and duct-to-hood collar connections are required to be liquidtight at all temperatures and have continuous external welds. Duct materials are required to be at least 0.054 in. (1.37 mm) (No. 16 MSG) carbon steel or 0.043 in. (1.09 mm) (No. 18 MSG) stainless steel. Specially listed grease ducts or assemblies can have other joining methods and construction.

Proper ductwork is constructed without dips or traps that can hold grease and are designed to be pitched to drain back to hoods or to special grease drains. The exhaust fan must be designed to drain grease to a closed external container. Discharge from the fan or the duct that terminates the system must not direct the flow toward the roof or any combustible surfaces, nor toward any operable windows or doors. These precautions serve two purposes: (1) to prevent a fire from igniting any combustible surfaces and (2) to keep a fire and any grease discharge from blocking proper ventilation or egress from building openings.

Exhaust Dampers

A fire damper sometimes is placed in a hood at the duct connection to the hood (Figure 10.5.16). Its intent is to prevent fire from getting into the ductwork. This is a controversial aspect of exhaust systems because there are advantages and disadvantages to the use of dampers.

Advantages. Fire dampers are helpful in commercial kitchen hood/duct systems because:

1. They keep fire out of existing ducts that may be substandard and would not contain the fire.
2. They keep the fire contained to the kitchen level of multistory buildings, thereby reducing the potential hazard of fire spreading to other floors and tenants.
3. They provide increased safety in the event the fire suppression system does not function.

Disadvantages. Fire dampers are problematic in commercial kitchen hood/duct systems because:

1. A properly designed and installed duct system can exhaust the fire and smoke out of the building in a safe manner if the system is designed to handle such fires, making a damper unnecessary.
2. Closing the damper will back the fire and smoke into the kitchen space, spreading the fire more quickly, and the smoke will make it much more difficult for the fire service to fight the fire.
3. A fire kept out of the duct system and in the kitchen space can spread to combustible or grease-coated ceiling and wall

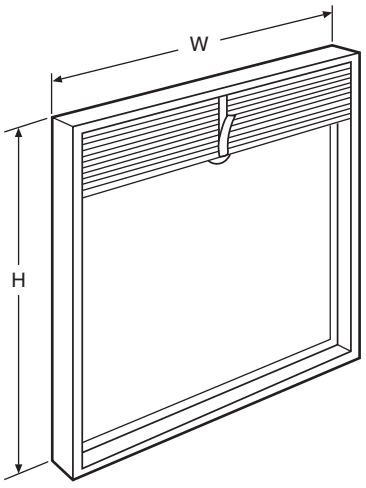

FIGURE 10.5.16 Fire Damper

surfaces, and from there to other hidden areas, increasing the hazard to other tenants and building areas.

4. The exhaust ducts may be so dirty that the damper cannot fully close so that the fire spreads to the ductwork anyway, or the fire gets into the ductwork before the damper closes, so the damper has only provided a false sense of security and makes it more difficult to access the fire in the duct.

It is clear that much of the concern with dampers has to do with the proper condition of the ductwork beyond the dampers, including its integrity and clearance to combustibles. If a hood assembly is listed, it must be installed in accordance with its listing and manufacturer's instructions.

Exhaust Fans

There are two primary concerns with exhaust fans relative to fire hazard. First, the fan must not trap grease within itself but drain it to an external covered metal container of not more than 1 gal (3.785 L) capacity. This minimizes the chance of the fan contributing fuel to any fire and places the drained grease in a sealed container of limited capacity that is not likely to catch on fire. Second, the fan must not discharge its effluent toward any combustible surface that might catch fire or toward any operable door or window or vent that might be a point of egress or fresh air for the occupants. This requirement limits a fire that may come from the discharge of a fan or the terminal section of ductwork and prevents fire spread to other combustible surfaces. Further, it allows building reentry and a path of potential egress. Fans should be mounted with hinges so that one person can easily lift the unit to gain access to the grease duct for cleaning. NFPA 96 requires fans to be hinged, but most mechanical codes do not.

Grease Extraction/Control Devices

Many commercial cooking establishments have additional grease extraction or control devices downstream of the hood in order to more completely remove the grease and odors from the effluent stream. This feature is required in many jurisdictions in order to reduce local environmental concerns and complaints. These devices may be installed in ceiling spaces or mezzanines, but most are installed on rooftops immediately before the fan. Some units have integral fans.

These units consist of various stages of filtration devices that may be metal baffles, metal mesh filters, dry bed or pleated filters, electrostatic precipitators, afterburners, or water-wash devices. All are designed to remove the remaining grease from the system. The afterburners also remove odors. Systems also can use activated carbon or some other chemical catalyst or odor control spray to control odors.

Each of these devices (except the afterburner) carries with it the possibility of igniting or providing fuel for a fire. (The afterburner has built-in safety controls and cabinetry to preclude a runaway fire in it.) Each of these units should be provided with a fire detection and suppression system that provides protection in the event of a fire. The cabinetry of the units should be of the same gauge as the ductwork to which it is attached and the access panels should match those of the ductwork, or the unit should be listed for equivalency with these requirements and applications in a grease-laden environment. (See NFPA 96 for fire safety requirements for such units.)

Grease Gutters, Cans, and Containers

Grease gutters may exist under the filter rack of a hood, around the lower perimeter of a hood, and on one or more sides of a cooking appliance. They are pitched to drain to a remote grease container. Grease cans or containers collect the grease from the gutters. They are also found as open or closed pans or containers under certain sections of cooking appliances and at the drain of grease fans. The obvious fire hazard with all of these is that they contain extra fuel in the event of a fire. For increased fire safety, the amount of grease that is contained in these at any time must be kept to a minimum. Therefore, the gutters should be pitched as much as practical to minimize the grease they can hold. Containers, cans, and pans should be kept at the minimum volume necessary to get through one major rush period, and not be expected to hold the grease for the entire day in a high-volume operation. NFPA 96 limits the container to 1 gal (3.785 L) capacity. It is also best that the container be capped on top, with only the minimum opening necessary to permit the grease to enter. Should a fire get into such a container, it most likely would smother itself rather than burn all the fuel.

Appliance Position

It is important that appliances be positioned under the hood in their designated position for three reasons. First, it ensures that the effluent generated by the appliance will be captured and contained by the hood and exhaust system and not escape into the room where it can extend the fire hazard potential. Second, in the event of a fire in the appliance, it ensures that the flames will be contained in the hood for the longest time possible, limiting the fire hazard potential. Third, it ensures that the fire suppression system nozzle will be able to apply the chemical suppressant to the fire as designed for that appliance and, thus, extinguish the fire.

Some appliances are supplied with appliance locks to ensure that they maintain their positions. Locator blocks on the floor or rear wall that position the appliances are also good. But even where these do not exist, it is important that operating personnel realize the importance of keeping the appliances in their designated positions under the hood.

Fire Suppression

In commercial cooking operations, the fixed fire suppression system is considered the primary means of fire control, with portable fire extinguishers being secondary. This approach to fire suppression requires special training of kitchen workers. Inadequately trained workers can exacerbate fire conditions by using water, milk, or other liquids on fires in cooking equipment. Major flare-ups and injuries can occur when workers try to extinguish fires using flour or cornstarch rather than baking soda (sodium bicarbonate).

At one time, dry chemical (sodium bicarbonate) fire suppression systems were the most common type to protect

commercial cooking equipment. Such systems, however, lack the cooling capability needed to pass UL 300, *Standard for Safety Fire Testing of Fire Extinguishing Systems for Protection of Restaurant Areas.* Now, wet chemical systems are the most common types used for fire suppression. Automatic sprinklers are also used, and the application is addressed by codes and standards. Large-scale food production lines frequently use carbon dioxide systems because carbon dioxide is a clean agent, which reduces the amount of cleanup and subsequent production downtime. There is a new trend to utilize water mist suppression systems for industrial-type cooking.

Fire Detectors. Fire detectors are used to activate the fixed fire suppression system (Figure 10.5.17). Whether they are of the mechanical link or electronic sensor type, they must be applied at a rating and location that permit them to respond *promptly* to any abnormal temperatures in the effluent from the cooking operation. With late activation, fire may have already spread to areas beyond the range of the suppression system, or the ignited surfaces may be so hot, especially in the case of deep fryers, that even if the suppression system initially puts out the fire, there will be reignition because the suppression agent will break down before the surfaces can cool. Whatever the autoignition temperature of the greasy surfaces, once the suppression system has discharged, the surface temperatures must cool at least 50°F (28°C) below the autoignition temperature if the surface is not to reignite.

The best way to choose the proper link rating and location is to monitor the temperatures of the normal effluent airstream under maximum cooking conditions. This monitoring is not often possible or practical, so an estimate is made and a rating and location selected. Even if this is all that can be done initially before the restaurant opens, temperature monitoring with a remote recorder can be done later, and then within a very short time the actual maximum normal temperature can be known and the link rating adjusted accordingly. Remember, a *fast* response is necessary, not just a response. The longest preburn time for systems listed to UL 300 is 2 minutes. Most of the older systems were listed for only 1 minute preburn. Links are normally installed behind filters, many feet above the cooking surface. It could easily take much more than 2 min for a fire in a single vat under a canopy hood to raise the temperature of a link to its rating, especially if a link is not directly in the line of flame and air flowing over it is diluted by the cooler air from the rest of the cooking operation. It is not unusual for fire to completely bypass links for 5 minutes or more. It is better to install more links than thought necessary, since the path of the flames and hot air will be strongly affected by the airflows created by the exhaust system.

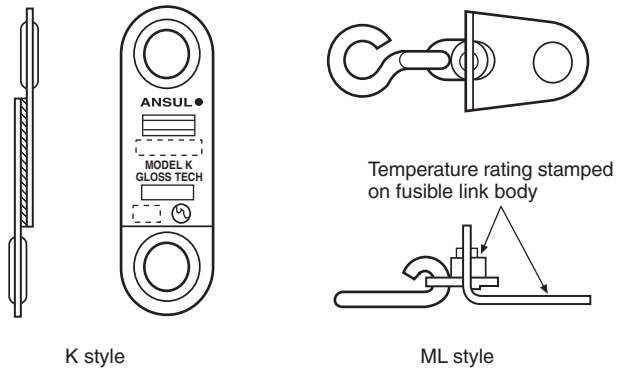

FIGURE 10.5.17 Detector Links

Fire detectors should be inspected a minimum of every 6 months, and mechanical links should be changed a minimum of every 6 months. Inspection must include that the rating and position of the detector are still appropriate for the application, especially for appliances that may have changed since the last inspection. Detectors covered with an insulating layer of grease or carbon can have a slower response time than designed. All detectors must have clean surfaces; otherwise, they should be changed out for new detectors.

Detection Lines/Elbows. Detection line conduits and the pulley elbows in them need to be inspected every 6 months, including doing a trip of the actuator by cutting the terminal link. This inspection will show that the cable is free to move in the conduit system. In grease exhaust applications, it is not unusual for grease to get into the horizontal conduits or into the pulley elbows and harden to such an extent that the cable cannot move. When this problem occurs, the system cannot operate automatically, which presents a serious fire hazard. If a cable will not move or moves only sluggishly, the conduits and elbows should be dismantled to find the problem. If they cannot be cleaned, they should be replaced.

Another concern with pulley elbows is when they are located in the hot flue gas from gas-fired appliances. When this problem occurs and they are not rated for such applications, they will melt in such a way as to seize the cable in the elbow, and, again, the cable will not be able to move when needed. Visual inspection will usually show this problem, but it can also be noted with an end-of-line detector test.

Makeup/Replacement Air

Integral. Where makeup air is integral to the hood, it is possible that some grease can also get into this makeup air compartment whenever it might be turned off. Grease deposited in hidden areas can spread a hood fire to this point when makeup air discharges inside the hood.

Nonintegral. Makeup replacement air can disturb the capture of the hood to the extent that grease leaves the hood and enters the room. Therefore, if a fire develops and grows rapidly, it will also leave the hood and track along the grease path provided by the escaping cooking effluent. This situation can create uncontrollable fire spread.

Operation During Fire. There is a tendency in some jurisdictions to have all supply air shut down in the event of fire. This action is not always proper. If the hood is able to capture all grease vapors properly, and if there is no fire damper at the hood/exhaust duct connection, it is better to keep the makeup air operating in the event of an appliance or hood fire, as there is an increased

chance the hood will be able to contain the fire and smoke. If the makeup air is shut off, the hood will be short of available air and will not be able to continue exhausting properly.

FIRE CONCERNS WITH SYSTEM MAINTENANCE

Maintenance is essential to ensure that a system performs as designed. Both the components and the system as a whole must be kept physically and operationally in the condition for which they were designed. Adjustments, repairs, and replacements must be made as necessary. Maintenance personnel must identify each part of proper system design and performance and review them on a regular basis to catch and correct the first slip from "normal." This maintenance will keep the system working as designed.

Ventilation Flows

The purpose of ventilation systems in commercial cooking applications is to keep greasy effluents captured, contained, and evacuated through the exhaust system, and keep the kitchen environment grease free. Any decay in the performance or flows of the systems may cause grease vapors to leak from the hood into the kitchen space, contaminating the area with fuel. In the event of fire in a faulty system, the flames may leave the hood more quickly and ignite the grease deposits in the room, seriously increasing the fire hazard. Airflows of the exhaust and makeup air should be checked at least once a year or more often if it is noticed that the hood is not capturing the effluent properly.

Exhaust Hoods

The primary fire concern with hoods is that they be kept (1) in the same structural condition in which they were installed, assuming compliance with NFPA 96, and (2) clean so they will not sustain a fire and transport it into the duct. No holes can be cut in the hood, no service lines run through it, and no notching made in end panels to provide additional clearance. The welded shell of the hood is supposed to be able to contain a fire. When holes are put in it, or its perimeter is cut and notched, it can no longer provide this function and the fire hazard increases. Penetrations through the hood structure to mount fire suppression system components or other equipment such as lighting should be sealed with locked screws and sealant.

The hood must be kept clean. The filters should be cleaned daily, and the interior surfaces of the hood (both in front of and behind the filters) should be cleaned to bare metal at least once a week. If the hood surfaces and filters are clean, there is little chance of a fire in an appliance spreading to the ductwork. (See NFPA 96 for a recommended frequency of cleaning for the exhaust system, based on type of fuel, type of cooked product, and volume of cooking.)

Grease Filters

Grease filters installed in hoods should typically be cleaned a minimum of once a day to minimize the grease buildup and reduce the fire hazard. The cleaning should be done after operating hours, or the facility should have a spare set of filters to install. The hood must not be operated without filters, as this increases the fuel loading in the hood and duct, and it will unbalance the ventilation.

Filters should be in good physical condition, with flat squared frames and no baffles damaged or missing. Damaged filters should be replaced immediately—they cannot filter effectively, and, more important, they cannot stop flame penetration into the hood. Mesh filters are not acceptable.

Some hoods have permanent grease filtration devices, and these will have built-in detergent and water-wash systems to clean the grease filtration devices on a daily basis. It is important that these cleaning systems be maintained in good working order to keep the grease filtration devices clean and reduce the fire hazard. Problems to watch for include cleaning systems without any detergent and systems with controls or water shut off, so they cannot operate. This violates the listing of the unit, thus increasing the fire hazard. Hoods with automatic washdown should be set to self-clean a minimum of once a day, and more frequently if conditions warrant. The washdown system should be inspected for proper operation at least once a month to ensure that all nozzles are open, pressures are adequate, and the controls are cycling properly.

Additional Grease Extraction/Control Devices

Some exhaust systems have additional grease removal devices somewhere in the duct system after the hood. They may be in the false ceiling space, in a mezzanine, or on the roof. These extraction devices also contain various types of filters. These filters must be cleaned or replaced according to the manufacturer's instructions. Failure to clean the filters builds up unnecessary fuel in the system, seriously reducing the airflow, and may cause the hood not to capture the vapors as designed. It is necessary with these units to make sure that the filters are in good physical condition so the grease cannot bypass them and to make sure that they are in place so they can function properly. Failure to keep these components operating as designed seriously increases the fire hazard. These units should be inspected a minimum of once a month to be sure the filters are still performing properly and that all panels, seals, and suppression system components are in good condition.

Exhaust Ducts

Exhaust ducts should be fully welded or possibly bolted if a listed duct system. Remodeling of the building, or other trades working in the vicinity of the ducts, can cause damage or changes to the ducts that reduce their integrity. Any time work is performed in the vicinity of the ducts, they should be inspected after the work is complete.

Many ducts also have bolted or gasketed connections at the hood or fan. These require more attention, as they are more subject to decay from normal use and vibration. Any grease leaks seen around these points are reason to have the connection checked and repaired, as necessary.

If, for some reason, a facility has an existing duct that is not fully welded, or in other ways does not fully meet NFPA 96,

it is all the more important to establish regularly scheduled inspection of the duct to ensure that grease leaks do not exist and that other damage has not occurred. Proper, frequent cleaning of ducts is critical.

Makeup Air Systems

The makeup air system is needed to provide replacement air to balance that taken out by the exhaust system. The makeup air system must operate whenever the exhaust is operating, be matched to the quantity of air taken out by the exhaust system, and not interfere with the performance of the exhaust hood.

The makeup air system usually operates at considerably higher air velocities than the exhaust system, and usually approaches the hood at different angles than those established by the exhaust airflows. Where these angle differences exist, they should be neutralized by distance before the makeup air nears the hood so as to not adversely affect the capture and containment effect of the exhaust airflows.

Makeup air introduced integrally at the exhaust hood is more likely to have a negative effect on capture and containment than makeup air introduced at the far side of the room from the exhaust hood. Therefore, integral makeup air needs more frequent attention to maintain proper performance. Some hoods with integral makeup air have operator-adjustable diffusers that can be set to operator preference for the season, but this adjustment can adversely affect the capture and containment performance of the hood.

Ambient conditions not acceptable to facility personnel should be brought to the attention of the design engineer. Fire safety should not be compromised for the sake of employee comfort.

Service Panels/Gaskets/Hardware for Hoods and Ducts

Inspection panels are often installed in ductwork and in some hoods in order to inspect and clean the ducts and hoods. When in place, these panels must have integrity equivalent to welded ductwork, which requires that (1) the panel be ridged and conform to the shape of the opening, (2) the gasket be complete and adequately thick to seal the full perimeter of the opening, and (3) the hardware used to hold the panel closed be tightened securely in order to create a grease-tight seal. If a panel cannot be sealed as described above, it must be repaired immediately. Panels that cannot seal will leak grease, possibly allowing burning grease to escape from the opening to ignite combustibles in the vicinity. This can spread a fire to relatively hidden areas that are difficult to locate. The integrity of these components should be closely inspected each time they are used.

Clearance to Combustibles

All hoods, ducts, fans, and other components of exhaust systems are required by codes to have adequate clearance to combustibles so as not to ignite the combustibles from the radiant heat of the metal shell in the event of an internal fire. Sometimes this clearance is provided by insulation and air gaps, sometimes it is provided by a noncombustible or fire-rated chase, and sometimes it is provided by only a physical distance to the closest combustible surface. Any protective system provided around the exhaust system must be kept intact, in order to maintain this crucial clearance. Chases must have access panels to enable inspection and cleaning. Access panels in the chases must be kept in good condition and secured in place in order to maintain the designed protection. These panels should be inspected and maintained with attention equivalent to that given the panels in the ductwork itself. In cases where there is only open space between the exhaust system and combustible construction, it is important to maintain that space. It is not uncommon in commercial cooking operations to use false ceiling and attic spaces for storage of combustible products. Where this is done, and the same spaces contain unprotected exhaust ductwork, it is best to put a wire mesh or expanded metal fence around the ductwork to ensure that no combustible materials can come closer than 18 in. (457 mm) to the ductwork.

Appliances

Grease effluent is produced by the products cooked on appliances. Much of the grease effluent is carried into the exhaust system, but a large quantity of grease stays with the cooking appliance. Fryers hold shortening in the vats. Grills collect grease on the surface, and then it drains (or is scraped) into scrap cans on the side or front of the grill. Ovens and some broilers usually have grease baked on the interior surfaces, but this grease can run out of drain openings to cups. Charbroilers usually burn grease in the fire or on the hot elements, but much of it just settles at the bottom of the bed. Fire safety requires that, where grease collects inside appliances or in containers from appliances, it be frequently removed during the day and not allowed to spill over onto the floor. Inspections and cleanings should occur multiple times each day to minimize the immediate hazard, and to facilitate the cleanup of the grease. The floor, wall, and rear area of appliances should be cleaned at least once a day.

Grease often condenses on the outside of appliances and hoods, or on lower hood or wall parts below any grease gutter. Most of this grease will drain onto the floor, and a path will show on the wall or side of the equipment. It is important for fire safety that such occurrences be corrected with additional gutters and remote covered grease cups, or that they be frequently addressed during each day with manual cleaning. Otherwise, there will be a buildup of mostly hidden grease that will create a fuel source in the event of fire.

As many appliances age, they develop internal grease leaks that permit a grease buildup in the immediate vicinity of the gas burner or electrical elements. This grease buildup can quickly become the source of a fire, and there is no detection or suppression system within this appliance area to suppress the fire when it occurs. Therefore, it is essential to inspect such areas and keep them grease-free. All grease leak sources should be located and repaired immediately. These repairs are especially important for fry vats, as a leaking vat can drain grease onto a burner and cause an immediate and serious fire.

Changes. Fire suppression systems are installed in hoods to protect the specific appliances that are under the hood at the time of original installation of the system. If these appliances are

later repositioned or changed out for other appliances, the suppression system may no longer be able to provide suppression for the new arrangement. Menu changes can impact the type and location of equipment. When appliances are repositioned or changed out for other appliances, even if the change involves only a different input rating or a different fuel, the local AHJ must review the system and see if it is still adequate or if a detector, nozzle type, or nozzle location needs to be changed. All restaurant operators should be aware of this concern. A change to solid fuel cooking takes special consideration.

Seals. Some appliances, notably closed ovens, must be sealed during normal cooking operations to contain the grease and other effluents. If a fire should occur in such an appliance and the seal is not complete, fire can escape from the appliance rather than be contained and smothered. It is important that all such seals be kept in good order to ensure fire safety.

Fire Dampers

Fire dampers in grease exhaust systems should only be installed in listed hoods at the hood to duct connection, or they may be a component of a listed grease extraction system that is installed downstream of the hood. In either case, they need to follow the same inspection schedule as the suppression system detectors, and they have the same problems if the detector link becomes grease or carbon coated. Exhaust hoods with integral makeup air supplies usually have fire dampers installed in the supply duct to hood connection, or at one or more of the makeup air register openings. Their links have the same inspection and replacement schedule.

Fire dampers need to be checked for proper and full operation. The damper should be able to close fully and rapidly. If it moves sluggishly or does not close fully, its track is coated with grease buildup, and it must be cleaned. If the fire damper cannot close quickly and completely, it cannot be effective.

Gas Valves

Any gas valve can stick open, but it is more likely to occur with mechanical gas valves than with electrical gas valves (Figures 10.5.18 and 10.5.19). Mechanical gas valves have openings that permit grease to get inside part of the mechanism, which causes it to seize or slow down. These must be operationally checked every six months. If any delay or incomplete closure is noted, the valve must immediately be cleaned or replaced. With mechanical gas valves, it is necessary to ensure that the cable line is not binding in any way and causing the problem.

Shunt Trip

Electrically powered equipment utilizes a shunt trip breaker that will cause the circuit to be de-energized on activation of the fire suppression system.

SUMMARY

Ventilation and fire protection systems for commercial cooking operations provide invaluable services to the industry and permit such operations in many locations where the potential for fire hazard is great due to the fuel, product, and greasy effluent that are inherent in commercial cooking operations. Systems can be designed to not only provide their prime function of capturing, containing, and removing the greasy effluent but also to contribute positively to a fire-safe environment. Knowledge exists for safe design and should be conveyed to facility operators, service personnel, and local inspectors. It is important that these people know the value of each component of the systems for operational and fire safety, and how to keep the components and the system in proper working order so that they can continue to safely provide their intended functions. As more education is provided on these issues, the fire safety record will improve.

Chapter Contents

Overview
Fuels
Oil- and Gas-Burning Systems
Piping and Control Devices
Pulverized Coal Systems
Fluidized Bed Combustion
Special FBC Hazards
Boiler-Furnace Hazards
Open Register Lightoff and Continuous Purge Procedure
Fire and Explosion Protection
Special Considerations for Small Boilers
Interlocks, Alarms, and Operator Competence

Key Terms

atomizer, burner flame, circular burner, fire-tube boiler, fluidized bed combustion (FBC) boiler, furnace, natural gas–fired boiler furnace, oil-fired boiler furnace, pulverized coal, Saybolt Universal Seconds (SUS), selective catalytic reduction (SCR) boiler, waste fuel, water-tube boiler

More than any other single invention, the steam engines of Newcomen and Watt led to the modern age. The primitive boilers that produced the steam for these early engines consisted of a furnace, a space for burning the fuel, and a separate boiler, with a large copper pot heated from beneath. Improvements in iron fabrication techniques made possible the integration of the furnace and boiler.

Although this chapter discusses water-tube boiler furnaces, the safety principles outlined also apply to fire-tube boilers. Fuel-burning systems and related control equipment for single- and multiple-burner boiler furnaces are discussed here. Furnaces for fuels burned in suspension and in fluidized beds are included; other solid-fuel-burning units, such as stokers, are not.

Further, it is not the intent of this chapter to include start-up, shutdown, or operating procedures or a detailed description of interlock and trip systems. This information is contained in the applicable NFPA standards listed at the end of this chapter.

For related topics see also Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 3, "Storage of Gases"; Section 8, Chapter 10, "Stationary Combustion Engines and Fuel Cells"; Section 10, Chapter 1, "Emergency and Standby Power Supplies"; and Section 10, Chapter 2, "Heating Systems and Appliances."

OVERVIEW

Development of Boiler Furnaces

In fire-tube boilers, the furnace is a large central horizontal tube surrounded by a water-filled boiler. The hot exhaust gases pass out of the furnace and then back through tubes that traverse the boiler. Failure to keep water in fire-tube boilers led to catastrophic boiler explosions, resulting in many deaths in the mid-nineteenth century. (Such explosions still occur occasionally.) Boiler explosions were especially a problem on early steamships, where exposed occupants had fewer options to escape the consequences of them. The deadliest fire or explosion in U.S. history was a boiler explosion and ensuing fire aboard the SS *Sultana* on the Mississippi River on April 27, 1865, where 1547 people died. Inventors were kept busy trying to solve this problem, as well as automating the feeding of coal by use of mechanical stokers. Another important "invention" of the time was the establishment of the Steam Boiler Assurance Company in 1859 in the United Kingdom, the beginning of the boiler inspection and insurance industry.

Further, material improvements led to the development of the water-tube boiler. Here the water is in the tubes and the hot gases pass across the tubes. Although individual water tubes could still burst, boiler safety was much improved. With the development of pulverized coal firing, water-tube boilers would grow to enormous size. The increase in size led to the possibility of catastrophic

L. Jeffrey Mattern is retired from FM Global in Philadelphia where his most recent positions were senior account engineer and chief engineer of Mid-Atlantic Operations. He has served on various NFPA technical committees and the NFPA Standards Council since 1968.

Eugene Catania (late) graduated from Stevens Institute of Technology with a B.E. in Mechanical Engineering. During his 37 years with Foster Wheeler, he worked with design, field commissioning, and troubleshooting of power and process equipment, both nationally and internationally.

Shelton Ehrlich, retired from Electric Power Research Institute (EPRI), is now principal consultant of Ehrlich Associates, Palo Alto, California, and a member of NFPA's Technical Committee on Boiler Combustion Systems Hazards.

furnace explosions. Steady improvements in design, materials, instrumentation, operator training, and supervision [addressed by the American Society of Mechanical Engineers (ASME International), insurance companies, NFPA, authorities having jurisdiction, etc.] have led to a great reduction in fire-tube boiler explosions and water-tube boiler furnace explosions.

The Combustion Process

Combustion is the rapid combination of oxygen with combustible elements of a fuel. There are three important combustible elements: (1) carbon, (2) hydrogen, and (3) sulfur. When burned to completion with oxygen, these elements unite according to the following:

$$C + O_2 = CO_2 + 14{,}100 \text{ Btu/lb (or 32,797 kJ/kg) of carbon}$$

$$2H_2 + O_2 = 2H_2O + 61{,}100 \text{ Btu/lb (or 142,119 kJ/kg) of hydrogen}$$

$$S + O_2 = SO_2 + 3980 \text{ Btu/lb (or 9258 kJ/kg) of sulfur}$$

Waste gases rich in carbon monoxide (CO) are often burned in boilers and release 4347 Btu/lb (10,111 kJ/kg) of CO. CO boilers or incinerators generally utilize a refractory-lined and auxiliary-fueled chamber to maintain temperatures needed to combust the CO in the off gas.

To compete effectively, designers must carefully balance the need to provide for complete combustion against the capital cost of the boiler and the auxiliary power needs. The key factors, often referred to as the "three Ts" of combustion, are (1) *time,* set by the size of the furnace; (2) *temperature,* set by the arrangement of heat-removal surfaces and the hydrogen content of fuel, its moisture and excess air; and (3) *turbulence,* set by the skill of the designer in manipulating flows of air and fuel and the interaction between all the burners in the furnace. A fourth critical factor is *continuity,* that is, the need to supply fuel, air, and ignition source on an uninterrupted basis.

Not only must the fuel and air be supplied continuously, but also the ratio of fuel to air must be kept constant within a relatively narrow range. The burner designer and the limits built into the automatic controls provide that the ignition source (feedback from the fuel just burned) be available for the fuel just entering. When any of these factors go awry (e.g., the fuel is interrupted for a few seconds; the airflow suddenly increases, say because a blockage is removed; or the burner does not hold the flame close), then ignition can be lost and the controlled flammable mixture becomes an uncontrolled explosive mixture. A large boiler-furnace is always just a few seconds away from catastrophe. It is only through the skill of the many people responsible for ensuring that events are always correct that large furnace explosions are so remarkably rare. Increasing sophistication in flame detection, condition monitoring, and other safety systems assist those people in maintaining this safe margin.

Figure 10.6.1 shows how fuel and air are introduced and burned in a furnace through a modern low-NO_x burner. Pulverized coal, carried by a small stream of air termed *primary air,* is injected through the center of the burner and meets with the swirling bulk of the air, termed *secondary air.* The several functions of this burner can be seen in the figure: a zone just at the burner outlet in which fuel is ignited and partially burned, but with a strong deficiency of air (A); and a second zone in which thermal NO_x is reduced to N_2 (C). The mixing and burning of the remaining air and residual fuel (the *char* that remains after the volatile fuel components have been driven off near the burner) takes place in the furnace. Radiation from the brightly luminous flame and the recirculation of hot gas due to turbulence provide a stable ignition source. The combustion process

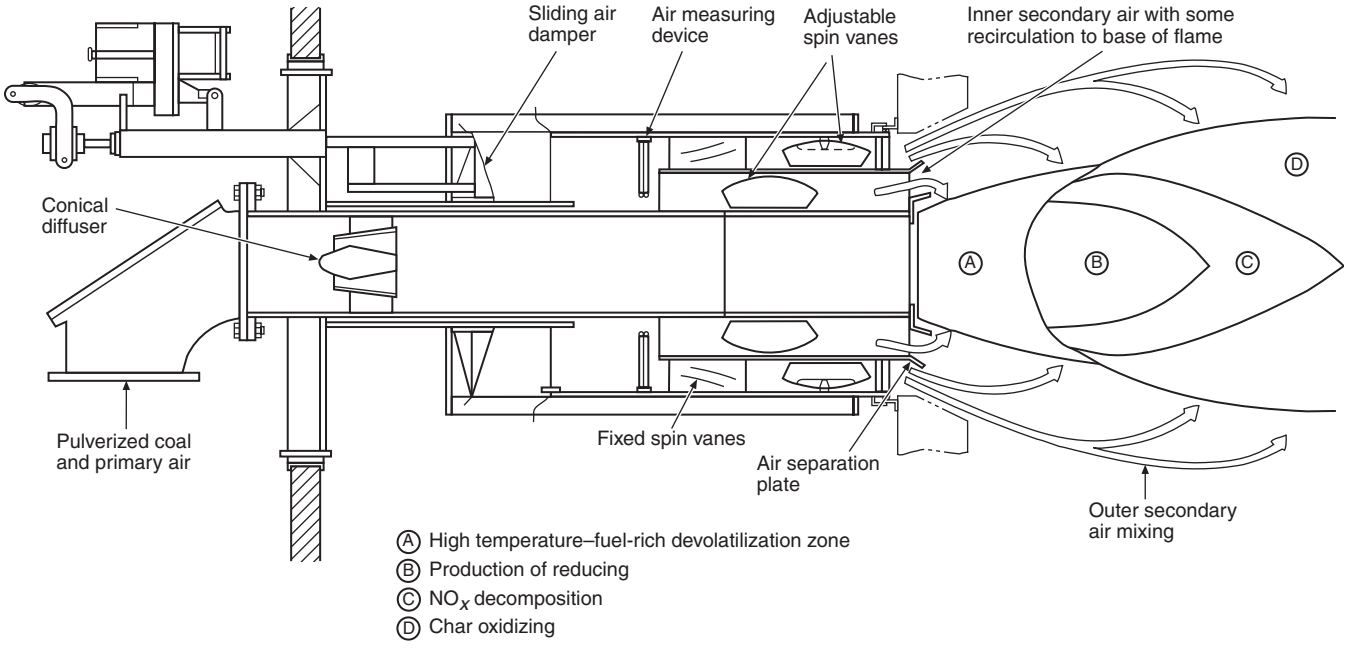

FIGURE 10.6.1 Burner Flame Conditions

proceeds toward completion through a wide range of fuel-air ratios, fuel-rich just at the burner exit and fuel-lean at the furnace exit.

The introduction of low-NO_x burners and overfire air systems (OFA) on existing and new coal boilers results in staging of the combustion process. In the near burner area, fuel-rich combustion conditions require the precise control of fuel and air so that high combustibles and unburned carbon content can be contained. Recent developments in burner system design include individual burner fuel flow monitoring and balance of individual coal burners with separate burner airflow measurement and control. By closely controlling the air-to-fuel ratio in near burner areas, the lowest NO_x values can be achieved while minimizing formation of combustible gases and unburned carbon in the fuel burned. Minimizing the NO_x produced in the flame basket also allows lesser usage of feed gases (e.g., ammonia) to downstream SCR systems.

FUELS

After several periods of rapidly rising oil prices, coal became the least expensive boiler fuel almost everywhere in the world. However, in 1999 natural gas use surpassed coal use for all thermal energy uses including heating processes and electricity. Some large boilers, built when fuel prices were more competitive, still burn residual fuel oil because (1) they are incapable of burning coal or (2) the use of very low sulfur fuel oil is virtually mandated. Other boilers, particularly in gas-producing regions, were designed to burn natural gas when gas prices were maintained low via federal controls. In winter, when gas is urgently required by pipelines, many of these boilers will burn distillate oil. Most boilers in commercial installations and in small industries also use natural gas and clean oil, although all fuels are, to some extent, used.

After a period when most new generation in the United States consisted of gas-fueled combined cycle units, large upswings in gas pricing coupled with high demand from competing users have impacted the cost and use of these plants for base-loaded around-the-clock operation. Recently, the use of large coal-fired or waste solid fuels has become a factor in planning new generating plants. Environmental regulations have required the use of strict environmental controls in the design of these new plants, including scrubbers, bag house, and selective catalytic reduction (SCR) units, as well as wider use of large circulating fluid bed (CFB) boilers. Likewise, older base-loaded, solid-fuel-burning units are having their operating life extended through major component upgrades, coupled with the addition of new environmental components to comply with environmental requirements.

In recent years, with the commercialization of fluidized bed combustion and a federal law making the use of waste fuels especially profitable for independent power production, a wide array of waste fuels is now used. Included are wood wastes, petroleum coke, coal-mining residues, and many others. Still, the dominant fuel worldwide remains coal, and its dominant form is a finely pulverized powder with a mean particle size under There are also waste fuels produced in oil refineries, chemical plants, paper mills, and so on that are burned in specially designed furnaces that demand special precautions in addition to those described here for the more common fuels.

With the large number of combined cycle gas turbine power plants installed in recent years, they will remain a major source of power for future generation scenarios. See Section 10, Chapter 1, "Emergency and Standby Power Supplies"; and Section 8, Chapter 10, "Stationary Combustion Engines and Fuel Cells," for some discussion of gas turbines. In a combined cycle the hot turbine exhaust generates steam in a boiler, called a *heat recovery steam generator* (HRSG). To maintain steam temperature and pressure at all loads, many of these HRSGs are also fired with natural gas or light oil, and they have many features in common with other boilers. However, the profusion of HRSG designs and supplemental firing schemes has led to a number of serious accidents. For more information on HRSGs, see NFPA 85, *Boiler and Combustion Systems Hazards Code.*

OIL- AND GAS-BURNING SYSTEMS

The burner is the principal component of oil- or gas-firing systems. Its purpose is to introduce fuel and air into the furnace in the proper proportion, swirl, and droplet size to sustain efficient combustion. The combustion efficiency of a burner (and furnace) should be as high as possible to minimize energy lost as either unburned fuel or excess air.

Normal use of a boiler requires operation at different outputs to meet varying loads. The specified operating range for a burner is the ratio of full-load heat production of the burner to the minimum load at which the burner is capable of stable ignition and reliable operation. For example, with a multiple burner-boiler rated at 1,000,000 lb/hr (450,359 kg/hr) steam capacity, a load range of 4:1 on the burners means that the unit can provide stable ignition and complete combustion at any load from its rated capacity down to 250,000 lb/hr (113,400 kg/hr) without requiring one burner to be taken out of service.

Because of the chemistry of combustion, more than the quantity of theoretical air is necessary to achieve essentially complete combustion. The amount of excess air needed for complete combustion with minimum stack loss must be balanced against compliance with NO_x emission requirements. The excess air normally required with coal, oil, and gas, expressed as a percentage of theoretical air, is given in Table 10.6.1. Many boilers operate with substantially higher excess air levels, some because of the particular fuel, the furnace design, or poor attention to optimum performance.

A frequently used burner for gas and oil is the circular burner (Figure 10.6.2). Normally, the capability of an individual circular burner is limited to about 200 million Btu/hr (58,620 kW). The tangentially displaced doors built into the air register provide the turbulence necessary to mix the fuel and air and to produce a stable flame. While the fuel is introduced to the burner in a fuel-rich mixture in the center, the direction and velocity of the air and the fuel-dispersion pattern thoroughly mix the fuel with the combustion air. A burner specially designed for low NO_x emissions is shown in Figure 10.6.3. An airflow monitor is incorporated in this burner to allow for balancing airflow from burner to burner.

TABLE 10.6.1 Usual Amount of Excess Air Required for Complete Combustion

Fuel	*Type of Furnace of Burner*	*Excess Air (wt.%)*
Pulverized coal	Completely water cooled	15–20
Crushed coal	Cyclone furnace	10–15
	Fluidized beds	15–20
Fuel oil	Oil burner, register type	5–10
	Multifuel burners and flat flame	10–20
Natural gas	Register-type burner	5–10

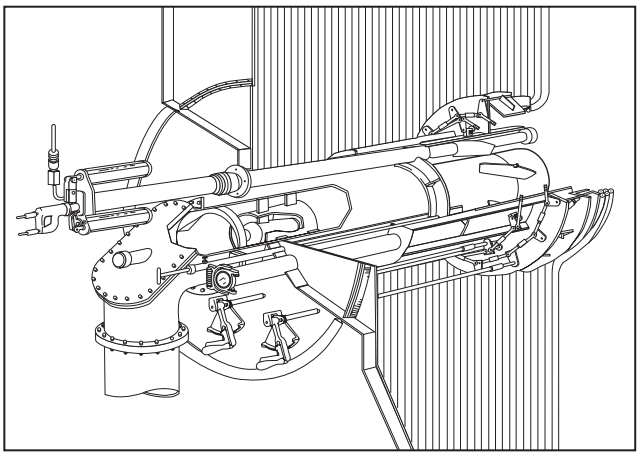

FIGURE 10.6.3 Burner for Low Emissions of NO_x (Source: The Babcock & Wilcox Co.)

Oil Burners

A main function of an oil burner is to atomize the oil, that is, turn the thick stream of oil into a very fine mist of oil droplets. This process provides the large oil surface area needed for rapid ignition and, as each droplet is surrounded by air, complete combustion. There are a number of types of oil atomizers, but the discussion here is limited to the two most popular types: (1) steam or air atomizers and (2) mechanical atomizers.

For proper atomization, oil heavier than No. 2 must be heated to reduce viscosity to between 100 and 150 SUS.* Steam or electric heaters are used to raise the oil temperature to the required level—approximately 135°F (57.2°C) for No. 4 oil, 185°F (85°C) for No. 5, and 200°F (93.3°C) to 220°F (104.4°C) for No. 6. With certain oils, better combustion is obtained at somewhat higher temperatures than are required for atomization. However, oil must not be heated to the point where vapor binding might occur in the fuel pump; this could cause flow interruptions and loss of ignition.

It is also important that oil be free of acid, grit, and other foreign matter that might clog or damage burners or their control valves. In order to prevent a loss of fuel, flow strainers installed to remove particles must be cleaned as often as an increasing pressure drop indicates.

Steam or Air Atomizers. Generally, the steam or air-oil atomizer operates by producing a steam-fuel (or air-fuel) emulsion that atomizes the oil through the rapid expansion of the steam (or air) when released into the furnace (Figure 10.6.4). The atomizing steam must be dry because moisture causes pulsations that can lead to loss of ignition. Where steam is not available, moisture-free compressed air is substituted.

The steam atomizer performs efficiently over a wider load range than do other types of atomizers. Normally, it properly atomizes oil down to 20 percent of rated capacity (turndown = 5:1); in some instances, steam atomizers have been successfully operated at 5 percent of capacity. This high level of turndown can be inconsistent with high efficiency because the total airflow must not be permitted to fall below 25 percent of full capacity rate (the purge rate). Also, these extremes in range cannot be fully utilized because the temperature of the furnace falls below that needed to complete combustion despite the excellent quality of atomization.

Mechanical Atomizers. In the mechanical atomizer, the pressure of the fuel itself is used as the driving force for atomization. A wide variety of mechanical atomizer designs has been developed over the years. Excessive maintenance is required to keep those having rotating mechanical parts that are close to the furnace operational.

Return-flow atomizers are used for many marine installations and some stationary boilers where the use of steam or air is inappropriate, impractical, or uneconomical (Figure 10.6.5). Oil pressure required for these atomizers ranges from 600 to 1000 psi (4.14 to 6.90 MPa), depending on capacity, load range, and fuel.

*Abbreviation for Saybolt Universal Seconds. This is the efflux time in seconds of 60 ml (approximately 2 oz) of sample flowing through a calibrated universal orifice in a Saybolt viscometer under specified conditions.

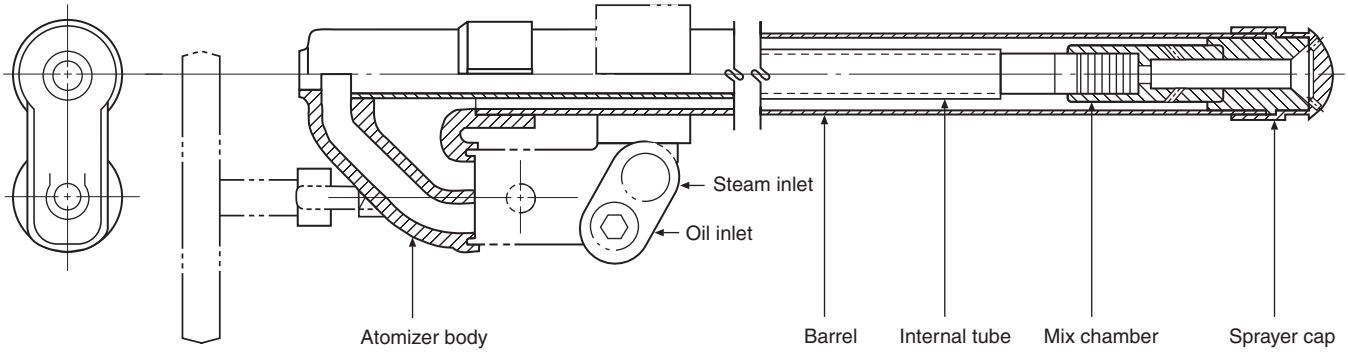

FIGURE 10.6.4 Steam-Fuel Atomizer Assembly (Source: The Babcock & Wilcox Co.)

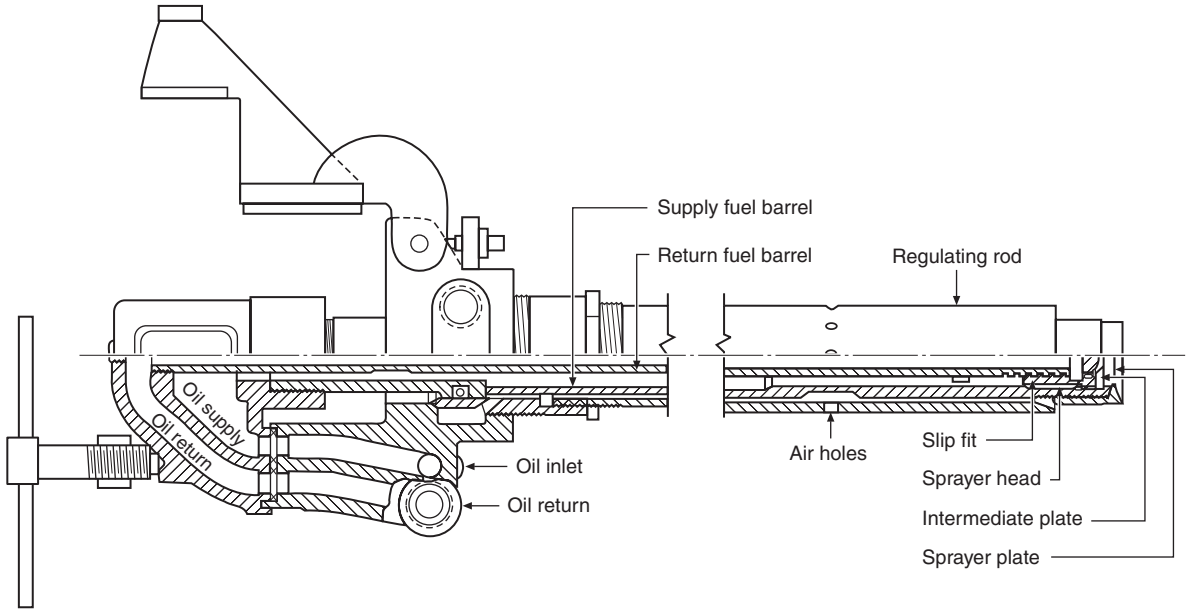

FIGURE 10.6.5 Mechanical Return-Flow Oil Atomizer Assembly (Source: The Babcock & Wilcox Co.)

Mechanical atomizers are also available in sizes up to 200 million Btu/hr (58,620 kW) input. The acceptable operating range may be as much as 10:1 or as little as 3:1, depending on the maximum oil pressure used, the furnace configuration, air temperature, and burner throat velocity. Return-flow atomizers are ideally suited for standard grades of fuel oil where it is desired to meet load variations without changing sprayer plates or bringing burners in and out of service.

Natural Gas Burners

Natural gas is the ideal boiler fuel, requiring no preparation for combustion and minimal postcombustion pollution control. Basically, gas burners mix fuel and air in either of two ways: (1) premix or (2) external mix. With the advent of stringent NO_x emission regulations, changes were required in the design and operation of large gas burners.

In a premix burner, gas and a portion of the air are mixed before the mix is introduced to the burner nozzle. A common method involves mixing gas and air in the suction side of a mechanical blower. Another method uses the venturi effect, wherein a gas jet creates a negative pressure at the air input orifice and draws air into the mixer. This design is familiar on kitchen stoves and home heating furnaces. The third premix method also uses the venturi effect but, in this case, an air jet draws fuel gas into the mixer, thus requiring a gas regulator to reduce fuel gas pressure to atmospheric before gas and air are mixed.

In external-mix gas burners, the fuel and air are mixed external to the nozzle. When external-mix gas burners have individual elements or spuds (Figure 10.6.6), part or all of the gas discharges in front of the impeller. This provides a local fuel-rich zone and thus serves as an ignition stabilizer at high gas flow rates. The burner contains several spuds, each a gas pipe with a number of precisely drilled holes near the tip, to discharge gas for ignition at the burner throat. Depending on

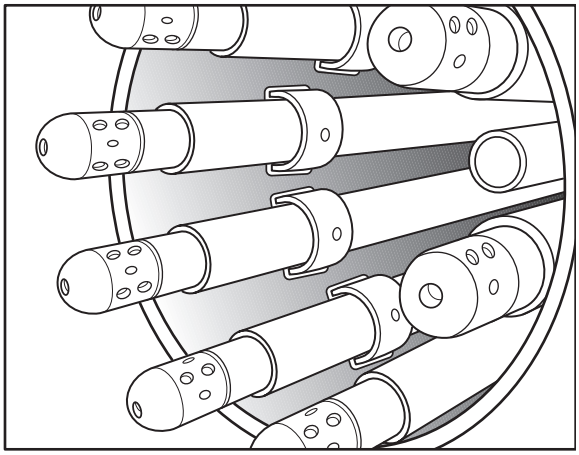

FIGURE 10.6.6 External-Mix Gas Burner with Individual Spuds

the manufacturer, each spud might be fitted with a flame holder or might share a common flame stabilizer to provide a local fuel-rich zone to stabilize ignition at low inputs. Gas ports are relatively large in order to minimize plugging. The spuds shown in Figure 10.6.6 can be withdrawn for service while the burner is in operation. Gas spuds are located so that oil will not impinge on them in multifuel burners.

With the proper selection of control equipment, a multifuel-fired furnace with a multiple spud-type burner is capable of changing from one fuel to another without a drop in steam pressure or output and is also capable of simultaneously firing natural gas and oil in the same burner. The control system's primary function is to achieve complete and efficient combustion by balancing fuel in the proper relationship with burner airflow. This type of element is designed for use with natural gas or other gaseous fuels containing at least 70 percent methane, 70 percent propane, or 25 percent hydrogen by volume. The element is also designed for a maximum input of 200 million Btu/hr (58,600 kw) per burner.

To provide safe operation, ignition of a gas burner should remain close to the burner impeller(s) throughout the full range of allowable gas pressures, at both normal airflows and abnormally high airflows. Ideally, it should be possible, at the minimum load, to pass full-load airflow through the burner without loss of ignition. It should also be possible to pass as much as 25 percent in excess of theoretical air at full load without loss of ignition. With this range of airflow, it is not likely that ignition can be lost, even momentarily, during some upset in airflow.

PIPING AND CONTROL DEVICES

Fuels must be essentially free of contamination and be under control to ensure combustion safety. The design and reliability of fuel-handling systems are, therefore, important factors in minimizing the risk of fire or explosion.

Oil-Fired Systems

The fuel-oil supply system should be designed to ensure a continuous, steady flow of fuel that will meet the requirements of the boiler over the entire load range. This includes coordinating the main fuel control valve, burner safety shutoff valve, and associated piping volume to prevent fuel pressure transients that might exceed stable flame burner limits as a result of placing burners in or taking them out of service (Figure 10.6.7).

Fill and recirculation lines should be connected to storage tanks so that they always discharge below the liquid level. This will avoid excess evaporation and the generation of static electrical charges in free-falling fuel.

Strainers, filters, traps, and sumps are some of the devices that are used to remove contaminants from oil systems. Examples of contaminants are salt, sludge, water, and a variety of abrasive particles such as sand and corrosion products. It is good practice to route piping and locate valves to minimize their exposure to (1) temperature extremes that might alter the oil's viscosity or pressure and (2) physical damage in the event of an explosion.

Burner shutoff valves should be located as close to the burner as possible to minimize the volume of oil that might remain in the burner line downstream of the valve. This will minimize the oil that could drain into the furnace following an emergency trip or burner shutdown. Positive means must be provided to prevent oil from leaking into an idle burner.

Fuel oil must be delivered to the burners at a specific temperature and pressure for proper atomization. Provisions must be made for adequately recirculating the oil to control its viscosity at the burners for initial lightoff and subsequent operation. Systems must also prevent excessively hot oil from entering fuel-oil pumps; otherwise, the pumps might vapor-bind and interrupt the supply of oil to the burners.

Positive means are needed to prevent fuel oil from entering the burner header system through the recirculating valves, particularly from the fuel supply system of another boiler. Check valves have been undependable for this function in heavy oil service. Provisions should also be made for clearing (scavenging) the passages of an atomizer into the furnace when a burner is taken out of service.

Gas-Fired Systems

Natural gas fuel-supply systems must be able to provide a continuous, steady flow of fuel over the entire load range. This includes coordination of main fuel control valve, burner safety valves, and the associated piping volume to avoid large gas pressure transients. Transients could cause burner limits to be exceeded and result in an unstable flame condition as burners are placed in or taken out of service. A well-designed system will also be capable of stable gas supply, despite anticipated furnace pressure pulsations.

The fuel supply system components located outside the boiler room need to be arranged to prevent excessive fuel gas pressure in the burner supply system, even in the event of failure of the main supply constant gas pressure regulator(s) (Figure 10.6.8). Usually, this is accomplished by providing a full relieving capacity pressure relief valve vented to a safe location. Where full relieving capacity is not installed, a high-supply gas pressure trip should be installed.

M	Flow meter		

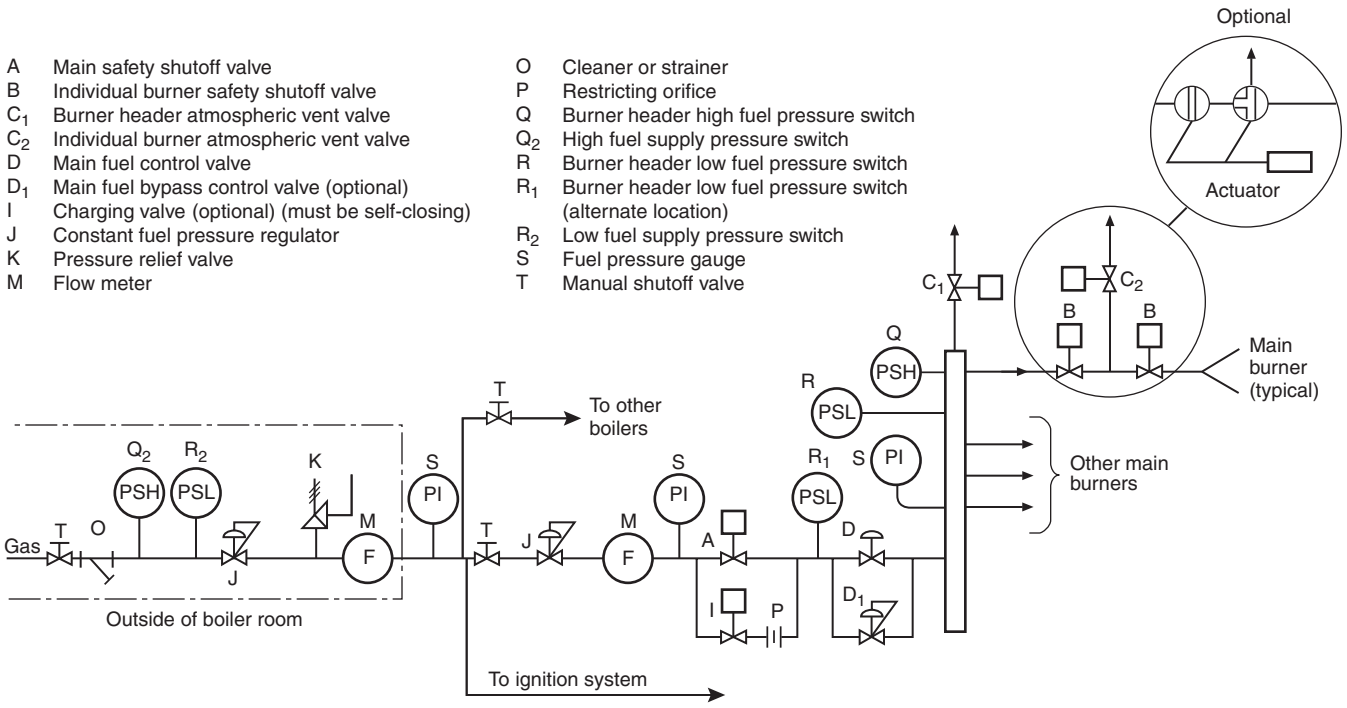

FIGURE 10.6.8 Typical Fuel Supply System for Natural Gas–Fired Multiple-Burner Boiler Furnace

The gas-fired system should have the following:

1. Positive means to prevent gas from leaking into an idle furnace
2. Piping vents located upstream of the last shutoff valve in any line to a main burner or igniter
3. Provision for leak tests and repair of the piping system
4. Permanent provisions to include means for making easy and accurate tightness tests of the main gas supply safety shutoff valves as well as the individual burner gas safety shutoff valves
5. Vents located so that there is no possibility of vented gas entering the boiler room or adjacent buildings
6. Vents placed high enough that escaping gas will not be a fire hazard
7. Header vent lines that run independently
8. Igniter vent subsystem that runs independently of the burner vent subsystem so there is no chance of backflow into the burner
9. No cross-connection between venting systems of different boilers

PULVERIZED COAL SYSTEMS

One of the variables in the design of a pulverized coal supply system is the location of the primary air fan relative to the air heater and pulverizer. The combination shown in Figure 10.6.9 is known as a "cold" system and includes a large primary air fan supplying drying air via the air heater to a group of pulverizers. The other basic system provides hot air to individual primary air fans for each pulverizer located downstream of the air heaters.

Pulverized-coal-fired systems capable of burning a wide range of coal fuels have several necessary functions. Raw stored coal must be transferred to the pulverizer in measured and controlled quantities. Hot air mixed with tempering cool air is blown into the pulverizer to dry the coal (see Figure 10.6.9). The mix temperature is controlled by the temperature of the air-coal stream at the outlet of the pulverizer, based on the type of coal being pulverized. A temperature that is too low, as when particularly wet coal is being fed, will impair pulverization. A temperature that is too high can cause coking and risk a fire in the pulverizer and burner piping.

Fuel changes in existing plants, brought about by economic or environmental benefits, must be carefully weighed by the user. Changes in coal qualities, such as heat content, hardness, moisture, and so on, may challenge the ability of existing pulverizer systems to dry and deliver an adequate supply of pulverized fuel to the boiler. The adequacy of pulverizer fuel systems to accommodate these fuel changes should be investigated when contemplating changes in fuel source.

The advent of NO_x emission regulations has increased the likelihood of unburned carbon in the fly ash. It is therefore even

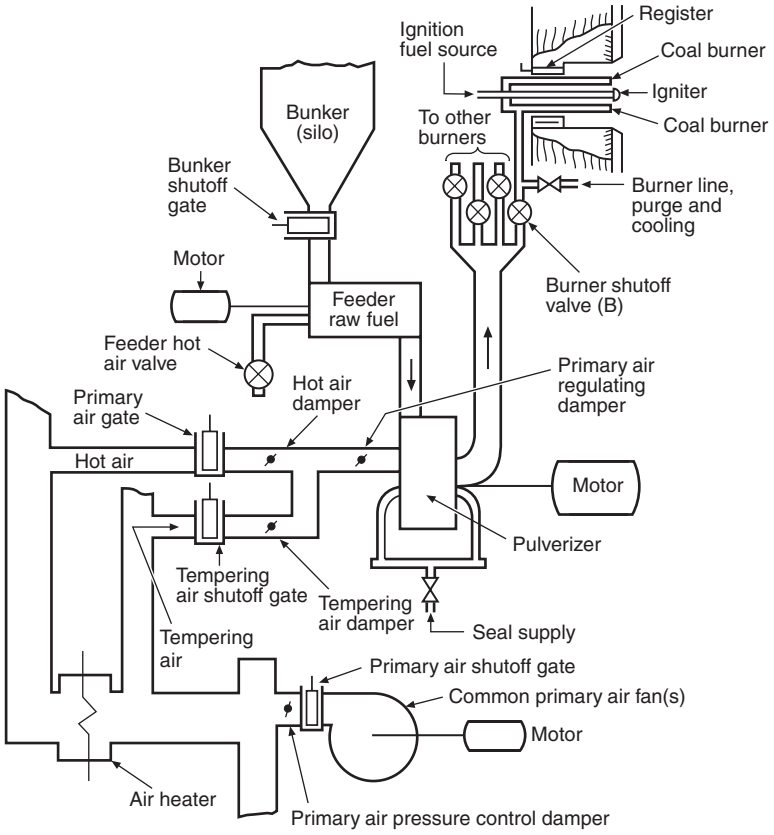

FIGURE 10.6.9 Direct-Firing System for Pulverized Coal

more important than in the past that coal be pulverized to the specified fineness. Testing and pulverizer maintenance will ensure proper sizing. Where needed, improved classifiers can be retrofit on existing pulverizers. On existing systems where additional fineness is desired, rotating, or dynamic, classifiers have been successfully retrofit on existing pulverizers. They are also an option on newly installed systems.

The primary air is designed to transport the fine coal from each pulverizer to its several associated burners in controlled amounts, well distributed among the burners. It is important to establish that the transport velocity in each pulverized coal pipe is equal. Periodic retesting is also required.

At the burner, the coal-air mixture is combined with a measured amount of secondary air to serve the following several purposes:

1. The fuel must be volatilized and completely consumed in a continuous process starting with an initial zone of stable ignition at the burner and continuing through the combustion process with minimum unburned combustibles in the stack gas and ash hoppers.
2. The total air to each burner and to the burner zone must contain the lowest level of excess air possible to minimize stack losses and NO_x while achieving a high level of combustion efficiency.
3. The air should surround the combustion process at each burner to minimize reducing atmospheres at tube surfaces. Some boilers are equipped with an "air boundary" to protect tubing near the burners.
4. Stable ignition is necessary at each burner to ensure continuous combustion. A means of flame detection is also needed at each burner. The ability to distinguish main and igniter flame separately is important, especially in starting and stopping burner operation.

Products of combustion are transported from the furnace through platen and pendant superheater and reheater surfaces, through the convection pass including the economizer surface, and through the air heater to accomplish the necessary heat transfer before being transported to the air pollution control system(s) by the induced draft (ID) fan. The boiler is designed, based on the specified coal, to minimize slag and other solid deposits on the heat transfer surfaces. As is the case with pulverized fuel systems, drastic changes in coal quality must be investigated with regard to their effects on combustion and slag formation in the furnace and downstream surfaces. Steam temperature and other unit performance parameters may change as a result and changes may be necessary to effectively use the new fuels.

The largest modern boilers are capable of supplying steam to 1300 MW reheat turbines. This large capacity coupled with poorer fuel quality created the need for large pulverizers capable of processing 75 tons (68.04 metric tons) or more of coal per hour. The pulverizer shown in Figure 10.6.10 is a roll-and-race type that utilizes three large-diameter rolls spaced equally around the mill. The rolls are mounted on axles; in turn, the roll assemblies are attached by a pivoted connection to a stationary overhead frame that keeps them in their roll path while permitting limited radial freedom of movement. Grinding pressure is supplied by springs that apply force to the axles of the rolls. The grinding ring rotates at low speed and is shaped to form a race in which the rolls run.

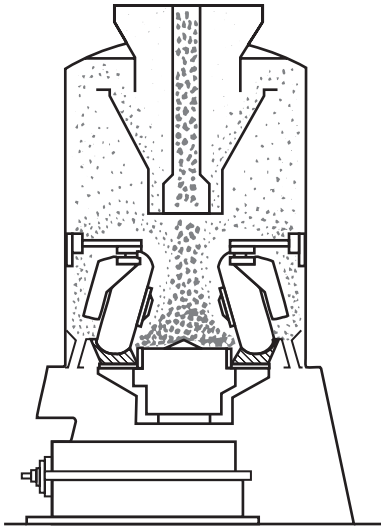

FIGURE 10.6.10 Large Coal Pulverizer

Raw coal is fed into the mill either inside or outside of the grinding race. It immediately mixes with the partially dried and ground coal that is circulated within the grinding zone by the airflow through the pulverizer. Coal fines are carried by the air to the classifier. The finest fraction of the coal, along with the air, leaves the pulverizer through the outlet pipes. Oversize coal is returned to the grinding zone through a seal at the bottom of the classifier.

FLUIDIZED BED COMBUSTION

The world's first fluidized bed combustion (FBC) boiler, a 0.5 MW(e) pilot unit, was placed in service in 1967. After being commercialized, hundreds of FBC units of moderate size, 10 to 200 MW(e), have been built around the world to exploit the availability of low-cost waste fuels. Several are over 300 MW (e). In 2009 a 460 MW(e) FBC will be placed in commercial service in Poland. There are many diverse FBC designs for the smaller units but the larger units use what is termed "circulating fluidized bed" technology.

Characteristics of FBC

The two central characteristics of the fluidized bed boiler, when compared to stokers and pulverized coal, are (1) the bed and (2) the bed temperature. *Bed* refers to the pile of granular solid particles in which the fuel is burned. Air flowing up from beneath and through the bed causes the individual granules to separate and move about. Fuel added to the bed is ignited by the hot bed particles. In turn, the burning fuel transfers the heat of combustion to the inert bed particles.

The bed, cooled by a variety of techniques, moderates the combustion and keeps the bed temperature in the range of 1500°F

(815°C) to 1650°F (899°C) (Figure 10.6.11), which, in turn, leads to reduced slagging and fouling, lower emissions of NO_x, and an environment where added limestone (primarily $CaCO_3$) can react with sulfur. The moderate combustion temperature and turbulence also provide an ideal environment for the combustion of a wide variety of low-grade fuels, for example, anthracite culm to wood wastes, as well as high-grade coal.

To control the bed temperature at about 1500°F (815°C), roughly 50 percent of the heat of combustion must be removed as rapidly as it is released. The bed solids play this role by giving up heat to boiler, superheater, and reheater surfaces, both inside and outside the furnace boundaries. In bubbling fluidized beds, water tubes are often placed in the combustion bed itself. Particles also recycle within the furnace, giving up heat to the water walls. In a circulating fluidized bed (CFB), heat is also transferred from the bed particles to the water walls and, in some designs, to a bubbling bed external to the furnace (see Figure 10.6.11).

CFB systems currently have the dominant market share. Although combustion and other system hazards are similar for bubbling and circulating FBCs, the remainder of this discussion describes CFBs.

To control NO_x, air is admitted both below and above the dense bed. Although the split of fluidizing (primary) and secondary air varies between designs, the values are roughly 50/50. Thus, the dense bed operates with an air deficiency; that is, it is fuel rich, and more than half the combustion occurs above the dense bed. This mode of operation is analogous to that of the low-NO_x burner shown in Figure 10.6.1. The temperature of the gas-solids stream leaving the furnace is roughly at the same temperature as the dense bed. Further, 99+ percent of the solids are removed by the large cyclone for recycling to the furnace.

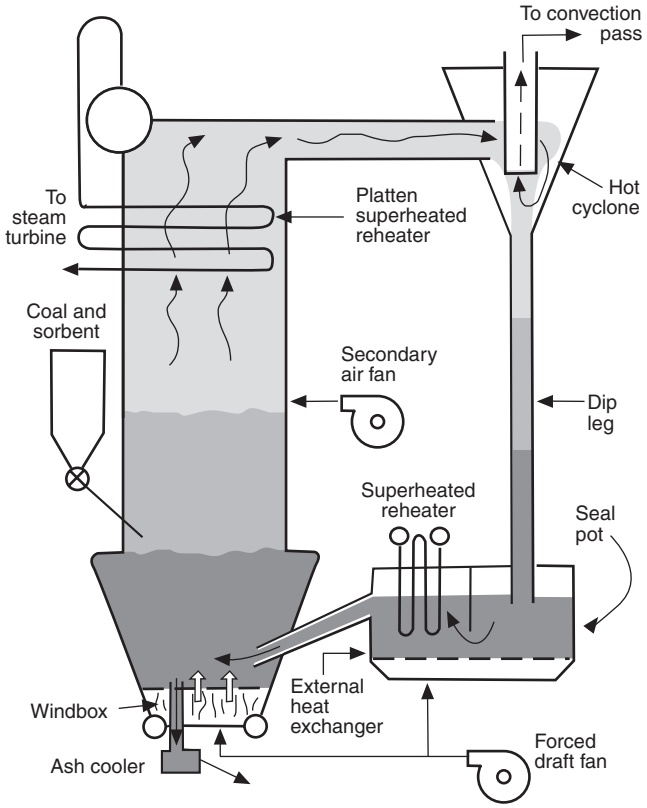

FIGURE 10.6.11 Circulating Fluidized Bed Boiler

SPECIAL FBC HAZARDS

Most potential FBC hazards are similar to those of suspension-fired boilers. In particular, storage of the fuels in piles and bins always poses the risk of spontaneous combustion. Owners of FBC plants should become familiar with the practices of industries that produce the waste fuels the FBC will be burning. There are, however, some hazards unique to FBCs. For this new technology, it is important that operators be trained to deal with relatively rare but serious possibilities. The special hazards are as follows:

1. *Hot solids spills.* A large FBC contains many tons of very hot aerated solids. Bottom ash-removal pipes have failed in several plants, leading to large spills. Plant designers should avoid placing critical components and controls in the vicinity of a potential spill point. Several maintenance workers have died when hot solids in the dip leg and seal pot of one unit flowed into the adjacent empty furnace many hours after the CFB was shut down.

2. *Lime burns.* Removal of most of the fuel's sulfur requires limestone feed rates that exceed the stoichiometric ratio of calcium to sulfur (40 lb/32 lb [18 kg/15 kg] C 1:1). Ratios of 2:1 or more are not unusual, which means that the fly ash and bottom ash are rich in CaO, that is, quicklime. High temperature can be generated when quicklime is mixed with water deliberately, as in an ash conditioner, or inadvertently, as when in-furnace maintenance is required. Removal of the bed before furnace entrance is now the common practice.

3. *Steam generation after trip.* The mass of hot particles contains sufficient sensible heat to continue steam production at near full capacity for several minutes after the fuel source is tripped if the fluidizing airflow is continued. Thus, a loss of feedwater should lead to a fan trip as well as a fuel trip.

4. *Operation at very high fuel-air ratios.* Because of the mass of hot solids, an FBC's inherent combustion stability permits operation with as much as four times the normal fuel-to-air ratio. In several such cases, the accumulation of fuel in the bed led to a rapid increase in bed temperature when some operational change occurred. It might also lead to a furnace explosion.

Although FBCs do have some special hazards that need to be considered by designers and operators, the safety record over FBCs' commercial history has been quite good. To start an FBC, it is necessary to heat the bed material to above the ignition point of the main fuel by use of oil or gas burners. Just as in any boiler, FBCs are most vulnerable to explosion during start-up. (See hazards discussed for oil and gas firing.)

BOILER-FURNACE HAZARDS

Explosion and fire are the most serious potential hazards in boiler-furnaces and their associated pipes, ducts, fans, and fuel bunkers. Explosions occur when an ignition source contacts a combustible mixture of fuel and air. When a combustible mixture has accumulated in a large, confined space of the equipment, a very damaging explosion can occur. Such accumulations can result from an equipment malfunction or an operator error associated with an inadequate or improper purge or incorrect operation of burner equipment. Because even a minute ignition source might initiate a substantial explosion and ignition sources abound in a furnace, for example, static electricity, hot slag, or glowing fly ash in a hopper, safe operation must emphasize avoiding creation of a large combustible mixture.

A temporary loss of flame caused by an interruption in fuel, air, or ignition energy can allow a combustible fuel–air mixture to accumulate before ignition is reestablished. Any momentary fuel-rich operation might also lead to a combustible accumulation. For example, leaking fuel could vaporize and collect in an idle furnace only to ignite explosively when the first burner is lighted. In multiburner units, the undetected loss of flame at a burner could allow an explosive mixture to accumulate somewhere in the volume of the furnace, only to be ignited by other burners. The classic example of operator error is failure to purge the furnace of combustible mixtures between repeatedly unsuccessful attempts to lightoff the burner. Another is to ignore the implications of small explosions, that is, puffs that do no damage but could be symptoms of a serious defect.

Modern burner management and flame detection systems are designed to assure proper sequencing and safe operation of the burner and fuel supply system. Maintaining that equipment in a fully functional mode will assist the operator in assuring safe operation and in taking appropriate action if an upset or abnormal condition is detected. Bypassing of these systems or its components must be carefully considered as it places a greater burden on operating personnel, who may not have the ability to monitor all the components of a modern boiler system and its many subsystems.

Hazards of Oil Firing

Fuel oil is a complex blend of hydrocarbons having a wide variety of molecular weights and boiling, freezing, and flashpoints. At a sufficiently high temperature fuel oil will partially volatilize, thereby creating new and unpredictable liquids, gases, and solids. Boilers have been fired with unrefined crude oil containing very volatile light ends, such as propane, butane, and pentane. However, with the rise of oil prices this is no longer common. Refined boiler fuels have had the light ends removed to produce gasoline and other valuable products and are thus less volatile. A new fuel form termed *Orimulsion*™ is a blend of bitumen (e.g., tar) and water. Any water-containing fuels can pose a hazard when separated water, rather than fuel, is pumped through the burner.

No. 1 and No. 2 fuel oil, and fuels commonly known as kerosenes, range oil, furnace oil, and diesel oil, are called *distillates,* whereas No. 5 and No. 6 fuel oil are referred to as *residuals.* Most large boilers designed for oil are designed for Nos. 5 or 6 oil. Distillates are used in boilers designed for natural gas as the primary fuel. Very volatile oils (sometimes used in very cold regions), crude oil, and many by-product fuels require that electrical motors, switches, and other components be designed to explosionproof standards.

For heavy oils (Nos. 4, 5, and 6), preheating is necessary to reduce the viscosity of the oil flowing to the burners and ensure proper atomization. This preheating is an important part of an integrated safety system designed to avoid flame interruptions. Also, if sludge is allowed to accumulate in storage tanks, it could plug strainers or burner tips. Water normally accumulates below the stored oil, which is less dense; it is therefore important to design tank suction lines so that they draw from above any potential water level.

Oils from different sources, even with similar specifications, can sometimes cause problems when stored in the same tank due to chemical reactions. When oil shipments having widely different viscosities or gravities are stored in the same tank, a significant change in fuel input rate (without a corresponding change in airflow) can occur and impair complete combustion. In any event, fuel oils should be tested for their conformance to specifications soon after receipt.

Where the same burner is used for heavy and light oil (depending on price or availability, for example), special care must be taken that the correct valve settings and interlocks are selected. When very light oils with low electrical conductivity are used, static electricity can build up and provide an uncontrolled ignition source. Light or heavy, oil leaks pose a potential fire hazard. Assembly and disassembly of pipes and equipment should be done with care to avoid leaks. Leaks that do occur should be promptly stopped and cleaned up.

Combustion efficiency of mechanical atomizing burners can be affected by a wear-induced change in orifice size. Improper cleaning can also damage burner tips. Individual burners operating fuel rich or with very low excess air can cause combustibles to accumulate in the furnace. Periodic flow testing may be necessary. Unsafe operating conditions can also be created by the failure of personnel to reinstall a tip, gaskets, or sprayer plate during burner reassembly.

Major oil flow transients can be caused by rapid operation of an oil supply valve, individual burner shutoff valve, or the regulating valve in the return oil line from the burner header. Uncontrolled changes in the fuel input to the furnace can produce hazardous conditions.

Oil flow to individual oil guns can also be adversely affected by such conditions as variations in burner elevation, distance from the regulating valve, and pipe size, all of which can be hazardous on low-pressure burners.

Hazards of Gas Firing

Hazards in gas-fired systems start with gas leaks and the development of fuel-rich mixtures within the boiler or ductwork. Potentially hazardous accumulations can also develop in other building areas, particularly where gas piping is routed through spaces that are not adequately ventilated. Unlike oil, gas leaks are not visible and plant noise can prevent the leak from being

heard. Odorants might or might not be present at sufficient concentration to be detected via the nose.

Within the furnace it is possible for air-fuel ratios to be altered severely without producing any visible evidence at the burners, furnace, or stack, thus allowing a combustible mixture to accumulate over time. Combustion control systems, when responding to falling steam flow or pressure due to an increase in demand for fuel, are potentially dangerous unless protected or interlocked to prevent the creation of a fuel-rich mixture and a loss of ignition.

Whereas gas liquids are normally removed in or near the gas fields, natural gas might be *wet*. A wet gas implies the presence of liquid fuel components, which, if carried into the burners, can result in momentary increases in fuel input and/or a flameout, followed by possible reignition and explosion. For this reason, systems using wet gas require special attention.

Gases supplied from one or more sources can introduce unacceptable hazards if they have significant differences in volumetric heating value due to the ratios of propane, butane, and so forth, to methane. With such variable supplies, it is necessary to provide instruments that are responsive to variations in heat value (e.g., specific gravity or heating value meters), and appropriate alarm and combustion compensation devices. Similar problems will be encountered if proper recharging of the gasline does not follow line maintenance.

Discharges from relief valves will produce a particular hazard unless vent lines are carefully designed with all potential weather conditions considered to avoid reentry of gas into the boiler room. Purging preceding maintenance can also lead to a hazard.

Burner pulsation or combustion-driven oscillations remain a mystery associated with gas firing and, to a lesser degree, with oil firing. When one or more burners on a large unit begin to pulsate, there is a feedback mechanism that leads to variations in furnace pressure, fuel input, and heat release. The action can become violent as each pulse adds energy to the next oscillation. At times, the whole boiler can shake. Adjusting only one burner might start or stop pulsation. At times, only minor burner adjustments will eliminate pulsation. In other instances, it might be necessary to make physical alterations to the burners. Alterations might include modifying the gas ports, impinging gas streams on one another, or installing a device that changes the fuel-air mixing characteristics.

Hazards of Pulverized Coal Firing

When coal is crushed, fresh reactive surfaces become available for oxidation. The coal in the storage bunkers ahead of any pulverizer is subject to self-heating and, in cases where the heat is not dissipated, spontaneous combustion. The three conditions that can lead from moderate self-heating to uncontrolled combustion are (1) excessive fines, (2) a source of air, and (3) storage for an extended period. Once a mass of coal is burning, quenching with water will lead to a reaction between water and hot carbon, producing combustible CO and H_2. Dealing with a bunker fire by running coal into the boiler via feeders, pulverizers, and burners is discouraged, as it can lead to pulverizer fires or explosion. In addition, the burning material is likely to damage fuel system components, such as feeders and internal pulverizer bearings. Self-heating can be detected by monitoring the CO content of the air in the empty space above the coal. Thermocouples can also be useful, but they can easily miss a hot spot since crushed coal is actually a good thermal insulator.

Very wide variations in the size of raw coal, moisture, or clay content can cause erratic feeding of the coal to the pulverizer and, often, complete stoppages. As-received coal might contain foreign matter, such as scrap iron, blasting wire, railroad ballast, wood, rags, excelsior, and so on, which could interrupt the coal feed, damage or jam equipment, or cause a spark within a pulverizer.

A large boiler may burn 100 lb (45.4 kg) of pulverized coal per second, but as little as 0.05 oz per cu ft (0.05 kg/m^3) of air forms an explosive mixture; therefore, as little as 3 lb per 1000 cu ft (1.0 kg per 20 m^3) can be hazardous. Thus, an explosive mixture will develop very quickly if a momentary flameout occurs. A special hazard is methane gas released from freshly crushed or pulverized coal, which can accumulate in enclosed spaces, such as bunkers, and within pulverizers and burner piping.

Pulverized coal, entrained in the primary air stream, is conveyed through pipes from the pulverizer to the burners. To prevent flashback or settling of coal particles in the burner pipes and preignition, it is necessary to establish a minimum air coal velocity for the pulverizer, generally in the range of 60 to 870 ft/sec, depending on volatility, temperature, and the existence of long horizontal runs of coal piping. Pulverizer condition may result in coarser particles, which may cause coal layout at higher velocities. Provisions should be made for cooling and emptying pulverizers and/or burner lines when the burners they supply are shut down to avoid spontaneous combustion and explosion in the pulverizer or burner lines. In addition, burners that have been out of service may have components that are at elevated metal temperatures from the furnace radiant heating. To prevent coking of the coal on initial introduction to the hot burner, performing a purge of cool primary air prior to coal flow initiation is also recommended.

Pulverizer fires and explosions are serious hazards. A sudden, large increase in temperature of the mixture leaving the pulverizer or in the temperature of the casing indicates that a pulverizer fire has started. Fires are caused by (1) feeding burning fuel from the bunkers or (2) spontaneous combustion of fuel in the pulverizer or piping. Although pulverizers are now designed to withstand a substantial overpressure, a fire is still serious and should be dealt with promptly. In a major overpressure incident, substantial damage and rapid escape of fire can be experienced in connecting components such as air ducting. Personnel in the area can be subject to severe injury. When a fire is detected in a pulverizer system, in addition to the steps listed later, a visible and audible warning system should be activated as soon as possible and all personnel should steer clear of the immediate hazard area until the hazard is abated. Essential personnel should exercise extreme caution in addressing the situation and performing their function once the situation appears under control.

The general steps for extinguishing the fire are as follows:

1. Remove the pulverizer from service without emptying to avoid creating a sudden air-rich (explosive) mixture condition.

2. Prevent air infiltration by closing all burner line valves and inlet air dampers and sealing the air valve.
3. Admit steam or inert gas into the pulverizer through the connection provided to
   (a) Smother the fire.
   (b) Maintain an inert atmosphere until the coal has been removed and the housing has cooled.
4. Dump the coal stored in the pulverizer through the pyrite gates.
5. Rotate the pulverizer without operating the primary air fan to complete the swirling and cleaning procedure.

Many manufacturers recommend the introduction of an inerting medium during routine start-up and shutdown sequencing of the pulverizer. Various pulverizer manufacturers have different requirements, and some of these precautions are guided by coal qualities.

Hazards of Low-NO_x Firing

Some steps, such as the following, taken to reduce emissions of existing units could lead to furnace safety problems:

1. NO_x reduction methods might reduce the margins of safety formerly available to prevent accumulation of unburned fuel during upsets.
2. Flue gas recirculation, a common method of reducing NO_x production, requires that operators be aware of the oxygen content of the combustion "air" and/or have knowledge of the distribution of air and of recycled flue gas.
3. Unburned combustibles often increase with low-NO_x firing. This means that horizontal ducts and hoppers can contain smoldering, carbon-rich ash—a hidden ignition source. Reliable CO analyzers are available for detection of combustible gases that are indicative of fuel-rich or imbalanced air-fuel mixing conditions in the furnace. Properly placed systems will alert an operator to conditions that may require action to correct.

Hazards of Fluidized Bed Firing

Attempting to start main-fuel flow before the bed is at the proven temperature for that particular fuel can lead to a furnace explosion. Interlocks are to be provided to prevent such maloperation and must be reset, after testing, when a very different coal is to be fired. Hot restarts without a purge, for example, following an emergency trip, are permitted only if the temperature of the fluidized bed is high enough to ensure proper ignition of fuel.

Although flame detectors are useful for proving a pulverized coal flame, they are not useful in FBC. Instead, the bed temperature is proved safe by a number of in-bed thermocouples. The thermocouple readings are only reliable indicators of an average "safe" bed temperature when the bed is actively fluidized and thus thoroughly mixed.

OPEN REGISTER LIGHTOFF AND CONTINUOUS PURGE PROCEDURE

Furnace explosions in large water-tube boilers in the 1960s led to the codification of the open-register lightoff and continuous purge procedure for all fuels. This procedure maintains airflows at or above the prescribed minimum of 25 percent of full-load *mass* rate airflow during all operations of the boiler. Until the 1995 edition of NFPA 8502, *Standard for the Prevention of Furnace Explosions/Implosions in Multiple Burner Boilers*—now NFPA 85, *Boiler and Combustion Systems Hazards Code*—the *volumetric* airflow rate was specified in recognition that mass flow rate must be increased at low (during start-up and shutdown) air temperature to maintain air and gas velocities. In any event, the continuous purge procedure has been shown to prevent the inadvertent accumulation of a hazardous air-fuel combustible mixture in the furnace or setting.

The continuous purge procedure is based on the concept that three basic conditions will significantly improve the margin of safety, particularly during start-up. These conditions are as follows:

1. Minimum number of required equipment manipulations, thus reducing the likelihood of operator errors or equipment malfunctions
2. Means for establishing the desired fuel-rich condition at individual burners during lightoff
3. A very air-rich furnace atmosphere during lightoff and warm-up, created by maintaining total furnace airflow at the same rate as that required for furnace purge

In its simplest form, the basic procedure that satisfies these three operating objectives is as follows:

- Place all or most of the burner air registers in a predetermined open position.
- Purge the furnace and boiler settings with the burner air registers in that same predetermined position. The total airflow for purge must not be less than 25 percent or more than 40 percent of full-load mass airflow.
- Light the first burner or group of burners without any change in airflow setting or in burner air register position.

At initial start-up a boiler should be tested to determine whether any modifications are required to obtain satisfactory burner ignition or to satisfy other design limitations during lightoff and warm-up. For example, some boilers will be purged with the registers in the normal operating position. In this event, it might be necessary to momentarily close the registers of the burner being lighted to establish ignition. However, unnecessary modifications in basic procedure are to be avoided, thereby satisfying to the greatest degree possible the three basic objectives given previously, particularly that of minimizing equipment manipulations.

Suggestions have been made to modify the continuous purge requirement to allow improved NO_x control and increased efficiency at low loads. No changes have been approved by the NFPA committee, since tests and data do not exist that prove reducing airflow below 25 percent (or purge) can be done safely.

FIRE AND EXPLOSION PROTECTION

Prevention is clearly the key to fire and explosion protection. Good facility design, selection of reliable equipment, system monitoring, and malfunction alarm instrumentation are key

elements in preventing fires and explosions in boiler furnace systems. With the cost of a major boiler explosion ranging to $100 million, replacement power costs included, operator training and maintenance critical to prevention are obviously worth the cost.

The entire system—boiler, furnace, fuel supply, air supply, vents, piping, and ducts—is designed to specific parameters and for specific operating limits. At no time should these limits be exceeded without a detailed engineering analysis and the modifications indicated. This is particularly relevant when new emission standards are imposed on an operational plant.

SPECIAL CONSIDERATIONS FOR SMALL BOILERS

Large boilers will be constructed as separate structures, but small boilers (under 12,500,000 Btu/hr [3,663 kW]) are often installed in existing buildings. Good facility design requires the boiler be installed in a separate room or structure, preferably of noncombustible construction. Boilers should be set on concrete floors or platforms that extend beyond the equipment for a distance of at least 4 ft (1.2 m) in each direction. If they must be set on combustible floors, there should be sufficient air circulation beneath the furnace to keep the temperature of the combustible floor below 160°F (71°C). (See Section 10, Chapter 2, "Heating Systems and Appliances," for an explanation of the temperature limits for protection of combustible surfaces.) This protection can be provided, for example, by laying 4 in. (102 mm) thick hollow masonry block covered with sheet metal on the floor.

If possible, metal chimneys or smokestacks should not pass through combustible floors, ceilings, or walls. If such chimneys must pass through combustible roofs, sufficient clearance and/or insulation should be provided to keep the temperature of the combustible materials below 160°F (71°C). Generally, minimum clearance is considered to be 18 in. (457 mm).

INTERLOCKS, ALARMS, AND OPERATOR COMPETENCE

A system of interlocks should be provided to prevent improper sequencing by operating personnel and to shut down operations if certain critical malfunctions occur. Both audible and visual alarms serve to warn operators to take certain corrective steps; others may indicate what automatic functions have occurred to reduce a hazard. New boilers should not be fired until adequate safeguards have been installed and tested. Bypassing safety interlocks with electrical jumpers, for example, should *never* be permitted by the contractor or the owner.

Safe operation cannot be ensured solely by equipment design and adherence to the manufacturer's operating instructions. Competent operators who understand the processes involved are also needed. Technical competence should be maintained by a program of periodic retraining so that increasing familiarity with the system does not tempt operating personnel to take shortcuts in operating procedures or to bypass safety devices. Where operator error has been responsible for a serious accident, inadequate training has often been found to be the root cause.

A program of preventive maintenance is needed for the equipment and control devices. Poor preventive maintenance will lead to the need for costly corrective maintenance. A comprehensive equipment history that records, for each date, the conditions found, work done, and the changes made will provide the records needed to plan the next maintenance effort. Forms for these records are often available from the boiler's insurer. Cleanliness and good housekeeping will also contribute to the prevention of fire and explosion. Where pulverized coal is the fuel, care should be taken in cleaning dust settled on ledges (and other spills) so as not to create a combustible dust cloud.

For smaller units, automatic sprinklers are commonly required in combustible boiler rooms; however, in noncombustible boiler rooms, where the potential for sustained fire is slight, portable fire extinguishers or small hose lines might be adequate. Additional guidance on fire protection for fuel-supply systems can be found in Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; and Section 7, Chapter 3, "Storage of Gases."

SUMMARY

In fire-tube boilers a water-filled boiler surrounds the furnace, which is a large central horizontal tube. Hot exhaust gases pass from the furnace through the tubes that traverse the boiler. Boiler explosions led to many deaths in the mid-nineteenth century. Material improvements led to the development of the water-tube boiler, in which the hot gases pass across the water-filled tubes, thereby improving boiler safety. This chapter described the combustion process, discussed fuels used in boiler furnaces, and examined oil- and gas-burning systems and the hazards of pulverized coal firing, of low NO_x firing, and of fluidized bed firing.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on the safeguards for boiler furnaces discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

SECTION

11

Fire Prevention Practices

Steven F. Sawyer

11.1 Waste Handling and Control
11.2 Housekeeping Practices
11.3 Building and Site Planning for Fire Safety
11.4 Fire Hazards of Construction, Alteration, and Demolition of Buildings
11.5 Control of Electrostatic Ignition Sources
11.6 Lightning Protection Systems

The fire prevention practices section focuses on selected activities that offer a high potential for preventing unwanted ignition. The reader is also encouraged to review Section 6, "Characteristics of Materials and Products"; Section 7, "Storage and Handling of Materials"; Section 8, "Special Equipment"; Section 9, "Processes and Facilities"; and Section 10, "Building Services."

The first two chapters in Section 11 address the related topics of waste and housekeeping. Chapter 1, "Waste Handling and Control," covers fire safety aspects of waste management processes, as well as systems and equipment used for waste treatment and disposal. Incinerators, waste compactors, and shredders are among the topics discussed. Chapter 2, "Housekeeping Practices," defines good housekeeping and presents the essentials of good housekeeping, in addition to describing specific steps related to building care and maintenance, floors, occupancy and process housekeeping, outdoor housekeeping practices, and inspections.

Chapter 3, "Building and Site Planning for Fire Safety," considers building interior design, building design and fire department operations, building design and fire suppression, and site planning. Exposure protection is also covered.

The contents of Chapter 4, "Fire Hazards of Construction, Alteration, and Demolition of Buildings," include construction and alterations, supervision of fire protection, demolition operations, asbestos removal, and underground operations.

The last two chapters in the section address fire prevention activities related to various forms of electricity. Chapter 5, "Control of Electrostatic Ignition Sources," defines static electricity and includes discussion on charge separation, dissipation of static electricity, control of ignitable mixtures, flammable liquids and gases, dusts and fibers, and static detectors.

Chapter 6, "Lightning Protection Systems," discusses the nature of lightning, describes the need for lightning protection, and presents a theory of lightning protection. The chapter then covers the protection of property and people from lightning.

Steven F. Sawyer is senior fire service specialist in NFPA's Public Fire Protection Division.

Although typical waste is rarely a source of ignition, it is a potential source of fuel for fires, and it can be ignited from other sources. Therefore, a proper and efficient waste management system incorporating prompt treatment and disposal is essential for good fire safety. This chapter covers fire safety aspects of waste management processes, as well as systems and equipment used for waste treatment, and disposal.

For related topics, see Section 11, Chapter 2, "Housekeeping Practices"; and Section 11, Chapter 4, "Fire Hazards of Construction, Alteration, and Demolition of Buildings."

SOLID WASTE MANAGEMENT SYSTEMS

Waste Management Defined

Waste management generally comprises the collection, internal transport, interim storage, treatment, and the final, or ultimate, disposal of waste or the residues resulting from waste treatment operations. A great variety of alternative processes and equipment are available for providing these functions as part of a total waste management system. Depending on specific waste types, constituents, forms, characteristics, quantities, and generation rates, waste management systems can range from a few simple processes to a complex combination of many processes.

Related Terms Defined

Waste Handling. Waste handling generally refers to those processes associated with the movement of waste after its creation. It comprises the collection of waste at points of generation, the transport of waste to storage areas or treatment systems, and the unloading of waste from the transport system. Waste handling systems can range in sophistication from fully manual to fully automatic operation. Waste handling systems and equipment typically include conveyors, chutes, carts, transport vehicles, elevators, and lifts. Waste handling systems also comprise equipment and devices for loading or charging waste into treatment systems and processes. For example, a mechanical loading device could be part of a system for charging solid waste into an incinerator or compactor.

Waste Storage. Waste storage includes the interim containment of accumulated waste within a confined and controlled area, after its collection and transport, and prior to subsequent handling, processing, treatment, or disposal. Depending on waste type, composition, characteristics, method of containment at points of generation, and means of collection and transport, stored waste can be loose, compacted, shredded, or in another processed form. Waste can also be stored in bulk, such as

Lawrence G. Doucet, P.E., DEE, is the eastern regional manager of the environmental engineering and consulting firm of Hydro-Environmental Technologies, Inc. He has more than 35 years of engineering and consulting experience in waste management, treatment, incineration, and disposal, as well as air pollution control, combustion, combustion control, and environmental compliance. He is also past chair of NFPA 82, *Standards on Incinerators and Waste and Linen Handling Systems and Equipment.*

Sharon S. Gilyeat, P.E., is a principal with Koffel Associates, Inc., with over 25 years of consulting experience. She is a Maryland state fire commissioner; chairs NFPA 82, *Standard on Incinerators and Waste and Linen Handling Systems and Equipment;* and is also an instructor for the Basic Life Safety Code course at the Center for Medicare and Medicaid Services.

in pits or silos, or in individual containers, such as carts, drums, corrugated boxes, special cartons, or bags.

Waste Processing. Waste processing generally includes functions that change or alter the physical characteristics of waste by changing its shape, size, uniformity, or consistency. Such processing is usually provided to facilitate waste handling, storage, treatment, recycling, or disposal operations. Typical waste processing systems and equipment include compactors, shredders, crushers, pulpers, pulverizers, baggers, encapsulators, extruders, and dewatering devices.

Waste Treatment. Waste treatment systems generally comprise devices and technologies for changing the physical, chemical, biological, and/or other waste stream characteristics to render the waste safe for disposal or for compliance with specific waste disposal regulations. For example, waste treatment systems are used for decontaminating infectious waste, for detoxifying or neutralizing hazardous waste, for destroying sharp items such as scalpel blades and needles found in medical waste, and for destroying obnoxious waste such as disposed animal carcasses. Typical waste treatment systems include incinerators, steam sterilizers or autoclaves, shredders, encapsulators, and an array of other processes, such as alkaline digestion, microwaving, infrared radiation, and gamma radiation.

SOLID WASTE STORAGE ROOMS

Rooms in a building or structure that are used for the storage or handling of waste in any form and in amounts exceeding 0.765 m^3 (1 yd^3) uncompacted measure are subject to the requirements of NFPA 82, *Standard on Incinerators and Waste and Linen Handling Systems and Equipment.* The walls, ceilings, and floors of such rooms are required to have fire resistance ratings of at least 2 hours protected by 1½-hour opening protectives. In addition, such rooms require automatic sprinklers in accordance with NFPA 13, *Standard for the Installation of Sprinkler Systems.*

WASTE CHUTES AND HANDLING SYSTEMS

Types of Waste Chutes

Waste chutes are basically fixed systems for transporting waste from points of generation or interim storage to centralized areas for collection, processing, treatment, or disposal. There are five types of chute systems:

General access, gravity-type system
Limited access, gravity-type system
Pneumatic system
Gravity-pneumatic system
Multiloading pneumatic system

General Access, Gravity-Type System. A general access, gravity-type chute consists of an enclosed vertical passageway through which waste is transferred downward by gravity alone. Occupants of buildings having this type of chute have unlimited access to the chute.

Limited Access, Gravity-Type System. A limited access, gravity-type chute is similar to a general access type except that access is restricted. Entry is gained through locked chute doors or locked service opening room doors. These chutes are used primarily in health care occupancies.

Pneumatic System. A pneumatic type of chute system uses airflow to transport waste from chute service openings to a central collection area. Such systems have chutes that may run horizontally, vertically, or inclined, depending on blower and design characteristics. High-velocity air, which typically transports waste through the chutes at speeds of about 60 mph (79 km/hr), is aspirated through the top of the chute and exhausted at its termination. These systems are often used in hospitals, but they can be used in any size or type of building. Figure 11.1.1 shows a diagrammatic view of a pneumatic chute system.

Gravity-Pneumatic System. A gravity-pneumatic type of chute system uses a conventional gravity-type chute to feed a collecting chamber, which, in turn, is connected to a pneumatic chute system.

Multiloading Pneumatic System. A multiloading pneumatic type of chute system is similar to a pneumatic type system except that entry is gained through automatic, or self-closing, positive-latching inlet doors. The doors are interlocked such that only one can be opened at a time and not when the material damper is open.

Waste Chute Design and Construction

Proper waste chute design and construction are critical to fire safety in waste handling systems. Should a fire break out, waste chutes could readily serve as channels capable of carrying smoke and flames throughout a building or facility. Also, they are often considered waste storage areas because they could

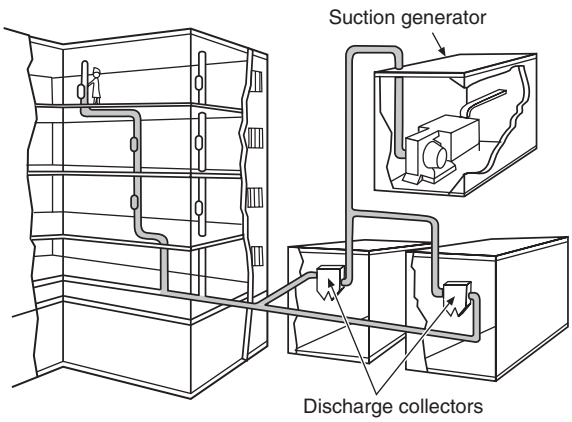

FIGURE 11.1.1 Buildingwide Pneumatic Chute System

become clogged with waste during use and, thus, present fire and smoke hazards. Criteria relative to chute construction, chute enclosures, fire dampers, sprinklers, service openings, and the like are all directed toward minimizing and controlling potential fire hazards. In this regard, strict adherence to the standards in NFPA 82 is required.

Chute Construction. Gravity-type chutes may be constructed of unlined steel, refractory-lined steel, or masonry. Pneumatic waste handling systems are required to be constructed of unlined steel. All unlined chutes are to be fabricated of stainless, galvanized, or aluminized steel for corrosion resistance. Separate design and construction criteria are specified for each type of chute in NFPA 82 for providing structural integrity combined with adequate fire safety measures.

Chute Size. Gravity-type chutes are required to be not less than 22.5 by 22.5 in. (570 by 570 mm) or not less than 24 in. (610 mm) inside diameter. Pneumatic system chutes are required to be not less than 16 in. (406 mm) inside diameter, but they may be smaller if all waste loaded into the chute is first shredded. Waste types and volumes, waste container sizes, user habits, and specific applications must be carefully considered before minimum sizes for chutes and service openings are accepted. For example, a kitchen compactor might produce a typical package measuring 16 by 16 by 9 in. (406 by 406 by 230 mm), which would have a recommended chute diameter of about 36 in. (915 mm).

Chute Service Openings. Properly sized chute service openings are necessary to prevent chute clogging. Oversized openings increase the probability that overly large waste containers or excessive quantities of waste will be loaded into the chute and become clogged. Standards for maximum service opening sizes, developed to prevent such conditions, are as follows:

1. General access gravity chute loading doors are limited to one-third of the cross-sectional area of a square chute and 44 percent of the cross-sectional area of a round chute.
2. Limited access gravity-type chute loading doors are limited to two-thirds of the cross-sectional area of the chute.
3. Pneumatic chute loading doors may have width equivalent to the diameter of chute and the height can be a maximum of 1½ times the diameter of the chute. The minimum door dimension permitted is 18 in. (45.72 cm).

Protection of Chute Openings. Chute service openings are required to be equipped with fire-rated door assemblies to prevent or minimize the spread of chute fires. Without adequate opening protection, the chute can serve as a vertical flue, spreading fire and smoke to multiple floors in a building. Chute doors must be self-closing and positive-latching. Also, pneumatic system service openings are required to have two electrically interlocked doors. For structural integrity, door frames are required to be securely fastened to both the chute and chute enclosure walls.

Chute Enclosures and Penetrations. In order to ensure fire integrity, chute system enclosures, including floor and wall penetrations, require fire-rated protection. Metal chutes, which in themselves offer no fire resistance, must be totally enclosed within masonry walls or other noncombustible, fire-rated material. However, masonry chutes meeting the fire resistance requirements of NFPA 82 are not required to be separately enclosed. If a masonry chute penetrates a floor without closing the opening entirely, the space between the floor and chute is required to be filled with material equivalent to the floor in fire resistance.

Wherever a waste chute penetrates a fire-rated floor-and-ceiling assembly, fire wall, or other fire-rated assembly, a fire damper is not required if the chute is enclosed totally within a fire-rated shaft. Schematic diagrams of typical chute system fire rating requirements are shown in NFPA 82.

Chute Discharge and Terminal Rooms. Waste chutes are required to discharge or terminate in an enclosed room or compartment separated from other parts of the building. Because waste contained within a chute-terminal enclosure area is subject to a potentially high fuel load and uncontrolled burning, the walls, ceiling, and floor of the room or compartment must have a fire resistance rating of 1 or 2 hours, depending on the number of stories in the building and whether a gravity or pneumatic system is used. Terminal enclosures are required to have fire-rated opening protection and automatic sprinklers. These requirements recognize the potential seriousness of fires from waste, which can be difficult to control and can generate large quantities of smoke.

In gravity-pneumatic-type chute systems, the collecting chambers, which can be considered interim discharge or terminal points, are vulnerable to potential fires. They are required to be adequately sprinklered and provided with ready access for fire-fighting measures. Also, the valve room of the system is required to be sprinklered to aid in cooling the space.

Some older gravity-type chute systems discharged directly into an incinerator, and, in some systems, the waste chute also served as the incinerator chimney. Because of the tremendous potentials for fire and smoke hazards, virtually all of these older installations have been discontinued or abandoned. Today, waste chutes are not permitted to discharge directly into an incinerator. Furthermore, because of the inherent difficulties in maintaining fire integrity, systems for automatically transferring waste from chute terminal enclosures directly into an incinerator are not recommended.

Chute Sprinklers. NFPA 82 requires chutes to be sprinkler protected. Chutes require automatic sprinklers at the top, at the lowest inlet level, and at alternate floor levels. Specific requirements for chute sprinklers are in NFPA 13. A good practice is to locate sprinklers where they can be inspected and maintained and yet be out of reach of vandals and beyond the range of falling waste.

Chute Service Opening Rooms. For many years it was general practice to locate chute service openings in public corridors for convenience's sake. This arrangement increased the risk associated with chutes, because any fire in the chute directly affected the exit access corridor system in the building. For this

reason, and for obvious aesthetic and sanitation reasons, NFPA 82 now requires every service opening to be located in a room or compartment separated from other parts of the building by a fire-rated enclosure consistent with the rating of the chute enclosure. Fire-rated opening protectives, including self-closing and latching doors, are also required.

INCINERATORS

Incineration Defined

Incineration is an engineered process using high-temperature combustion for the treatment and disposal of waste. Properly designed and operated incinerator systems can reduce the weight and volume of most municipal, commercial, and institutional solid waste by as much as 95 percent, thereby greatly reducing off-site haulage and disposal costs. Incinerators are often used for the destruction of biomedical and pathological waste at health care facilities, universities, research facilities, and the like. Incinerators are also used for the destruction of hazardous and toxic wastes. In addition, incineration with waste heat recovery is an attractive and cost-effective alternative energy source for many facilities. In terms of fire safety, incineration enables prompt and complete waste destruction, which substantially reduces interim waste storage requirements and associated potential fire hazards.

Incinerators of the past comprised little more than enclosed, single-chamber fireboxes in which uncontrolled burning took place. Such systems provided poor waste destruction and were notorious sources of smoke and odor problems. However, modern incinerator technology offers systems that are readily capable of meeting demanding waste destruction and performance requirements in compliance with stringent environmental regulations. In addition, properly designed, constructed, and operated incinerator systems can be completely fire safe.

Incineration Fire Safety

The very nature of incineration presents potential fire hazards. It typically involves the storage and handling of combustible, sometimes highly volatile waste; the presence of high-temperature, flaming combustion; the exhaust and ducting of high-temperature combustion gases; the handling of hot ashes; and the presence of fuel handling and combustion systems.

Incineration fire safety must fully take into account not only obvious measures, such as the presence of sprinklers and room fire rating, but also less apparent, indirect measures as related to facility planning and design, such as system layout, equipment orientation, waste flow patterns, system operations, and maintenance practices.

Solid Waste Incinerator Categories

There are several different incinerator technologies and designs and wide variations in the types and characteristics of waste that can be incinerated. This section is not intended to cover all of the different technology variations and associated design and construction details for each possible type of solid waste incinerator system. All solid waste incinerator systems and facilities are required to incorporate design details, construction quality, control features, and other measures, as needed, to minimize fire hazards to the extent possible. The basic types of solid waste incinerators that are typically used in industrial, institutional, and commercial facilities are as follows.

Multiple-Chamber Incinerator. A multiple-chamber type incinerator consists of a primary combustion chamber and one or more secondary chambers; it is designed to operate with high-excess combustion air levels—typically 200 to 300 percent. Waste is loaded into the primary chamber for combustion and burnout, and most combustibles entrained in flue gases exiting the primary chamber are fully combusted in the secondary chambers. These types of incinerators are designed and constructed in accordance with standards developed in the mid-1950s. They are almost exclusively used today for burning pathological-type waste, such as animal carcasses and remains (Figure 11.1.2).

Controlled-Air Incinerator. A controlled-air type incinerator is designed on the basis of a two-stage combustion process. In the first stage, waste charged into a primary combustion chamber is burned under starved-air, or oxygen-deficient, conditions. In the second stage, smoke and volatile gases from the primary chamber are combusted in the secondary chamber under excess-air conditions—typically 100 to 200 percent. Controlled-air type incinerators are also commonly called modular combustors and pyrolytic type incinerators. It is estimated that most of the solid waste incinerators built over the last 30 to 40 years have been of the controlled-air type (Figure 11.1.3).

Rotary Kiln Incinerator. A rotary kiln type incinerator comprises a cylindrical combustion chamber, or kiln, that is oriented at a slight incline to horizontal and that rotates slowly on its axis. Waste is loaded at one end, and kiln rotation provides turbulence for thorough waste destruction as well as for enabling the discharge of ash residues from the opposite end. Combustibles entrained in the flue gases from the kiln are burned in a separate secondary chamber. Rotary kiln incinerators have primarily been used in large-capacity industrial and commercial applications burning hazardous waste and widely varying waste mixtures containing sludge-like waste.

Design and Construction

Incinerator systems and equipment, including hot flue gas ductwork, or breechings, and stacks, are subject to extremely severe operating conditions. These include very high and widely fluctuating temperatures; thermal shocks from loads of wet waste; ash residues that damage incinerator refractory linings by slagging and spalling; explosions within combustion chambers from such items as aerosol cans; corrosive attacks from acids and other chemicals; and mechanical scraping and abrasions from metal objects in the waste stream, as well as from operating and cleanout tools. Accordingly, it is critical that incineration systems be suitably designed, constructed, structurally supported, and reinforced to resist any cracking, warping, or distortions that might be caused by such severe conditions and that could allow flames

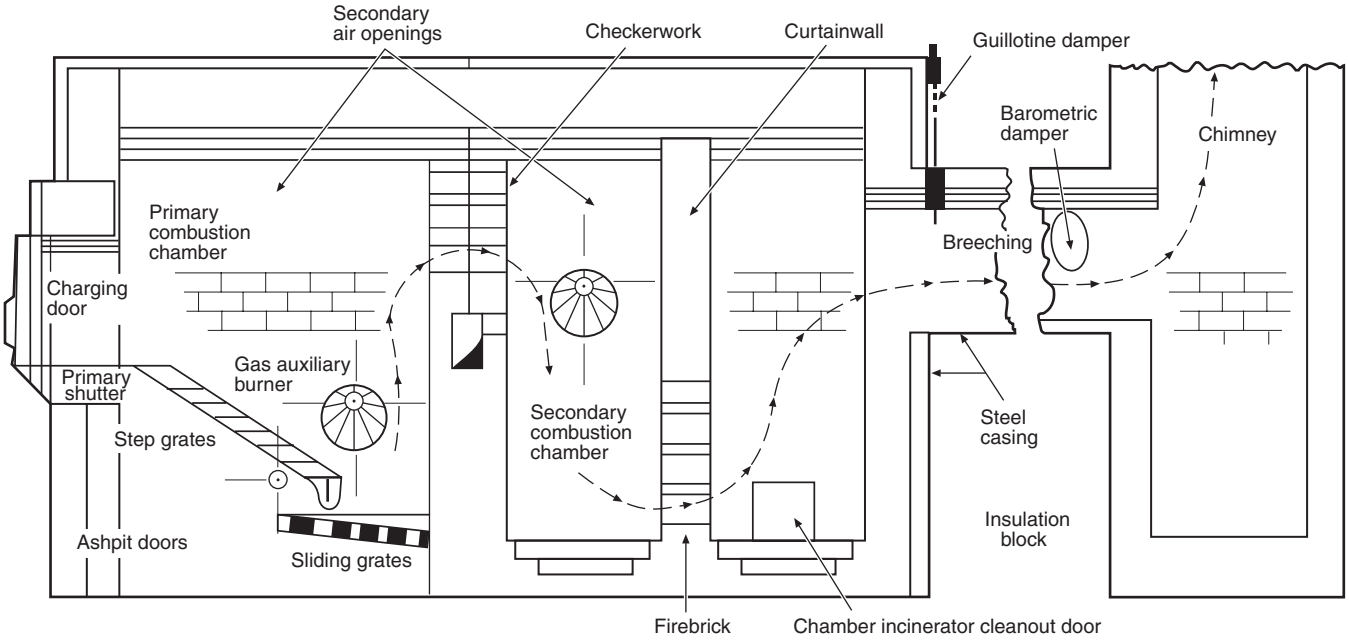

FIGURE 11.1.2 Typical In-Line Type Multiple-Chamber Incinerator

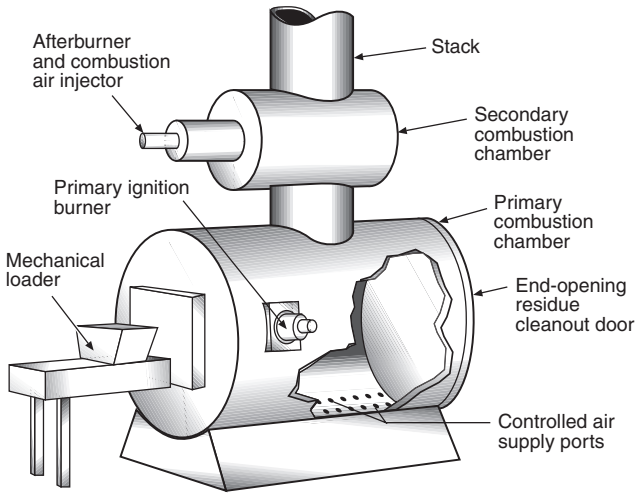

FIGURE 11.1.3 Typical Controlled-Air Incinerator

and hot gases to escape into building areas. Also, the temperatures of exterior surfaces, such as furnace and breeching casings and cleanout doors, must be limited by proper design and construction. Incinerator casings normally accessible to personnel must be insulated, shielded, or appropriately shrouded so that surface temperatures do not exceed 160°F (71.1°C). Handles of operating doors and similar devices must be designed for a maximum 40°F (25°C) rise if metallic and 60°F (37.5°C) rise if nonmetallic. In addition, incinerators must be equipped with a suitable explosion-relief door or panel with an effective area of 1 ft^2 per 100 ft^3 (0.0929 m^2/2.83 m^3) of primary combustion chamber volume.

Location and Arrangement

Incinerator systems and associated facilities are required to be well planned, designed, and implemented to ensure maximum fire safety protection at all times. For example, waste and ash residue containers must never block or obstruct waste charging and cleanout operations or access to work areas or passageways. Waste handling patterns should be such that waste can be charged in a smooth, efficient manner. All parts of the incinerator system, including the ash removal and handling areas, all combustion chambers, and breechings must be easily and safely accessible for routine inspection, cleaning, repair, and servicing. In addition, clearances from furnace charging openings, and between the incinerator top and sides to combustible materials, must be in full compliance with codes and standards.

Waste Charging Systems

The charging of waste into an incinerator has a particularly high fire hazard potential, because the waste loading process typically provides a direct interface between high-temperature, flaming combustion conditions within the incinerator and surrounding building areas. Accordingly, incinerator system design, construction, components, and operating measures must be implemented to ensure that flames and combustion products do not escape from the incinerator into building areas during waste loading procedures or at any other times. Two basic methods of solid waste incinerator charging are manual loading directly through a charging door and mechanical loading with an automatic charging system.

Direct Manual Loading. Direct manual loading has mostly been used on incinerators that burn less than a few hundred

pounds per hour, as well as on systems that are batch loaded or that require loading at infrequent intervals. The environmental regulations in many states have made direct manual loading unacceptable because of its potential to cause excessive air pollution emissions. On those systems where manual loading is allowed, fire prevention measures and design precautions must be implemented, whereby the time that the charging door is open is minimized, and control devices or measures are in place to prevent waste spillage and blockage. The following specific measures should be provided:

1. Charging-door openings large enough to accept the largest or bulkiest waste items without blockage or obstruction. Clear opening areas should not be less than 24 by 24 in. (610 by 610 mm). However, excessively oversized openings must be avoided.
2. Charging-door openings and frames that have smooth edges and are free of projections that may catch or hang up waste materials and cause spillage.
3. Charging doors that operate easily and have positive latching devices and handles that remain relatively cool. Guillotine-type charging doors should be counterweighted or motor operated.
4. Interlocks to stop primary chamber burners from firing when the charging door is opened.
5. Loading trays, where appropriate, in front of charging doors to assist operators in handling and loading heavy and unwieldy waste materials.

Mechanical Loading. Automatic, mechanical charging systems are almost always used on incinerators greater than about 300 lb/hr (230 kg/hr) capacity and, where controlled, charging rates are needed. They are also employed on smaller capacity systems where a continuous airlock interface is required or when mandated by environmental regulations. Mechanical loaders are also used to protect against incinerator overcharging conditions.

NFPA 82 requires that waste charging systems be provided with appropriate controls that will prevent the direct discharge of flames, combustion gases, and heat from the incinerator during waste loading operations. To accomplish this requires a mechanical loader system. NFPA 82 also stipulates that the only exceptions to this requirement are those incinerators that are loaded on a batch basis, whereby the charging door is not opened while waste combustion is taking place.

The most common type of mechanical loading system is termed a *hopper/ram loader,* as shown in Figure 11.1.4. Typically, waste is put into the charging hopper and, on actuation of a system-start switch, the hopper cover closes, the fire door opens, the charging ram injects the waste into the primary chamber, the charging ram returns, the fire door closes, and the hopper cover opens for the next loading cycle. The charging hopper volume and a loading cycle timer help limit the amount of waste that can be loaded into the incinerator per hour, which helps prevent overcharging. In effect, an airlock interface is provided between the incinerator and ambient conditions, because the fire door and hopper cover are not both opened simultaneously and one of them is always in the closed position.

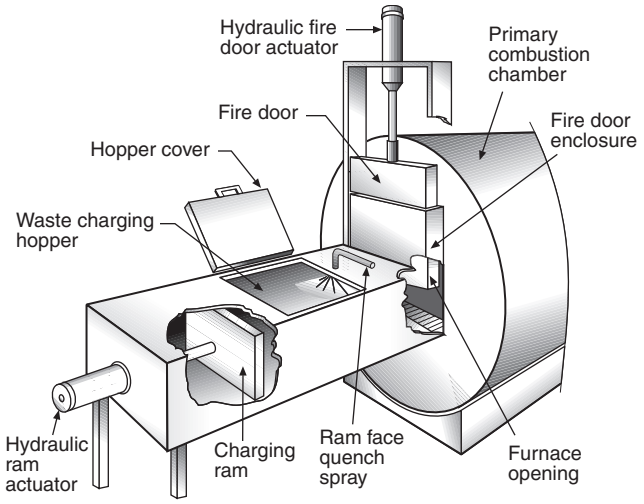

FIGURE 11.1.4 Typical Mechanical Loader

Two potential causes of fire and smoke problems that must be guarded against in hopper/ram loader systems are as follows:

1. *Partial closing of fire door.* Waste can lodge under the fire door and prevent it from closing tightly. This waste could ignite and spread fire back into the hopper and beyond. A partially closed door could also significantly affect incinerator draft, or negative pressure conditions, which in turn could result in heavy smoke escaping from under the partially closed door. To prevent this condition, the fire door should be closed by power, not gravity, in order to seal the opening as tightly as possible should any waste become lodged beneath.

2. *Ram ignition hazards.* When the charging ram injects waste into the incinerator, its face is directly exposed to high temperatures. Eventually, it could heat up enough to be a potential fire hazard. The hot ram face could cause plastic waste bags and similar materials to melt and adhere to it. If these items do not drop from the ram during a particular loading cycle, they could become ignited and carried back into the hopper where they could ignite waste in the hopper.

To prevent this condition, the charging ram should be cooled either by internal water circulation or by a water-spray system that quenches the ram face after every charging stroke. In addition, the loading-hopper volume should be such that a single ram stroke completely empties it of waste. This will minimize the risk of waste being in the hopper to catch on fire. Additional recommended considerations to protect against accidental ignition of wastes in loading hoppers include the following:

- Provision of a flame scanner for immediate detection of hopper fires. Actuation of the scanner could sound an alarm, activate a hopper water-spray system, and/or automatically initiate the loading sequence to inject the burning materials into the incinerator.
- A high-temperature, automatic sprinkler directly over the hopper which is independent of the room sprinkler system

- A manually actuated water spray located above the loading hopper
- An emergency switch that would override the normal automatic loading-cycle-control sequence and cause immediate injection of hopper contents into the incinerator

Residue Removal and Handling Systems

Residue, or ash, removal and handling systems range from fully manual to fully automatic. Because of high costs, space limitations, operational complexities, and technological limitations, older incinerators, and those of small capacity, are cleaned out manually. However, almost all newer incinerators, and almost all incinerators burning more than about 1000 lb/hr (454 kg/hr), are equipped with either an automatic or a semiautomatic ash removal and handling system.

Manual Residue Removal. Manual residue removal cleanout involves the raking or shoveling of ashes from the primary chamber into barrels, bins, or tubs, and sometimes directly onto the floor. Small-capacity incinerators can be readily cleaned from outside the primary chamber through a cleanout door. However, large-capacity incinerators might require the operator to enter the primary chamber for ash cleanout procedures. Except for small-capacity incinerators that are operated infrequently, and which have small ash volume accumulations, manual ash removal is onerous, objectionable, and potentially dangerous in many respects, including intensive, difficult labor requirements; dangers to personnel from heat, ash, dust, and noxious gases; and fire hazards from the handling and containment of unquenched ash residues and embers.

The spraying of water into incinerators to facilitate ash removal by quenching is not recommended because the water will damage the furnace refractory due to thermal shock. As such, water quenching for cooling and dust suppression should be limited to ash already removed from the incinerator.

Ash cleanout without proper containment or quenching is a potential fire hazard if the ashes are hot or contain embers or smoldering material. Also, hot ash containing partially burned items and carbon residues could readily ignite when exposed to ambient air during cleanout procedures. Because of these conditions, NFPA 82 requires that a specially designed system and appropriate measures be implemented to adequately quench and/or fully contain ash residues removed from the incinerators during cleanout. Such measures could include water sprays, a wet quench pit, or a special containment enclosure to enable ash cleanout with minimal exposure to ambient conditions.

Automatic Residue Removal. These systems utilize moving grates, transfer rams, rotating kilns, pulse hearths, or other mechanisms to transfer and discharge ash residues from primary chambers into containment and handling devices. With semiautomatic type systems, ashes are collected in residue carts for subsequent transfer and dumping for eventual off-site disposal. With fully automatic systems, ashes are discharged onto a conveyor or a similar device that continuously and automatically transfers them to a large container for off-site disposal. Most residue conveyor systems are equipped with water troughs or sumps that fully saturate, or quench, the ashes. With cart-type containment systems, the ashes are typically quenched by water sprays surrounding the discharge chute from the incinerator.

For fire safety protection, it is recommended that ash carts used in both manual and semiautomatic type systems be handled with care and, prior to off-site disposal, stored in a fire-rated area in a location that is isolated from stored waste materials. Even when quenched by water sprays or hoses, the containers might still be very hot, and residues within them might tend to ignite spontaneously if disturbed and exposed to room air. It is also recommended that consideration be given for dumping ash carts either directly into an off-site transfer truck or at a landfill rather than within facility building areas.

Incinerator Chimneys and Breeching Systems

The design, construction, termination, and clearances of incinerator chimneys and flue gas ducting, or breeching, systems are required to be designed and constructed in strict accordance with NFPA 82 and NFPA 211, *Standard for Chimneys, Fireplaces, Vents, and Solid Fuel-Burning Appliances,* as well as per applicable building, fire, and mechanical codes.

Chimneys and breeching systems handling low-temperature, wet, and saturated incinerator flue gases downstream from a scrubber system used for air pollution control must be designed and constructed to withstand acidic corrosion conditions. Chimneys and breeching systems handling high-temperature flue gases should be refractory lined and insulated. Special design, construction, and materials are needed for scrubber by-pass chimneys that are used for ducting both hot and wet saturated flue gases. It should be noted that no single type of chimney-refractory lining, construction material, or family of materials is suitable for ensuring chimney integrity and fire safety for all incinerator operating conditions and waste types. Such materials must be carefully evaluated and selected for each site-specific application.

NFPA 82 stipulates that chimneys for incinerators serve no other purpose and that they must not be connected to boiler chimneys unless they are of suitable construction and properly designed and controlled for serving both services.

Auxiliary Fuel Systems

Incinerators require auxiliary, or supplemental, fuel for ignition, warm-up, and maintaining proper, elevated combustion temperatures. Most incinerators fire either natural gas or distillate fuel oil. It is imperative that auxiliary fuel systems, including storage and handling systems, burners, and controls, be installed and tested in accordance with all applicable requirements of local codes and NFPA standards. Burners should be of a type specifically designed and constructed for use in incinerator systems. Burners should also be equipped with automatic ignition systems, flame safeguards, and management systems.

Combustion and Ventilation Air

Depending on the types and heating values of waste burned, incinerators typically require 10 to 20 lb of combustion air per lb (10 to 20 kg of combustion air per kg) of waste incinerated. Ventilation air is required to remove heat that is normally transmitted, or

radiated, through incinerator casings and associated equipment into surrounding spaces, in order to maintain comfortable operating conditions and acceptable incinerator-room temperature levels. Insufficient supply of combustion and ventilation air can result in operational problems and unsafe conditions. Incinerator room areas that are confined spaces or enclosed by tight-fitting partitions are required to be provided with an air-supply louver or air-supply blower system in strict accordance with NFPA 82 requirements, as well as those of NFPA standards applicable to fuel-fired burners. Louvers and ducts providing direct outside air are required to be sized for a minimum of 1 $in.^2$ (645.2 mm^2) of free area per 4000 Btu/hr (1172 W/hr) of total heat input.

Electrical Service

Power and control wiring, including electrical components and control devices, are required to be designed and installed in accordance with applicable local codes and NFPA 70, *National Electrical Code®*. It is recommended that wiring and conduit not be attached directly to incinerator casings, and wiring within about 1 ft (0.30 m) of incinerator casings should have high-temperature insulation. It is also recommended that incinerator system control panels not be located less than 3 ft (0.92 m) from incinerator or hot breeching casings. Wiring, relays, transformers, and other electronic devices for auxiliary burners and other appurtenances should be either remotely mounted or protected from high-temperature damage.

Incinerator Rooms

Incinerators, including associated waste and residue handling systems, are required to be located in a separate, fire-rated room or compartment with fire-rated opening protectives. Such rooms may also be contained in the same enclosure with the building heating system and equipment.

Incinerator Operations

Well-trained operating personnel are required to properly manage the severe and complex operating conditions typical of incinerator systems. Training programs and comprehensive operating and maintenance manuals and instructions are highly recommended and mandated in the environmental regulations of many states. Such training should ensure not only proper incinerator operations but also the continued implementation of safe operating conditions.

WASTE COMPACTORS

Waste compactors are devices that use electromechanical-hydraulic means to reduce the volume of waste and to package it in the reduced condition. Both domestic and commercial-industrial compactors are governed by NFPA 82.

Domestic Compactors

Commonly called kitchen compactors, domestic compactors are designed for use in dwellings and apartment units for compaction of single-family residential waste. Both under-the-counter and movable types are commercially available. Domestic compactors reduce the fire hazard of stored waste by retaining it in a metal container under compaction. However, they must have the capability for manual opening such that waste can be readily removed in the event of equipment electrical failure.

Commercial-Industrial Compactors

Commercial-industrial compactors are typically used in multiple-family dwellings and in many other occupancies as a prime waste treatment system to deal with limited waste storage areas and to facilitate waste handling operations. They may be located either indoors or outdoors, and can be either chute-fed or hand-fed. The four types of these compactors follow:

Bulkhead Compactor. With a bulkhead type compactor, waste is compacted against a fixed plate or bulkhead. When the compacted block is ready for removal, a bag is inserted into the unit and filled with the compacted block.

Extruder Compactor. With an extruder type compactor, waste is forced through a cylinder having a restricted cross-sectional opening. Waste becomes compacted as it is pushed through the cylinder by a driving force. At the cylinder discharge, waste is extruded into a "slug," which is broken off and either bagged or placed into a container. The operation of this type of compactor is shown in Figure 11.1.5.

Carousel Bag Packer Compactor. With a carousel bag packer type compactor, waste is compacted sequentially into bag-lined containers mounted on a carousel type mechanism. As each bag is filled, the carousel rotates to place another bag in position to be filled.

Container Packer Compactor. With a container packer type compactor, waste is compacted directly into a bin or container. When full, the bin or container is either manually or mechanically removed from the compactor unit and replaced with an empty bin or container.

Chute-fed compactors are required to be provided with an automatic, special, fine-water-spray sprinkler in the compaction

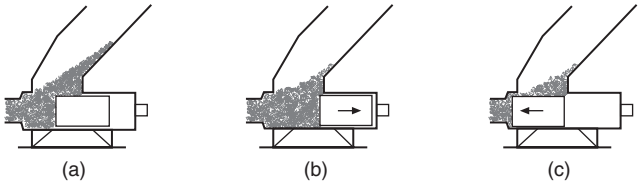

FIGURE 11.1.5 The Sequence of Operation of an Extruder-Type Refuse Compactor. Waste falling from the chute (a) trips a sensor and starts the compacting cycle. The ram moves backward (b) to let refuse fall into the compactor chamber and then moves forward (c) to push the waste through a system of restrictors that compacts the waste and pushes it out of the machine.

chamber. However, hand-fed compactors do not require such protection.

Compaction containers are required to be provided with either a hose connection located near the top of the unit that is suitable for standard fire-fighting equipment, or with an access door that can be opened without disconnecting the container from the compactor.

Chute Termination Bins

Most waste chutes serving compactors do not feed directly into the compactor but into a small storage chamber, a chute connector, or an impact area that is usually large enough to temporarily hold small quantities of waste. Waste collected within these chute termination bins can be potential fire hazards. Accordingly, chute-fed bins are required to be equipped with sprinklers and access doors sufficiently large enough to enable direct access to the interim storage areas in the event of fire. However, if a compactor is loaded manually from a large bin with an open top, the bin need not be sprinklered, because it is sufficient to rely on the sprinklers protecting the compactor room for fire protection.

The bottom enclosure areas of termination or storage bins require special design considerations as needed to enable direct access in the event of fire conditions. For example, should there be an equipment failure, waste will build up not only in the chute termination chamber but also in the chute itself. Subsequently, in the event of a fire and sprinkler discharge, the weight of watered-down waste could become excessive and jam bin closure and discharge devices. Accordingly, sufficient strength should be built into these devices such that they can be operated without breakage or binding under such conditions. A more favorable alternative would be a system that allows discharge into other receptacles, bins, or equipment without the possibility of excessive chute collection.

Compactor Rooms

Compactor systems are required to be enclosed within fire-rated rooms with suitable fire-rated opening protectives as well as with automatic sprinklers.

Compaction ratios, which express the differences in volumes between uncompacted waste and compacted waste, vary widely as a function of waste types and the design capabilities of the particular compactor units and types. Compaction ratios typically range between about 3 to 1 (3:1) and as much as about 5 to 1 (5:1) or greater for special systems. Therefore, compacted waste has widely varying densities, and, if ignited, it can burn to produce large volumes of smoke relatively difficult to extinguish. Accordingly, the storage of compacted waste in buildings should be minimized to the extent possible.

SHREDDERS

Shredders—as well as granulators, grinders, pulpers, chippers, and the like—are sometimes used to process or treat solid waste for volume reduction in order to minimize storage space requirements and to facilitate systems where waste must be mechanically transferred before storage or subsequent treatment. Waste feed bins and hoppers serving shredders are potential fire hazards, and it is strongly recommended that they be protected by automatic sprinklers. If shredders are fed by chutes, it is required that design arrangements be made such that the shredder feed can be diverted or bypassed to enable shredder repairs and servicing and to prevent waste accumulations within the feed chute. All bypass areas and storage areas are required to be sprinklered and enclosed within fire-rated rooms with suitable fire-rated opening protectives. The discharges from shredders are also required to have sprinkler protection.

Potentially explosive conditions are inherent with high-speed type shredders because their operations can produce dust-laden air mixtures that, under certain conditions, could be ignited and deflagrated very rapidly. A recommended method of protection against such possibilities is to provide an explosion-suppression system within the shredder room and an explosion vent, preferably above the shredder, to safely relieve the impacts of a rapid pressure buildup or explosion.

INDUSTRIAL WASTE SYSTEMS AND EQUIPMENT

The term *industrial waste* generally describes waste emanating from manufacturing facilities, processing plants, factories, and the like. However, it essentially has no meaning without further definition, because it encompasses an almost infinite variety of waste.

According to best available estimates, in excess of about 6.8 billion metric tons of industrial waste is generated annually in the United States, of which about 36 million metric tons is designated as hazardous, according to the U.S. Environmental Protection Agency (EPA).[1] Hazardous waste must be managed and disposed of in compliance with specific EPA regulations.

The approximate distribution of hazardous waste generated by major industries is shown in Figure 11.1.6.[1] Table 11.1.1 lists annual waste generation rates for prominent manufacturing industries.

Under the Resource Conservation and Recovery Act of 1976 (RCRA), the EPA instituted a complex set of regulations for controlling hazardous waste from generation through final disposal. This is known as "cradle-to-grave" control. To deal with dumpsite cleanup costs and liabilities not covered by RCRA, the EPA enacted legislation known as the "Superfund" bill. The Toxic Substances Control Act of 1976 (TSCA) was established to regulate chemicals not controlled under other regulations. This act, for example, specifies disposal requirements for polychlorinated biphenyl compounds (PCBs).

For most industries, particularly those generating hazardous waste, the evaluation and selection of waste management and disposal systems is difficult and complex. First, there are numerous options and alternative technologies available, each with differing benefits, risk factors, and costs. Second, the forms and properties of waste vary widely and greatly impact the feasibilities and cost-effectiveness of the alternative technologies. Third, regulatory requirements and restrictions may limit the suitability of various technologies. These complexities and multiplicities are also site specific, making it necessary to evaluate

options and alternatives for each facility on an individual, case-by-case basis.

WASTE MATERIALS

Industrial waste is as varied as the raw materials used in production and manufacturing operations. However, the nature of the industry generally determines the nature of its waste. A furniture plant, for example, discards wood scraps, sawdust and shavings, fabric scraps, glues, stains, and varnishes. Within any specific industry, there can be many different types and forms of waste materials, ranging from plant trash to spent chemicals and aqueous sludges. Other items may include production residues and by-products, packaging scraps, reject products, returned goods, and even animal carcasses from biomedical and veterinary research activities. Such waste can be in the form of solids, sludges, liquids, or gases. The waste can be hazardous or nonhazardous, and combustible or noncombustible.

Hazardous Waste

Hazardous waste is generally defined as any waste, or combination of wastes, that poses a substantial danger or risk, now or in the future, to human, plant, or animal life, and that cannot be handled or disposed of without special precautions. The RCRA regulations covering hazardous waste are contained in Title 40 of the Code of Federal Regulations (CFR) Parts 239 through 299. RCRA hazardous categories include those wastes that have specific, defined characteristics making them toxic, flammable, corrosive, reactive, or explosive. The RCRA regulations also include specific listings of disposed chemicals, residues, by-products of manufacturing process, various substances, and an array of waste sources that must be managed, treated, and disposed as being hazardous. In addition, other waste categories that might be considered potentially hazardous or requiring special handling, treatment, and disposal under other regulations include low-level radioactive waste and infectious or biomedical waste. If improperly handled or disposed, hazardous waste can contaminate surface and ground waters, soils, and the ambient atmosphere. It could potentially poison, burn, maim, blind, and kill people and other living organisms. Most hazardous waste is nondegradable and persists in nature indefinitely. Depending on

treatment and disposal methods, some can accumulate in living things and some work their way into the food chain. Also, some can catch fire or explode at normal temperatures and pressures when exposed to air or water, or by being jarred or dropped.

Radioactive waste is regulated by the Nuclear Regulatory Commission (NRC). Biomedical or infectious waste is regulated by state and local environmental agencies and health departments. Biomedical waste management is not regulated on a federal level. The EPA, however, has promulgated regulations governing new and existing medical waste incinerators, and the Department of Transportation (DOT) has promulgated regulations governing the off-site transport of biomedical waste.

Hazardous Characteristics

The characteristics that define hazardous waste, according to RCRA and other regulations, are ignitability, corrosivity, reactivity, toxicity, explosivity, radioactivity, and infectiousness.

Ignitability. Liquid waste is considered ignitable, or flammable, if its flashpoint is less than 140°F (60°C). This consists mainly of contaminated organic solvents, but can include oils, plasticizers, complex organic sludges, off-specification chemicals, and pharmaceutical by-products.

Nonliquid waste is considered ignitable if it is capable, under standard temperatures and pressures, of causing fires through friction, absorption of moisture, or through spontaneous chemical changes. These include pyrophoric materials, such as phosphorous and aluminum alkyls, which ignite when exposed to air.

Organic vapors can be ignitable if released in combustible concentrations. Vapors can travel considerable distances, reach an ignition source, and ignite. NFPA 86, *Standard for Ovens and Furnaces,* identifies specific requirements for the safe venting of such gases.

Corrosivity. Corrosive waste can severely damage skin and other living tissues, as well as materials, such as metals and finished surfaces. Wastes are defined as corrosive if their pH values are 2 or less, 12 or more, or if they corrode steel at a rate greater than ¼ in. (6.35 mm) per year. These wastes typically comprise strong acids and alkalis.

Reactivity. Hazardous waste characterized as reactive is normally unstable and readily undergos violent changes without detonation. Some reactive wastes are capable of detonation or explosive decomposition at standard temperatures and pressures. Also, some reactive wastes react violently with water, and some form potentially explosive mixtures or toxic vapors if mixed with water. Reactive materials, such as sodium, potassium, and aluminum alkyls, react violently with water and burn fiercely. Strong oxidizers in contact with organic materials can cause rapid combustion or explosion.

Toxicity. Toxic waste kills, poisons, or produces injury on contact with or through accumulation in or on the body of a living organism. This can occur by inhalation or through contaminated food or water. It is both a short-term and long-term problem. Toxic waste might contain either metals, such as arsenic, barium, cadmium, chromium, mercury, and lead, or synthetic chlorinated organics, such as various pesticides. RCRA specifies an extraction procedure test to determine whether such materials are present in significant concentrations to be designated a toxic hazard.

Explosivity. Explosive waste consists mainly of obsolete ordinance and manufacturing wastes from commercial explosives industries. It can also contain waste from the manufacturing of various propellants and pyrotechnics. However, some waste types are formed as carbon and organic dusts that can be potentially explosive in various air concentrations when exposed to ignition sources such as open flames or sparks.

Radioactivity. Most radioactive waste consists of conventional, nonradioactive materials contaminated with radionuclides in concentrations ranging from parts per billion to as much as 50 percent. These are typically called *low-level radioactive wastes.* The biological hazards from radioactive materials are due to the effects of penetrating and ionizing radiation rather than chemical toxicity. The long-term hazards associated with specific radioactive waste are not necessarily proportional to the nominal level of radioactivity, but rather to the specific toxicity and decay rate of each radionuclide that might be present.

Radioactive waste is often generated from biomedical-type research activities. These wastes typically comprise items such as animal carcasses and liquid scintillation counting (LSC) vials having tracer-level, or low-level, concentrations of radioactivity. The NRC specifies maximum permissible concentration (MPC) levels in the environment for the spectrum of radionuclides.

Infectiousness. Waste characterized as being potentially infectious contains pathogens, or disease-producing microorganisms, that are capable of producing disease in humans. However, to be considered a health risk, such pathogens must be virulent, or living, in significant concentrations, and there must be a means by which they can enter the human body such as through inhalation, ingestion, moist body parts, or puncture wounds. Industrial wastes that are potentially infectious are almost exclusively generated from biomedical research activities.

Waste Characterization

Waste stream characterization provides the starting point for designing and selecting waste management, treatment, and disposal systems. This process involves identification of average or representative waste compositions and properties, deviations from the averages, and the forecasting of likely changes.

A characterization program usually begins with a detailed inventory and classification of all waste stream sources, components, and constituents. These are then organized into various groupings or categories to facilitate further evaluations. Typical groupings include form, such as solids, sludges, and liquids; combustible versus noncombustible; and hazardous versus nonhazardous. See Table 11.1.2 for an example of a waste classification system.[2]

The next step in a characterization program usually involves the determination of the physical and chemical properties of the

TABLE 11.1.2 Waste Classification System

Class	*Remarks*	*Example*
I. Solid wastes		
A. Putrescibles		
Household garbage		
Vegetable and fruit processing wastes		
Animal manure		
Dead animals		
Meat, poultry, and seafood processing wastes		
Others, not elsewhere classified*		
B. Bulky combustibles	*Bulky* is defined as a material of a size to present problems by jamming in a compaction truck hopper, an incinerator feed chute, or other such problems in handling or disposal. Its dimensions may not be defined, except by the size and nature of handling or disposal equipment.	
Wood		Timbers, pallets, cross-ties
Paper and paper products		Large cardboard packing boxes, boxcar linings
Cloth		Filter cloths, mattresses
Plastics		Styrofoam™ logs, polystyrene sheets, garden hose
Rubber		Belting, tires
Leather		Conveyor belting
Yard and street wastes		Tree limbs
C. Bulky noncombustibles		Drums, bedsprings
Metal		Carboys, bathroom fixtures
Mineral		
D. Small combustibles	*Small* is defined as a piece of waste material of a small enough size to present no danger of jamming equipment, or otherwise causing problems because of its size. It refers to the size of a piece of the material, not the size of the delivered load.	
Wood		
Paper and paper products		
Cloth		Gloves
Leather		Shoes
Plastics		Milk cartons
Rubber		Galoshes, butyl rubber crumbs
Yard and street wastes		Street sweepings, leaves
E. Small noncombustibles		
Metal		Cans
Mineral		Bottles
Ashes		Furnace ashes
F. Nonempty cans, bottles, and drums	This functional class will require precise definition of the contents by one of the other classes. This establishes the quantity of material delivered in this manner instead of in bulk form.	Bottles of wastes from laboratories
G. Gas cylinders		Oxygen, acetylene
H. Powders and dusts		
Organic		Pesticides, grain dusts, chemical powders, coal dusts
Metallic inorganic		
Nonmetallic inorganic		
Explosive		

TABLE 11.1.2 Continued

Class	*Remarks*	*Example*
I. Pathological wastes Cloth, paper, and plastic Animal and human wastes Instruments and utensils		
J. Sludges	Materials that are solid in appearance, but are wet, either from water or liquid organics. The solids portion is classified.	
Chlorinated		
Brominated		
Fluorinated		
Acid		
Alkaline		
Water-reactive (unhydrolyzed)		
Air-reactive	May represent a material highly reactive with the moisture or oxygen in the air	
Putrescible	May represent the wet form of any of the materials listed under the functional class of the same name, but also includes such materials as wastewater treatment plant sludges	
Miscellaneous organic		
Metallic inorganic	Refers to metals in the uncombined form	Particles of metal in oil
Nonmetallic inorganic	Inorganic compounds	Filter cakes, $CaCO_3$ precipitate
K. Demolition and construction	This functional class is subdivided into the analytical classes shown for bulky and small, combustibles and noncombustibles. It is included as a separate class to quantify materials from this source and to recognize that a delivery may contain a wide mixture of large and small combustibles and noncombustibles.	
L. Abandoned vehicles		
M. Radiological wastes	This functional class will require further definition by one of the other classes. It must be considered to define this type of contamination to refuse, and to consider the special measures involved.	
II. Liquid wastes		
A. Wastewaters	Waste liquids composed almost entirely of water, but containing contaminants in low enough concentration (usually much less than 1.0 percent) to be handled through a sewer system to a wastewater treatment plant. This definition is proposed for exclusion purposes, because these wastes are not normally considered as refuse.	
B. Contaminated waters	Waters containing contaminants in a concentration too high, or of a nature, that handling through a wastewater treatment plant is unacceptable	
Chlorinated		
Brominated		
Fluoridated		
Acid		
Alkaline		Blood, grease
Putrescibles		
Insoluble oils		
Soluble oils		
Toxic organics		
Toxic inorganics		
Soluble metals		
Others (not elsewhere classified)*		

(continued)

TABLE 11.1.2 Continued

Class	*Remarks*	*Example*
II. Liquid wastes *(continued)*		
C. Liquid organics	Liquid at all ambient temperatures	
Chlorinated		
Brominated		
Fluoridated		Many solvents
Sulfurated		
Acid		
Alkaline		
Water-reactive (unhydrolyzed)		
Shock-reactive		
Toxic and hazardous		Pesticides
Soluble metals		
Others (not elsewhere classified)*		
D. Tars	Stiff materials that are semisolid at low ambient temperatures.	
Chlorinated		Chlorinated-substituted hydrocarbons
Brominated		Brominene-substituted hydrocarbons
Fluorinated		Fluorine-substituted hydrocarbons
Sulfurated		Sulfur-substituted hydrocarbons
Acid		Low pH, corrosive solvents
Alkaline		
Water-reactive		Unhydrolyzed materials that react violently with water
Chemically reactive		
Self-reactive (monomers)		
Toxic and hazardous		Sodium, calcium
Soluble metals		
Others (not elsewhere classified)*		
E. Slurries	Liquid materials that contain solids, but that readily flow or pump. The liquid and solid materials are both classified.	
Organic in water		
Inorganic in water		Lime slurry
Organic in liquid organic		
Inorganic in a liquid organic		Metallic sodium in oil
III. Gaseous wastes	This classification is restricted to those gaseous materials that have been or might become the responsibility of a disposal group or department to treat, burn, or otherwise alter before discharge to the atmosphere.	
A. Odorous		Mercaptans, H_2S
B. Combustible particulate		
Solids		
Mists		
C. Organic vapors		Volatile solvents
D. Acid gases		SO_2, HCl

**Others (not elsewhere classified)* represents the "cleanest" of material and is not intended as a catch-all grouping.

Source: U.S. Congress, Office of Technology Assessment, *Managing Industrial Solid Wastes from Manufacturing, Mining, Oil and Gas Production, and Utility Coal Combustion,* OTA-BP-0-82, 1992.

waste materials or groups of waste materials. Physical properties of concern typically include physical state, size, shape, weight, volume, density, temperature, viscosity, and pressure. Chemical properties typically include elemental constituents, toxicity, corrosivity, explosivity, flashpoint, heat of combustion, and products of combustion. Table 11.1.3 is a comprehensive checklist of parameters that may be significant in a waste characterization program.[3]

Depending on the specific waste, sufficient characterization data might be readily available in published literature, from faculty records, and/or in engineering handbooks. When such data are not available or are inadequate, laboratory testing and analytical work might be required. Waste testing methodologies are typically done in accordance with American Society for Testing and Materials (ASTM) procedures. Hazardous waste sampling and analysis procedures are usually in accordance with "Test Methods for Evaluating Solid Waste—Physical/Chemical Methods," SW-846, as published by the EPA.

WASTE MANAGEMENT SYSTEMS

A great variety of alternate processes and equipment is available as part of a total industrial waste management system. Depending on the specific types, forms, quantities, and hazardous constituents of the waste, management systems can range from a few simple processes to a complex combination of many processes.

Waste handling systems and equipment include conveyors, chutes, carts, and transport vehicles, elevators, and lifts, as well as pumps and piping for liquids, and ducts and blowers for gases, vapors, and fumes. These systems can range in sophistication from fully manual to fully automatic operation.

Systems for storing and handling liquid chemical wastes often require special designs and safety provisions. Problems of concern typically include viscosity, freeze protection, abrasion, corrosion, slagging, and adverse chemical reactions, such as spontaneous ignition, rapid heat release, foaming, precipitation, solidification, and the vaporization of low-boiling-point compounds. Safety provisions include spill and runoff containment, static electricity prevention, flame arresters, and systems for handling the vapors or fumes vented from the storage tanks. In addition, special precautions are sometimes necessary to ensure that incompatible wastes are segregated to prevent undesirable reactions.

For safely handling vapors from industrial ovens and furnaces, dilution air is often required such that the combustible concentrations are below 50 percent, and usually less than 25 percent, of lower explosive limits (LELs). Potentially explosive dusts require controls to prevent combustible air mixtures from forming and being ignited.

See Table 11.1.4 for applicability of various waste management and disposal methods for different waste classes.

TREATMENT AND DISPOSAL SYSTEMS

Because of the high costs and liabilities typically associated with waste treatment and disposal, initial efforts are usually directed at reducing waste quantities, as well as eliminating or minimizing hazardous constituents. Techniques include reuse and recycling of materials that would otherwise be waste, changes in manufacturing and production operations, and substitutions of raw materials to others generating less waste. Also, substitutions and reductions in the use of hazardous and toxic chemicals can result in reduced hazardous waste disposal requirements.

Industrial and hazardous waste processes include physical treatment, chemical treatment, biological treatment, and thermal treatment. They provide such functions as volume reduction, the separation of waste stream components, and the destruction and detoxification of hazardous constituents. Often several treatment processes are linked in series to provide a required degree of treatment. Residues from solid waste treatment processes require disposal, such as land burial, and, if the residues have hazardous characteristics or contain hazardous constituents in unacceptable concentrations, they require disposal in a permitted hazardous waste landfill or disposal site.

The selection of treatment processes for any particular application depends on the type, form, and quantities of waste, required performance to satisfy environmental requirements, and overall system economics. Table 11.1.5 summarizes the available hazardous waste treatment and disposal processes, as discussed below.

Physical Treatment

Physical treatment processes generally provide for separation of waste stream components. These processes are particularly useful for concentrating specific hazardous constituents from dilute waste solutions or mixtures, thereby reducing the overall quantities requiring disposal as hazardous waste. These also provide for the recovery of specific materials in resource recovery operations such that the recovered materials and/or remaining constituents need not be treated as hazardous waste.

The following processes are potentially feasible for the physical treatment of waste:

- Absorption
- Centrifugation
- Dialysis
- Electrodialysis
- Electrolysis
- Electrophoresis
- Filtration
- Flocculation
- Flotation
- Freeze crystallization
- Freeze drying
- Freezing
- High-gradient magnetic separation
- Reverse osmosis
- Stripping
- Ultrafiltration
- Zone refining

Chemical Treatment

Chemical treatment processes are particularly useful for the detoxification of hazardous waste stream components and constituents. They also provide for the separation and possible recovery and reuse of specific waste stream components. However, they are generally limited to liquid forms of waste materials. The following chemical treatment processes are potentially feasible for waste:

- Chemical oxidation
- Chemical reduction

Thermal Treatment

Thermal treatment processes use temperatures ranging from as low as 250ºF (182ºC) to over 20,000ºF (12,000ºC). Such processes include pyrolysis, incineration, high-temperature plasmas, infrared radiation, and microwaving. Thermal treatment processes can be designed to destroy, disintegrate, or dispose of virtually all types and forms of waste and hazardous waste constituents, but only organic constituents can be destroyed by thermal treatment processes involving combustion or pyrolysis. Some industries utilize thermal treatment processes in conjunction with their production operations for the conversion, reclamation, and reuse or recovery of residues and by-products.

Table 11.1.6 summarizes the basic parameters of the most common industrial waste incinerator systems.[4] The following section includes general descriptions of thermal treatment processes used for waste treatment.

[a]Functions: VR = volume reduction; Se = separation; De = detoxification; Di = disposal; St = storage.
[b]Waste types: 1. inorganic chemical without heavy metals; 2. inorganic chemical with heavy metals; 3. organic chemical without heavy metals; 4. organic chemical with heavy metals; 5. radiological; 6. biological; 7. flammable; 8. explosive.
[c]Waste forms: S = solid; L = liquid; G = gas.

Pyrolysis. Pyrolysis is a thermal treatment process similar to incineration except that decomposition occurs in the absence of oxygen. Heat usually is added externally and temperatures typically are maintained lower than incineration temperatures.

The pyrolysis process basically distills volatiles from the waste, leaving inorganics, or ash, and fixed carbon, or char, behind. The volatiles emitted from the waste are typically combusted in a separate chamber into which excess air and heat are added, but they can also be burned as fuel in a boiler or furnace. If the remaining inorganics have nonslagging characteristics and comprise only a small percentage of the solid residues, the char can also be burned as fuel.

Pyrolysis is a potentially useful process for treating waste containing salts, metals, and other contaminants that would otherwise inhibit conventional incineration system operations. However, several types of incinerators, including rotary kilns, multiple-hearth incinerators, and special designs, can be operated in a pyrolytic mode.

Incineration. Incineration is an engineered process that uses high-temperature combustion. Variables most affecting incineration system design, construction, and operations include waste combustibility and heating values, operating temperatures, retention times for both waste and products of combustion, turbulence within the combustion zones, and emission requirements. There are many basic types of industrial incinerators. Each is generally suitable for specific waste types, forms, and quantities, and each has limitations, advantages, and disadvantages.

The standard, basic types of industrial incinerators include the following.

Multiple-Chamber Incinerator. The description of multiple-chamber incinerators is similar to that of general solid waste

TABLE 11.1.6 Summary of Waste Incinerators

Type	*Process Principle*	*Application*	*Combustion Temp.*	*Residence Time*
Rotary kiln	Slowly rotating cylinder mounted at slight incline to horizontal; tumbling action improves efficiency of combustion	Most organic wastes; well suited for solids and sludges; liquids and gases	1500–3000°F (815–1650°C)	Several seconds to several hours
Multiple hearth	Solid feed slowly moves through vertically stacked hearths; gases and liquids fed through side ports and nozzles	Most organic wastes, largely in sewage sludge; well suited for solids and sludges; also handles liquids and gases	1400–1800°F (760–980°C)	Up to several hours
Liquid injection	Vertical or horizontal vessels; wastes atomized through nozzles to increase rate of vaporization	Limited to pumpable liquids and slurries (750 SSU or less for proper atomization)	1200–3000°F (650–1650°C)	0.1 to 1.0 sec
Fluidized bed	Wastes are injected into a hot agitated bed of inert granular particles; heat is transferred between the bed material and the waste during combustion	Most organic wastes; ideal for liquids; also handles solids and gases	1400–1600°F (760–870°C)	Seconds for gases and liquids; longer for solids
Pyrolysis	Thermal decomposition in the absence of oxygen; transforms organic materials into solids, liquids, and gaseous organic materials of simpler structure	Primarily as fuel; useful with solids and sludges; potential for resource recovery of breakdown products	900–1500°F (480–815°C)	Normally 12 to 15 min

type incinerators. This type of incinerator is usually limited to solid waste, but special hearth designs can accommodate sludges, and liquid waste can be burned in suspension.

Controlled-Air Incinerator. The description of controlled-air incinerators is similar to that of general solid waste type incinerators. This type of incinerator is usually limited to solid wastes, but limited quantities of sludges can be co-combusted and liquid waste can be burned in suspension.

Rotary Kiln Incinerator. The description of rotary kiln incinerators is similar to that of general solid waste type incinerators. Rotary kilns are versatile systems suitable for combusting most types and forms of waste, including solids, sludges, liquids, fumes, and volatile organic compounds. Liquid waste can be burned in suspension or loaded in drums or containers.

Multiple-Hearth Incinerator. The multiple-hearth type incinerator is almost exclusively used to burn or treat sludge-like residues and waste. Waste is fed at the top of the furnace and moves slowly downward across and through vertically stacked refractory hearths within a vertically oriented, cylindrical chamber. Rotating rabble arms with plow blades move waste across each hearth row so that it eventually falls downward to each hearth level through openings. These can be designed to accommodate granulated solid waste, and liquid waste can be injected between various hearths.

Fluidized-Bed Incinerator. With a fluidized-bed type incinerator system, waste is injected into a very hot, rapidly agitated bed of granular particles, such as sand, that are suspended within a cylindrical chamber by a high-pressure blower. Rapid combustion takes place and the heat of combustion is transferred to the sand bed. The system is primarily limited to organic sludges, but it can be designed to accommodate granulated solid waste and the injection of liquid waste into the bed.

Infrared Treatment Devices. With infrared treatment devices type systems, waste is heated by infrared heating elements such that volatile organics are driven off and, depending on waste type and form, deformation takes place. Such systems are usually limited to sludge-like materials and granulated solids. They can be either batch-fed processes or continuous-fed processes using conveyor belts.

Plasma Arc Treatment Systems. Plasma arc treatment type systems use high-temperature plasmas, comparable to those created by welding arcs, into which virtually any type or form of waste can be loaded and destroyed or disintegrated.

Liquid Injection Incinerators. Liquid injection incinerator type systems generally refers to those systems designed to burn liquid waste in suspension within a combustion chamber. Depending on heating value and hazardous constituents and characteristics, liquid waste can sometimes be injected through

TABLE 11.1.7 Matrix for Matching Waste Type with Incineration Process

Waste Type	*Rotary Kiln**	*Multiple Hearth**	*Fluidized Bed**	*Liquid Incinerator*	*Multiple-Chamber Incinerator*
Solids					X
Granular homogeneous	X	X	X		X
Irregular bulky (pallets, etc.)	X				
Low melting point (tars, etc.)	X		X	If material can be melted and pumped	
Organic compounds with fusible ash constituents	X	X			
Gases					
Organic vapor-laden			X		
Liquids					
High organic strength aqueous wastes, often toxic	If equipped with auxiliary liquid injection nozzles		X		
Organic liquids	If equipped with auxiliary liquid injection nozzles		X	X	
Solids/liquids					
Waste contains halogenated aromatic compounds (2200°F [1204°C] minimum)	X	X	If liquid		
Aqueous organic sludges	Provided waste does not become sticky on drying	X	X

nozzles or combusted through a conventional fossil fuel–fired burner system.

Gaseous Waste Incinerators. Gaseous waste incinerator type systems generally refer to systems designed for the combustion of vapors, fumes, volatile organics, odors, and the like. Three basic types of gaseous waste incinerators are flares, thermal burners, and catalytic burners:

- *Flares.* Flares involve open burning of combustible gases that are either near or above their lower explosive limits (LELs) of concentration or above their upper explosive limits (UELs) of concentration.
- *Thermal burners.* Thermal burners involve the combustion of dilute, or low-combustible, gases in the presence of a burner flame within a chamber.
- *Catalytic burners.* Catalytic burners involve the combustion of dilute gases that are preheated, exposed to a catalyst material, and oxidized at relatively lower temperatures.

Table 11.1.7 shows the incinerator technologies that are best suited or recommended for different waste types and forms.[5]

Other thermal treatment technologies, including variations to conventional incineration, used for waste include the following:

- Incineration in conventional boilers
- Cement kiln incineration
- Industrial furnace or oven incineration
- At-sea incineration
- Mobile incineration

Steam sterilization, or autoclaving, is a thermal treatment process for infectious waste. Autoclave equipment is designed to kill pathogens in waste by exposing them to relatively high temperatures, typically between about 240 and 280°F (about 116 to 138°C), for periods ranging from about 15 minutes to several hours. Retention times for effective treatment are dependent on steam temperatures and pressures, types and forms of the waste, quantities of waste, and the specific type and design of the autoclave system.

Biological Treatment

Biological waste treatment processes utilize microorganisms for the decomposition of organic compounds in the waste stream. These are most applicable to aqueous waste streams containing solids or solvent organics. Composting is also a biological treatment process used for solid and sludge-like waste. The following biological treatment processes are potentially feasible for waste:

- Activated sludge
- Aerated lagoons
- Anaerobic digestion
- Composting and co-composting
- Enzyme treatment
- Trickling filters
- Stabilization ponds

ULTIMATE DISPOSAL

Ultimate disposal refers to the final treatment or disposition of treated and untreated waste and residues. For example, with solid waste incineration a significant quantity of ash residues as well as sludge from a connected air pollution control system require transport and off-site disposal at a permitted site. If the residues contain significant levels of listed hazardous constituents, they may likely require disposal as hazardous waste at a permitted facility. Likewise, ash residues from incinerating low-level radioactive waste would likely require disposal at a site meeting NRC standards if radionuclide concentrations exceed MPC limits. Ash residues from the incineration of infectious and nonhazardous wastes must typically be analyzed to determine whether heavy metal concentrations exceed specified toxicity concentration levels before they can be placed in landfills. Alternate disposal processes include land burial, deep-well injection, and ocean dumping.

Land Burial

Two basic types of land burial are termed sanitary landfills and secure, or industrial, landfills. Both types are engineered systems and must be designed, constructed, and operated to meet stringent regulatory standards.

Sanitary Landfills. Sanitary landfills are used primarily for the disposal of municipal type solid waste that is considered nonhazardous. At sanitary landfills, waste is covered daily with earth to minimize health vector problems, blowing of debris, and open burning, and they are equipped with liners to prevent contamination or leaching into ground or surface waters. They are also equipped with venting systems to release gases generated during waste decomposition, as well as monitoring and test wells for ensuring continued integrity of liners.

Secure Landfills. Secure landfills, which are primarily used for the disposal of hazardous waste, are subject to RCRA regulations. These also require special liner materials to prevent leaching, special caps to prevent surface exposures, venting systems for handling gases, and monitoring and test wells for verifying the integrity of liner structures.

Deep-Well Injection

Deep-well injection involves the pumping of liquid waste into underground cavities or reservoirs that have been identified as being geologically secure. Because a prime concern is to protect all usable underground water, the reservoirs must be located far below potable water aquifers and isolated by thick, nearly impermeable strata, such as shale, limestone, or dolomite. Average well depths are about 5000 ft (1525 m), with some as deep as 10,000 ft (3050 m). Most are located in the southwestern part of the county where the geology can accommodate this disposal technology.

Ocean Dumping

Sewage sludge, industrial waste, and explosives have been dumped at sea for years in designated and approved locations. The U.S. Army Corps of Engineers and the U.S. Coast Guard are basically responsible for the sea transportation and disposal areas for such wastes. The primary concern with this type of disposal is the threat to marine life and coastal areas from improperly sealed waste containers or from uncontained waste having potentially toxic constituents. Because of washups of sewage sludge on beaches across the country, national legislative measures were promulgated to outlaw ocean dumping of such waste. Table 11.1.8 compares key parameters of the major hazardous waste treatment and disposal technologies.[6]

CODES, REGULATIONS, AND STANDARDS

The proper and safe management and disposal of industrial waste requires in-depth knowledge and a full understanding of the waste properties, alternative treatment technologies and processes, and all applicable regulations, codes, and standards. The following are the most significant regulations.

Federal Codes and Regulations for Waste Management and Disposal

1. Resource Conservation and Recovery Act of 1976 (RCRA), Subtitle C, Hazardous Waste Regulations, 40 CFR, parts 260–265 and 122–124
2. Nuclear Regulatory Commission (NRC), Part 20, Standards for Protection Against Radiation, 10 CFR
3. Toxic Substances Control Act of 1976 (TSCA)
4. Clean Air Act of 1963 (CAA) and Clean Air Act Amendments of 1970 and 1990, including:
   (a) National Ambient Air Quality Standards (NAAQS)
   (b) National Emission Standards for Hazardous Air Pollution (NESHAP)
   (c) Prevention of Significant Deterioration (PSD)
   (d) Nonattainment Regulations (NA)
5. Federal Pesticide Control Act of 1972; also known as Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA)
6. Oil Pollution Act of 1961
7. Federal Water Pollution Control Act of 1948 (FWPCA)
8. Occupational Safety and Health Act of 1970 (OSHA), including National Institute of Occupational Safety and Health (NIOSH)
9. Hazardous Substances and Hazardous Waste Response, Liability and Compensation Act; also known as “Superfund”

TABLE 11.1.8 Comparison of Some Hazard Reduction Technologies

	Disposal		Treatment		
	Landfills and Impoundments	*Injection Wells*	*Incineration and Other Thermal Destruction*	*Emerging High-Temperature Decomposition*[a]	*Chemical Stabilization*
Effectiveness: how well it contains or destroys hazardous characteristics	Low for volatiles, questionable for liquids; based on lab and field tests	High, based on theory, but limited field data available	High, based on field tests, except little data on specific constituents	Very high, commercial-scale tests	High for many metals, based on lab tests
Reliability issues	Siting, construction, and operation uncertainties: long-term integrity of cells and cover, liner life less than life of toxic waste	Site history and geology; well depth, construction, and operation	Monitoring uncertainties with respect to high degree of DRE; surrogate measures, PIC incinerability[b]	Limited experience mobile units; on-site treatment avoids hauling risks; operational simplicity	Some inorganics still soluble; uncertain leachate test; surrogate for weathering
Environmental elements most affected	Surface and groundwater	Surface and groundwater	Air	Air	Groundwater
Least compatible wastes[c]	Liner reactive; highly toxic, mobile, persistent, and bioaccumulative	Reactive; corrosive; highly toxic, mobile, and persistent	Highly toxic and refractory organics; high heavy metals concentration	Some inorganics	Organics
Costs: low, moderate, high	L to M	L	M to H (Coincin. = L)	M to H	M
Resource recovery potential	None	None	Energy and some acids	Energy and some metals	Possible building material

[a]Molten salt, high-temperature fluid wall, and plasma arc treatments.
[b]DRE, destruction and removal efficiency. PIC, product of incomplete combustion.
[c]Wastes for which this method may be less effective for reducing exposure, relative to other technologies. Wastes listed do not necessarily denote common usage.

General Standards for Waste Treatment and Disposal Systems

NFPA 30, *Flammable and Combustible Liquids Code*
NFPA 82, *Standard on Incinerators and Waste and Linen Handling Systems and Equipment*
NFPA 86, *Standard for Ovens and Furnaces*
NFPA 801, *Standard for Fire Protection for Facilities Handling Radioactive Materials*

General Standards for Burners and Equipment

NFPA 31, *Standard for the Installation of Oil-Burning Equipment*

NFPA 54, *National Fuel Gas Code*
NFPA 86, *Standard for Ovens and Furnaces*
NFPA 850, *Recommended Practice for Fire Protection for Electric Generating Plants and High Voltage Direct Current Converter Stations*
UL 296, *Standard for Safety Oil Burners*
UL 372, *Standard for Safety Primary Safety Controls for Gas- and Oil-Fired Appliances*
UL 795, *Standard for Commercial-Industrial Gas Heating Equipment*

The above list of codes and standards is not all-inclusive. Other agencies, such as Industrial Risk Insurers (IRI), American National Standards Institute (ANSI), Underwriters Laboratories (UL), and American Society for Testing and Materials (ASTM), may have standards applicable to specific waste management and disposal operations. In addition, state and local regulations and requirements may be more stringent than federal regulations or standards.

SUMMARY

Waste management must take into account potential fire hazards that can arise starting at points of generation, through waste handling processes, internal transport, interim storage, treatment, and final disposal. The design, construction, and use of waste handling and treatment systems and equipment, such as chutes, incinerators, compactors, and shredders, must take fire safety into full account and require strict adherence to all applicable codes and regulations. Waste generated at industrial type facilities varies widely and typically requires special design consideration for proper, safe, and efficient treatment and disposal in compliance with highly complex regulations. One important aspect of minimizing fire hazards in industrial waste management is reducing the quantity of waste, as well as its hazardous constituents by reusing and recycling materials, by changing manufacturing and production operations, by substituting raw material to others generating less waste, and/or by substituting and reducing hazardous chemicals.

Chapter 2

Housekeeping Practices

L. Jeffrey Mattern

Chapter Contents

Good Housekeeping Defined
Essentials of Good Housekeeping
Building Care and Maintenance
Occupancy and Process Housekeeping
Outdoor Housekeeping Practices
Inspections

Key Terms

combustible refuse, dust, exhaust duct, facility manager, hazardous waste, materials handling and storage, solvents

Good housekeeping is the keystone to good fire prevention. Housekeeping, in terms of fire prevention, refers not only to a sense of cleanliness, but also to a sense of orderliness, as well as repair and maintenance. All of these aspects are important in the prevention of fire, the minimization of fire spread, the preservation of clear escape paths, and the ability to easily access areas to fight a fire, should one occur. Good housekeeping is a basic requirement for all types of facilities, from the smallest business occupancy to the largest manufacturing plant or warehouse.

A fire at a textile location in North Carolina in 1999 demonstrates how a combination of poor housekeeping situations can result in a very significant fire. Waste product was staged on the floor near an electrical motor. The motor failed, with the resultant arcing igniting the waste material. This quickly grew into a sizeable fire. Before sprinklers could operate and control the fire, lint on the tops of piping, conduit, and ducts above the fire area ignited, allowing the fire to quickly flash along the piping, conduit, and ducts. Some of the burning lint fell to the floor, igniting some 30 spot fires throughout the weaving area of the mill.

In a 2000 incident at a Pennsylvania newspaper printing plant, waste materials were placed in noncombustible open-top containers adjacent to the presses. An electrical arc in a motor controller directly above one of the containers allowed sparks to fall and ignite the waste material. The fire quickly spread to ink residue that was not properly cleaned from areas around the press. The residue allowed fire to spread to the shielded areas of the press. The press was severely damaged.

In one final example, oily residue was not cleaned from the underside of a roof at a West Virginia steel mill (1989). A fire in a press pit quickly spread to the oily residue on the underside of the roof and further spread the full length of the building. Had the roof been properly cleaned, it is expected that the fire would have been contained to the area of the press pit.

Good housekeeping means minimizing the quantity of unstored, exposed combustibles. The combustibles in question can be separated into waste and clutter, where waste refers to combustibles of no value that have not yet been removed and clutter refers to combustibles with value that are out because they are being, have been, or will be worked on. Most of this chapter addresses waste, because there are a number of generic types of waste and a number of generic strategies for minimizing its accumulation. Clutter is different. To determine whether clutter is unnecessary, it is necessary to analyze work flows, work spaces, storage space, methods of accessing and returning stored materials, and all other specific characteristics of a particular facility and its operations. It can be all too easy for clutter to accumulate in a busy environment where cleanup activities never seem to be as important or as urgent as other assignments. At the same time, an inordinate focus on reducing clutter can achieve a largely aesthetic benefit while interfering with efficient work flow and routines. Generic advice that is realistic and effective is elusive, and so this chapter will offer little generic advice.

This chapter provides an overview of good housekeeping practices. It provides specific details for some high-frequency housekeeping hazards and also highlights common housekeeping aspects that lead to deficiencies that need attention in many facilities.

It is important that each facility have a written, effective housekeeping program in place. To be effective, this program should include the involvement of all facility employees. An important part of this program should be a fire safety plan that includes housekeeping practices. In addition,

L. Jeffrey Mattern is senior account engineer (retired) with FM Global in Philadelphia. He has served on various NFPA technical committees and the NFPA Standards Council since 1968.

the plan should include provisions for inspections, equipment layout, storage and handling practices, and an effective preventive maintenance program to limit or eliminate potential sources of ignition.

In addition to reduced fire hazards, a well-planned housekeeping program can yield the following benefits:

- Reduced operating costs
- Increased production
- Improved production control
- Conservation of material and parts
- Reduced production time
- Better use of space
- Improved traffic flow (i.e., permits faster travel)
- Reduced accident rate

For additional information on related topics see Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems"; Section 8, Chapter 1, "Air-Moving Equipment"; Section 7, Chapter 5, "Hazardous Waste Control"; and Section 11, Chapter 1, "Waste Handling and Control."

GOOD HOUSEKEEPING DEFINED

Good housekeeping is really common sense. It is not a sophisticated concept. It relates to keeping everything in its place, keeping facilities and equipment in good repair and in good operating condition, and keeping processing areas free of accumulations of by-products and waste materials. Identifying the amount of such accumulations is sometimes a most difficult task. What may be acceptable for one operation might be excessive for another. In some areas of a facility, it is necessary to regulate such personal practices as smoking, which, without reasonable controls, could lead to hazardous conditions. It is fundamentally based on occupancy-specific operating conditions. Good housekeeping is important; however, it is essential that the criteria for good housekeeping be clearly spelled out in advance and that the criteria be documented.

In looking at the theory of accidents, one can find information that can help in the prevention of fire. For each serious fire that is reported, there might be 10 minor fires; 100 "close calls" or near misses that could have led to fires; and 1000 unsafe conditions, recognized or unrecognized, that could have led to near misses. These hypothetical illustrative numbers might be high or low, but the bottom line is that many conditions do exist in the workplace that can cause a fire. And, in fact, a facility might be fortunate enough while having these conditions, even over a long period of time, to not experience a fire.

If one can recognize hazardous conditions and eliminate them, the potential for a disastrous fire in the workplace will be substantially reduced. This can be accomplished through good inspection procedures and good housekeeping practices.

Poor housekeeping contributes to loss potential by increasing fire and explosion hazards in several ways. Poor housekeeping:

- Provides a greater combustible loading for the initial fire to feed on
- Creates a greater continuity of combustibles, which makes it easier for fire to spread
- Creates the potential for flash fire or dust explosions when layers of lint or dust are allowed to accumulate
- Allows spills or drips of flammable or combustible liquids to accumulate, which could catch fire (including spontaneous ignition in some situations)
- Increases the potential for spontaneous ignition

When not properly addressed, friction, static, or electrical connections can be sources of ignition. Poorly controlled smoking policies can lead to a source of ignition.

In addition to the increased hazard, poor housekeeping can have a negative effect on production. Quality is hard to maintain when the workspace is crowded and messy. Efficiency suffers because people normally tend to work more productively and more accurately if their surroundings are clean and in good order. Maintenance of good workspaces and adequate aisle spaces to allow not only the free flow of materials into and out of the work area but also good exit capabilities is as important as keeping things clean and well laid out. Thus, good housekeeping will not only prevent fires and possibly save lives, but it can improve production and employee morale as well.

ESSENTIALS OF GOOD HOUSEKEEPING

The degree of effort and attention needed for proper housekeeping is influenced, of course, by the type of building and the overall size of the facility involved. But most significant are the specific occupancies of the facility. Some processes produce more waste, leakage, and vapors than others, thus contributing to the challenges in maintaining good housekeeping. In addition, the acceptable level of cleanliness varies from occupancy to occupancy. What is satisfactory in a foundry would not be tolerable in an office building. And the cleanliness of the average office would hardly be satisfactory for a semiconductor "clean room."

To have good housekeeping, the program must start at the top. In today's business atmosphere, all sorts of titles are used, from the traditional manager and supervisor to the title of team or crew leader. Whatever the title, the top facility manager/team leader must set the tone. This is not to say that an individual supervisor/team leader/crew leader at the department level cannot go it alone, but the success of such efforts will be much improved if the top management of the facility is behind the program. To begin, team leaders (at all levels) must define what is meant by good housekeeping. To do this, each level of leadership should inspect the plant and then determine the following:

- Is the present level of housekeeping acceptable?
- Are the appropriate tools provided for general plant cleanup? Are they available for emergency cleanup?
- Are adequate storage areas provided for both incoming raw materials and outgoing products?
- Are leadership's offices reflective of the good housekeeping required of the facility areas?
- Are adequate waste receptacles provided?

Proper housekeeping does not just happen. It requires visible support of and direction from management as well as the cooperation of all employees, visitors, and vendors. Management cannot merely decree that good housekeeping is a desired goal. It is important that management provide a written policy regarding facility cleanliness and general housekeeping. Good housekeeping requires effort from everyone.

First, management must set the tone, specifically, the level of acceptable housekeeping. Next, management must enlist the aid of everyone to help. Employee ideas should be solicited on how to maintain good housekeeping. Management must either act on the employee ideas or explain why it cannot. It is important that all employees accept the responsibility for housekeeping in their respective areas. Ensuring that materials, tools, wastes, and so on, are placed in their proper locations is the job of each employee who handles them.

Safety inspections are important. When doing so, management must demonstrate with their actions and words the level of housekeeping they will accept. Where proper housekeeping does not exist, it is usually because inadequate attention is paid to, or inadequate action is taken in, one or more of the areas of communications, equipment, layout and storage, environment, and personnel.

Communications

Management must publicize its commitment to good housekeeping. This publicity must be reinforced periodically and recognition given whenever notable improvement or outstanding performance takes place. Team leaders must provide feedback to management on how the program is working and what they need to meet the program goals through safety inspection reports prepared by team leaders and employees and periodic inspections by management. In addition, team leaders must be able to meet with management periodically to review performance, to revise goals, and to offer and substantiate recommendations. These team leaders should also encourage feedback from employees in the form of suggestions and constructive criticism. One important place to discuss these issues is at monthly safety meetings. Assign employees to teams to find innovative methods to identify solutions to problems that have been brought forth either through inspections or by employee suggestions. The worker who uses the area can often readily identify more efficient housekeeping methods.

Equipment

Housekeeping efforts should not flounder from lack of necessary tools or equipment. The simple step of placing a sufficient number of easily accessible wastebaskets or trash receptacles at points of need can reduce the amount of waste deposited on the floor or in the product. In some production and handling areas, dust, lint, and other waste might be produced constantly. In these cases, vacuum pick-up stations tied into an exhaust and collection system might be needed at specific points of waste generation. Keep in mind that this dust or lint might be combustible, and care must be taken to ensure that there is no possibility to ignite this material. For area cleaning, powered floor sweepers or rail-mounted traveling cleaners might be necessary. Areas in which large quantities of scrap or discarded packaging materials continuously accumulate might need not only large trash containers but also motorized equipment that can be emptied or replaced frequently. In areas where grease or oil can accumulate, a high-pressure steam floor-washing system might be required. A well-planned preventive maintenance program on all equipment will find and eliminate leaks of liquid, electrical hazards, static buildup, and friction caused by lack of lubrication.

Layout and Storage

Overcrowding is a major impediment to proper housekeeping. Blocked or restricted aisles limit access and hamper efficient cleaning and trash pickup, not to mention slowing egress. Lack of sufficient workspace and storage capacity results in inefficient operations, an inability to maintain order, and worker frustration. The creative use of racks, shelving, and bins, or marking aisles and storage areas by painting lines on the floor can provide solutions.

With its negative influence on good housekeeping, disorganized and haphazard storage is usually a detriment to effective fire protection as well. Fire extinguishers, small hose stations, and sprinkler system control valves can become blocked and inaccessible, whereas other fire equipment, such as fire doors, can be made blocked and, thus, inoperable. Last, in a fire emergency, it will be more difficult for the industrial fire brigade or the public fire service to attack and extinguish a fire even in a facility protected by automatic sprinklers.

Environment

Equally important as the natural environment is the artificial environment created in the workplace. The control of process fumes, vapors, and dusts required for the well-being of the worker has also had a beneficial impact on overall cleanliness in many work areas. Consideration should be given to totally enclosed dust and vapor-tight process equipment in addition to the ventilation equipment mentioned previously (Figure 11.2.1).

Personnel

Employees must be informed on the necessity of keeping their respective work areas clean as a critical part of a housekeeping program. To do this, management must constantly communicate to the employees what is acceptable and unacceptable about the way the facility is being maintained from a housekeeping standpoint. In addition, employees should be encouraged to discuss ways to eliminate hazards and improve working conditions.

BUILDING CARE AND MAINTENANCE

Basic Requirements for Good Housekeeping

The three basic requirements for good housekeeping are proper layout and equipment, correct materials handling and storage, and cleanliness and order. Any facility that implements these basics has laid the foundation for good housekeeping. Using

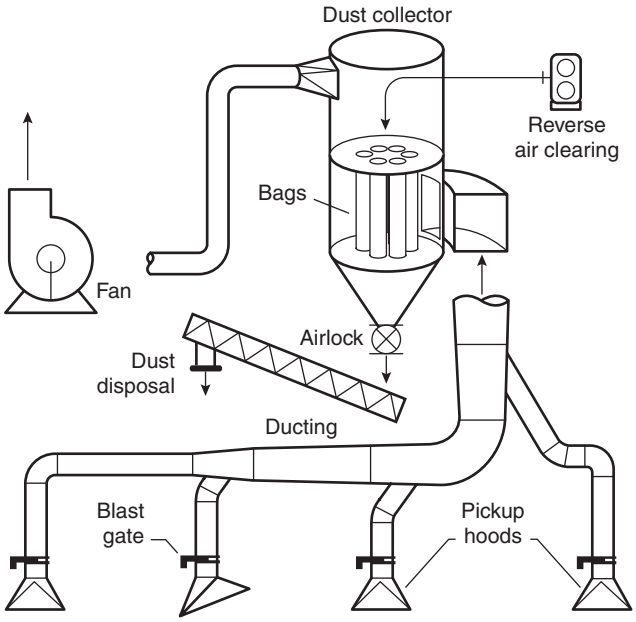

FIGURE 11.2.1 Dust Collection System (Source: http://en.wikipedia.org/wiki/Dust_collector)

FIGURE 11.2.2 Oily Waste Can (Source: Courtesy of the Protectoseal Company)

them, the facility can develop special housekeeping practices to deal with its own specific problems. In pursuing cleanliness and order, effective care and maintenance of buildings require special housekeeping practices to reduce the fire danger to buildings.

Proper Layout and Equipment. Good industrial engineering not only facilitates the movement of raw materials, in-process goods, and finished product but also concentrates the hazards associated with specific aspects of the product process in a single area. For example, in a woodworking facility, all handling of flammable liquids and associated cleaning materials are in one area of the plant. Wiping rags can be concentrated and stored in the appropriately listed waste material storage container (Figure 11.2.2). Doing so does not negate the importance of periodic removal of such waste material but does limit the exposure to these materials.

Correct Materials Handling and Storage. Proper material handling allows for materials to be moved to their specified location without staging them in an area that does not contain the needed level of fire protection, most specifically, automatic sprinklers designed for the hazard. For example, hazardous materials are typically received at the loading dock. Such materials should be properly coded by the supplier so that, when they are received, they are readily identified and can be moved expeditiously to their designated, adequately protected, special hazards storage area, versus being left on the loading dock, which might not be designed for such storage.

Cleanliness and Order. The type of operation will dictate the level and frequency of cleaning required. Many locations will only require cleaning once per day, but some manufacturing processes might require cleaning at the end of each shift, or possibly even periodically during the shift.

Floors

The general care, treatment, cleaning, and refinishing of floors can present a fire hazard if flammable solvents or finishes are used or if combustible residues are produced in quantity. One option is a floor cleaning system that does not use flammable solvents or finishes. In general, cleaning solvents with flashpoints below room temperature are too dangerous to use to clean floors. When selecting a cleaning agent, care should be taken about its toxicity to employees and to the environment if it is eliminated through the sewer system. Safe materials are available for most of the following purposes.

Sweeping Compounds. Many excellent compounds are available for sweeping floors and absorbing oily materials. Noncombustible materials should be used for this purpose. Sawdust and similar combustible materials should be avoided or, if used, should be disposed of in covered metal containers.

Floor Oils. Compounds containing oils and low-flashpoint solvents are a hazard, particularly when freshly applied. In addition, component oils might be subject to spontaneous heating. To reduce the fire hazard, suitable attention must be given to the safe storage of oily mops, sponges, and wiping rags in metal or other noncombustible containers. Any combustible oil used to excess increases the combustibility of the floor. Oil-soaked floors, the product of years of use, also show increased combustibility.

Floor Waxes. Waxes formulated with low-flashpoint solvents are hazardous, especially when used with electric polishers. In

such instances, ignition might result from friction and sparking. Water-emulsion waxes are preferable.

Dust and Lint

A necessary procedure for many occupancies is the removal of combustible dust and lint accumulations from walls, ceilings, and exposed structural members. Unless this procedure is performed safely, as by vacuum cleaners or air-moving (blower and exhaust) systems, the removal procedure could present a fire or explosion hazard. In some cases, vacuum-cleaning equipment must have dust-ignition-proof motors to ensure safe operation in dust-laden atmospheres.

It does not take a lot of "fugitive" dust on building system components, process equipment, utility lines (such as pipes or conduit), or ductwork to create a fire or explosion hazard. Dusts of organic materials such as wood, food products, paper, and so on of the correct particle size with a depth of less than ⅛ in. (3 mm) can, under the right set of conditions, result in a flash fire or explosion. Some believe that as little as 1/32 in. (0.8 mm) of finely divided dust can propagate a flash fire. Typically, a severe explosion can occur if a localized or primary explosion at a piece of equipment shakes the building, dislodging dust that has accumulated on surfaces at some distance above the floor, resulting in an area-wide flammable cloud of dust that can be ignited by the flames from the primary explosion. In such a scenario, the secondary explosion causes the most severe damage.

Flash fires occur when there are lesser amounts of dust. These flash fires occur when a flame impinges on the dust accumulation, and the fire spreads along the surface of the building system component, utility lines, or ductwork. The fire spread can be rapid, as with lint, or slow but progressive, as with many dusts. One of the hazards of flash fires is that they can lead to drop-down conditions where burning material falls on combustible materials near floor level, igniting them, which can result in many spot fires throughout a facility and can open many sprinkler heads, often overtaxing water supplies.

When cleaning, care should be taken not to dislodge into the atmosphere any appreciable quantities of combustible dust or lint that might ignite or form an explosive mixture with air. A great deal of cleaning work can be eliminated by installing dust collection equipment with pickup ducts at points where dust is liberated from processing machinery and conveying the dust to dust collectors outside the building.

The preferred method of cleaning is with the use of soft brooms and brushes and with vacuum equipment to avoid getting the dust in suspension. "Blowing down" dust with compressed air is the least desirable approach for removing dust from high-level points of accumulation, as this can create dangerous dust clouds. If blow-down is the only option, it should be done with extreme care and when all equipment is shutdown. The area should also be inspected for other sources of ignition, which should be eliminated. In most localities, it is possible to obtain the services of reliable professional industrial cleaning specialists to remove dust accumulations safely. These services use large vacuum trucks with hoses that can be used throughout a facility.

Furniture Polishes. Furniture polishes containing oils subject to spontaneous heating become hazardous when rags that are saturated with these polishes are not disposed of properly. An example of such occurred when personnel were using rags soaked in linseed oil to refinish the wood panel wall of an office. At the end of the day, the soiled rags were thrown in a cardboard carton. Some 4 hours later, the rags heated, ignited, and resulted in a prolonged, uncontrolled fire. Such oil-soaked rags should be placed in metal or other noncombustible containers.

Nonhazardous Cleaning Agents. Flammable solvents need not be used since a number of nonhazardous cleaning agents are available. These relatively safe materials are stable and have high flashpoints and low toxicity. There are several commercial stable solvents available that have flashpoints ranging from 140 to 190°F (60 to 88°C) and have a comparatively low degree of toxicity. Safe materials are available for most of the preceding purposes.

Concealed Spaces and Plenum Areas. These areas present a serious fire exposure to a facility if not kept clean and free of combustible material. Concealed spaces below floor areas (crawlspaces) and even raised floors in computer rooms, for example, can become an accumulation point for trash and debris. Also, crawlspaces can be a "temporary" storage area for material to be used for future installation of equipment.

In occupancies where manufacturing processes produce dust or lint, concealed spaces above the ceiling and below the floor can be accumulation points for the dust and lint. If these spaces are not protected with automatic sprinklers and a fire enters these spaces, a severe challenge for manual fire fighting can be created, as it becomes very difficult to identify exactly where the fire is concentrated.

Another area of concern is plenum spaces. A plenum is a space used for moving air from one point to another. Plenums can be between a finished ceiling and the roof or floor above, or between a finished raised floor and the ceiling of the floor below or the grade level floor. These areas typically accumulate large quantities of cable and associated materials. The cables should be noncombustible, limited combustible, or meet the requirements of a variety of fire tests as defined in NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems.* Additionally, any unused cable or other materials should be removed from the space. (See Section 10, Chapter 4, "Air-Conditioning and Ventilating Systems.")

Periodic inspections of concealed spaces and plenum areas are an important part of the facility housekeeping inspection.

Exhaust Ducts and Related Equipment

Exhaust ducts from the hoods over cooking ranges, such as those found in cafeterias, can present problems because grease condenses inside the ducts and on exhaust equipment. Sparks from the range or, more often, from small fires in overheated cooking oil or fat can ignite grease accumulations. Without these grease accumulations in the hood and duct, stovetop fires can often be readily extinguished. Fires are a special danger in frying because cooking oils and fats are heated to their flashpoints

and can reach their autoignition temperatures when accidentally overheated or spilled on the hot stovetop.

Grease Removal Devices. All exhaust systems for cooking equipment must be equipped with grease removal devices. These include such items as grease extractors, grease filters, or special fans designed to remove grease vapors effectively and provide a fire barrier. Grease filters, including frames, and other grease removal devices should be made of noncombustible materials.

Ducts. There is no practical method for preventing all kitchen duct fires, but the danger can be minimized through a combination of precautions as outlined in NFPA 96, *Standard for Ventilation Control and Fire Protection of Commercial Cooking Operations.* It is good practice to clean hoods, grease removal devices, fans, ducts, and associated equipment frequently. The exhaust system should be inspected daily or weekly, depending on its use, to determine if grease or other residues are accumulating in it. Clean ducts are essential to fire safety, but cleaning them is a difficult and unpleasant job. One source of help is a commercial firm that specializes in this sort of work. Automatic duct cleaning systems are also available that are designed to clean the ducts on a daily or other scheduled basis. In any case, never try burning the grease out; it is a dangerous practice, even though duct systems installed according to NFPA standards are designed to withstand burnout.

In cleaning the exhaust system, avoid using flammable solvents or other flammable cleaning aids. Do not start the cleaning process until all electrical switches, detection devices, and extinguishing system supply cylinders have been turned off or locked in a "shut" position. Doing so will prevent both the exhaust fan and the fire extinguishing system (if the exhaust duct is equipped with one) from actuating accidentally. Once the cleaning process is completed, the switches and other controls should be returned to normal operating positions. Should a fire occur during cleaning, it should be understood that the fire extinguishing system should be manually operated.

Satisfactory cleaning results can be obtained with a powder compound consisting of one part calcium hydroxide and two parts calcium carbonate. This compound saponifies the grease or oily sludge (i.e., converts it to soap), thus making it easier to remove and clean. The process requires proper ventilation. Another cleaning method is to loosen the grease with steam and then scrape the residue out of the duct. This can to be quite effective.

Spraying duct interiors with hydrated lime after cleaning is a fire prevention method used commercially. This procedure tends to saponify the grease and can facilitate subsequent cleaning, but it does not provide permanent fire retardancy.

The use of a professional cleaning company or specially trained employees should be considered to ensure proper handling of the dust and dirt from ducts. This is especially true if the dust is combustible or explosive, since special equipment is needed to clean this type of system. (See Section 8, Chapter 1, "Air-Moving Equipment.")

Ducts Carrying Solid Materials. Ducts that carry solid materials must have the proper pickup and carrying velocities in order to assure that dust at the work site is minimized and that dust traveling through the ducts does not settle out along the flow path. The proper velocities for the type of dust to be transported virtually assures that there will be a minimal accumulation of dust in the duct and at the workstation. Periodic inspections of the ducts should be conducted to assure that materials have not accumulated within the ducts. Where accumulations are detected, frequent cleaning is necessary until modifications can be made to assure proper velocities. (See Section 8, Chapter 1, "Air-Moving Equipment.")

Other Duct Systems. Air distribution duct filters should be changed frequently. Particular attention should be given to building ventilation systems, including fire cutoff devices. In today's tight building design, it has been shown that microorganisms can build up and cause problems in these systems, or cause illness. Dirty outlets on ceilings and walls are evidence of the effects of neglect.

OCCUPANCY AND PROCESS HOUSEKEEPING

Housekeeping programs for a particular occupancy or process must give special consideration to disposal of rubbish, control of smoking habits, and other housekeeping hazards. It is a good idea to have an inspection of facilities by security officers after employees have left a facility for the day or weekend. This inspection should occur about 1 hour after the facility has been vacated and should be repeated on a regular basis while the facility is vacated.

Disposal of Rubbish

The key is not to give fire a place to start. The proper handling and disposal of rubbish is an integral part of the housekeeping process, and its success depends primarily on having and observing a satisfactory routine. The proper and regular disposal of combustible waste products is of the utmost importance.

In both industrial and commercial properties, the removal of combustible waste products at the end of each workday or at the end of each work shift is a common practice. In some occupancies, more frequent waste disposal is necessary. In others, the collection, storage, and disposal routine varies with the nature of the plant operations. In all cases, however, an adequate program for dealing with this problem is a fire safety essential. Keeping a place tidy also depends on providing enough wastebaskets, bins, cans, and other proper containers so that building users will find tidiness convenient.

Recycling. The problem of accumulating combustible waste has increased with the advent of recycling efforts. Many building owners supply small personal recycling containers at each worker's desk (Figure 11.2.3) and larger storage containers, or bins, to collect the recyclable material from the individual containers (Figure 11.2.4). The bins are then emptied at a larger collection point. The collection and storage process of this recycling material has resulted in delayed removal of many types of combustible waste from a building or property. It is important to recognize this situation and to attempt to control the loca-

FIGURE 11.2.3 Typical Personal Recycling Container

tion and amount of recyclable material in buildings as well as the ignition sources in the vicinity of its storage. Proper storage prevents the spread of fire in these areas.

Waste disposal sites should be equipped with the means to extinguish or control the spread of fire in the disposal area until the arrival of the fire department. The fire department should evaluate the fire potential and work with the property owner to ensure adequate water supplies for fire department use in case of fire. Ensuring adequate water supplies might require extending water mains with additional hydrants or, if the site is remote from a municipal water system, the provision of on-site water storage.

Burning or smoldering debris should be dumped at a specific site used exclusively for hot debris. The debris should be monitored, wet down if necessary, and, when cold, placed with normal debris.

There have been many dumpster fires that extended into an adjacent building because the dumpster was not placed a sufficient distance from the adjacent building. For example, in Figure 11.2.5 the dumpster is placed directly against the building's exterior wall.

Dumpsters should be placed a minimum of 10 ft (3 m) from combustible walls, openings, combustible roof eaves, or any other area that might pose a fire risk. The 10 ft (3 m) is measured perpendicularly from the farthest projection, as shown in Figure 11.2.6. Permanent barriers should be installed to ensure that dumpsters are not inadvertently placed within 10 ft (3 m) of these combustible building components.

FIGURE 11.2.4 Storage Bin for Recyclables

Receptacles. Noncombustible containers should be used for the disposal of waste and rubbish. This is true even of such small receptacles as ashtrays and wastebaskets and applies, of course, to the larger units found in commercial and industrial properties. Industrial waste barrels should be made of metal and equipped with fitted covers. Care should be taken to avoid mixing waste materials where such mixing introduces hazards of its own. Although plastic receptacles are popular because they are quiet, attractive, and scratch and dent resistant, only noncombustible containers should be used for rubbish disposal.

Segregation of Waste. It is not good housekeeping practice to dump all manner of dry waste down refuse chutes or to place it in a common bin or storage receptacle. For example,

FIGURE 11.2.5 Dumpster Against Building Exterior

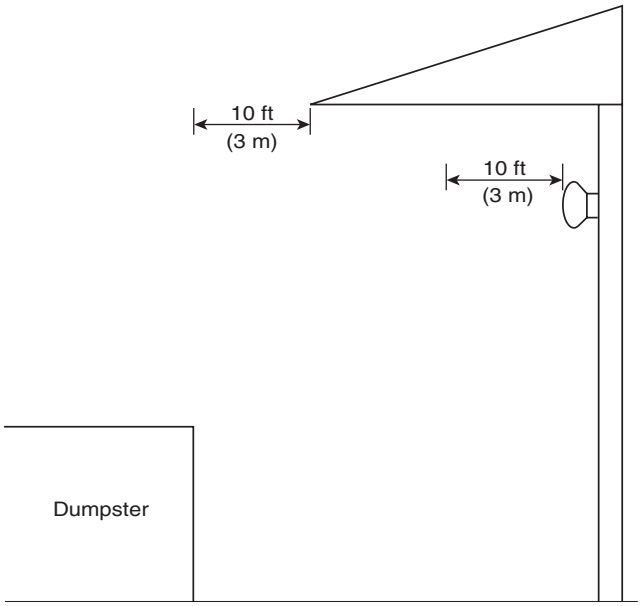

FIGURE 11.2.6 Distance Measurements

combustible metal dusts and metal powders dumped into chutes might explode if ignited. Mercury batteries and pressurized containers, such as the ubiquitous aerosol can, might also explode when incinerated or mixed with rubbish that is subsequently burned. Precautions should be taken to keep combustible items separate from each other and from noncombustible items.

Some materials are susceptible to spontaneous heating. These materials should not be combined with other materials. They should be placed in a closed, noncombustible container. Materials of this type are common in furniture refinishing, floor and wood wall refinishing, spray painting, and similar operations. Waste rags associated with materials such as nitrocellulose and linseed oil are of particular concern.

In the United States, requirements of the U.S. Environmental Protection Agency (EPA) and the state waste control departments must also be considered. Many countries have similar regulations on waste disposal. Agencies that govern these regulations should be consulted in order to establish appropriate waste disposal procedures.

Most chemicals must be handled in a specific prescribed manner. In the United States, rules are contained in the Resource Conservation and Recovery Act (RCRA) and the Hazardous Waste Amendment to that act. Contact the EPA and local state agencies for further information. Many countries have similar regulations on handling chemicals. Agencies that govern these regulations should be consulted in order to establish appropriate chemical handling procedures.

Control of Ignition Sources

Control of Smoking. Although society in general has made many changes in the smoking habits of employees, there are still a significant number of employees who smoke. From the standpoint of fire safety, the best policy is to prohibit smoking altogether. This eliminates the possibility of smoking materials being improperly discarded. It is critical that such a policy be strictly enforced and have the support of all employees. Where this is not a possible consideration, smoking regulations must be specific as to location and, preferably, time. Areas in which smoking is permissible, as well as those areas in which it is limited or prohibited entirely, must be clearly marked by appropriate signs that leave no question as to what is allowed where (Figure 11.2.7).

In addition to sensible regulations, smoking control also requires adequate receptacles for spent smoking materials. Properly designed ashtrays are essential to safe smoking. They should be made of noncombustible materials with grooves or snuffers that hold cigarettes securely. Their sides should be steep enough to force smokers to place cigarettes entirely within the ashtray. In industrial buildings, large containers of sand are often used to conveniently and safely extinguish and dispose of spent smoking materials.

Improperly designed ashtrays can constitute a hazard, particularly if they allow a lit cigarette or cigar to fall or roll away. A lighted butt also might easily come in contact with combustible materials and start a fire under certain circumstances. The contents of ashtrays must be disposed of carefully because a live butt might well be mixed in with apparently innocuous ashes. If lighted smoking materials were to be dumped into an ordinary wastebasket, they could set paper or some other piece of combustible rubbish on fire. To prevent this from happening, reserve special covered metal containers for discarded smoking materials only.

Control of Static. Static can be produced by the flow of dissimilar materials past each other. For example, liquid or dust conveyed through a pipe or duct can produce an electrical potential. Under the right conditions, if adequate oxygen is present, a static discharge can occur that will ignite the flammable vapor or combustible dust. Another source of static electricity-induced fires is associated with flammable liquid dispensing. It is important that low conductivity flammable liquids have a good bonding system where the dispensing object, the receiving object, and the ground device are all interconnected (bonded together). If the grounding system is defective, flammable liquids being dispensed can be ignited. If spills and droppings of such flam-

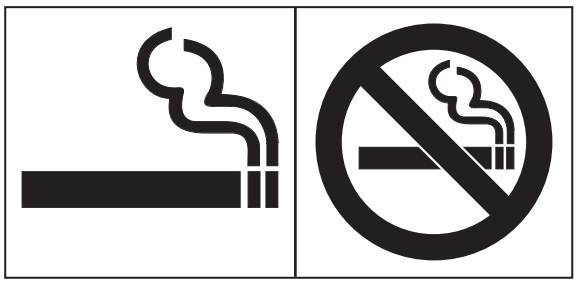

FIGURE 11.2.7 Examples of Signs Permitting or Forbidding Smoking in Designated Areas

mable liquids are present, the fire can quickly spread beyond the point of origin. Part of the site-preventive maintenance program should be periodic inspection and testing of all grounds, including building grounds and bonding.

Control of Friction. A preventive maintenance program must be in place to identify and eliminate potential sources of friction. Lubrication is one important part of this program. Additionally, in areas where there is potential for friction, it is important that housekeeping be of high quality to ensure that debris is not a "wick" to spread a fire to surrounding materials. An example of friction-associated problems is the drive roller on rubber belt conveyor systems. These rollers need to be inspected periodically for proper lubrication. Overheating can ignite not only the rubber belt but also any surrounding debris associated with an inadequate housekeeping program.

Control of Electrical Hazards. Routine inspections should identify overloaded electrical circuits, excess electrical extension cords, frayed cords, missing grounding plugs, and so forth. Infrared testing can also be an important feature of preventing fires of electrical origin. A good housekeeping plan that manages the proper disposal of waste materials and the removal of residue from manufacturing processes helps minimize the potential for a common electrical fault from spreading beyond the point of origin.

Industrial Housekeeping Hazards

Some industrial occupancies have special housekeeping problems inherent to the nature of their operations. For these particular problems, specific planning and arrangements are necessary.

Clean Waste and Rags. Clean cotton waste or wiping rags are generally considered to be mildly hazardous, chiefly because they are readily flammable when not baled, and there is always the likelihood that dirty waste can become mixed with them. The presence of dirty waste or small amounts of certain oils can lead to spontaneous heating. Reclaimed waste is considered somewhat more hazardous than new waste. It is common practice to handle clean waste in the same manner as dirty waste, although the fire hazard is relatively small.

Large supplies of clean waste are best kept in bins made entirely of metal and provided with covers that are normally kept closed. Several bins can be provided where the supplies are large or where different kinds of waste are kept. The covers on such bins should be counterweighted so that they can be readily raised and lowered. The counterweight ropes can have fusible links to ensure that the covers are closed automatically in the event of fire.

Local supplies of clean waste are usually kept in small, properly marked waste cans. Providing local supply points for clean waste can help eliminate the practice of keeping waste in clothes lockers, drawers, benches, and similar locations. If clean waste is put in such places, workers might mistakenly believe that other, more oily waste is also allowed there when, in fact, the combination of the two can result in fire. These same policies should apply to reused (clean) cotton gloves and possibly also to cotton coveralls and uniforms.

Coatings and Lubricants. Paints, greases, and similar combustibles are widely used in industrial occupancies, and a good housekeeping program will make sure that their combustible residues are collected and disposed of safely. The discharge of vapors from spray booths should be so arranged that the vapors are conducted directly to the outside, and the residues accumulate safely. Use of wash-water spray booths for painting should also be considered. No matter the type of spray booth, it is important that "overspray" be removed from the walls of the spray booth, any area outside the booth, the area behind the filter bank on a dry spray booth, and the exhaust stacks on all type booths. Only nonferrous scraping tools should be used for such cleaning activities. The residue removed should be placed in a closed noncombustible container to await disposal.

Drip Pans. Drip pans are essential at many locations, notably under motors, machines using cutting oils, and bearings, as well as beneath dispensing drums or other containers for flammable and combustible liquids. Drip pans should be made of noncombustible material and contain an oil-absorbing compound. The exception is where flammable liquids are dispensed, in which case the drip pan should be a listed device that would include a flame arrestor screen. All drip pans should be inspected, emptied, and cleaned periodically. At some industrial occupancies, commercial oil-absorbing compounds consisting largely of diatomaceous earth are used instead of sawdust or sand. Although not a recommended practice, regular removal of such oil-soaked material is an important aspect of good housekeeping.

Flammable and Corrosive Liquids Waste Disposal. The disposal of combustible liquid waste often presents a troublesome problem. Any waste material that is a corrosive liquid (PH ≤ 2 or ≥ 12.5), or is a liquid with a flashpoint of 140°F (60°C) or less, is considered a hazardous waste under the United States Federal RCRA. Regulatory agencies in other countries have similar regulations. Drums of this waste must be labeled in accordance with these regulations, which includes labeling the liquid as hazardous waste in accordance with the requirements of the governing local codes. These waste products must be disposed of in a facility that is licensed to handle this waste. Care should be taken to ensure that the facility taking the waste does in fact properly dispose of it. (See Section 7, Chapter 5, "Hazardous Waste Control.")

Flammable Liquid Spills. Flammable liquid spills can be anticipated wherever such products are handled or used and some means of coping with these spills must be kept on hand. These means include a supply of suitable absorptive material and special tools to help limit the spill. Workers should understand and promptly take the steps needed to cut off sources of ignition, ventilate the area, and safely dissipate any flammable vapors.

Flammable Liquid Storage. Flammable liquids should be stored in a segregated area. Good housekeeping practices will ensure that only limited quantities of flammable and combustible liquids are kept on the production floor or work area. These should be protected in suitable containers. No storage of flammable liquids should be allowed in the general storage area,

except as allowed in NFPA 30, *Flammable and Combustible Liquids Code.* Combustible liquid storage should be limited and protected as allowed in NFPA 30 (Figure 11.2.8). Any spills of these materials should be cleaned promptly.

Oil Puddling. Accumulations of oil can present a housekeeping problem at industrial locations where a considerable amount of oil is used. Poor maintenance of industrial hydraulic oil operated equipment such as hydraulic oil pumping systems, extruders, presses, lathes, and elevator equipment can result in oil leaks that eventually form puddles. These puddles can form on floors surrounding the equipment, as well as on and under the equipment. Although most oils used in hydraulic oil systems have high flashpoints, any combustible oil can be a source of fire or lead to an enhanced fire spread, particularly when it is found in puddles that contain accumulations of debris. Puddled oil and materials used to absorb oil spills should be disposed of in metal barrels. Frequent inspection and cleaning of these areas are an important aspect of the housekeeping program.

Oily Waste. Oily wiping rags, sawdust, lint, clothing, and other items can be highly dangerous, particularly if they contain oils subject to spontaneous heating. To dispose of all such materials in ordinary quantities, a standard waste can that has been listed and labeled by testing organizations is best. For large amounts, heavy metal barrels with covers are ideal. Good practice calls for cans containing oily waste to be emptied daily and for wiping rags to be kept in covered metal containers until they can be laundered.

Packing Materials. Almost all packing materials are combustible and, consequently, hazardous. Cellular plastic packing pellets and rigid forms, excelsior, shredded paper, sawdust, burlap, and other such materials should be treated as clean waste. However, large quantities might have to be kept in special vaults or storerooms. Automatic sprinklers are the best protection for areas where considerable quantities of packing materials are stored or handled. These areas also require an extra level of attention to assure that transient materials are cleaned up and returned to their receptacles.

Used or waste packing materials and the crating materials from receiving and shipping rooms must be removed and disposed of as promptly as possible in order to minimize the danger of fire. Ideally, the packing and unpacking processes should be conducted in an orderly manner so that excessive quantities of packing materials do not become strewn about the premises. A specially marked (or identified) area should be provided to accumulate this material. This area should be cleaned frequently and the debris removed to an outside storage receptacle. Outside receptacles should be noncombustibles and placed at least 10 ft (3.048 m) from building walls of combustible construction or where there are windows and doors that can provide an avenue of fire spread.

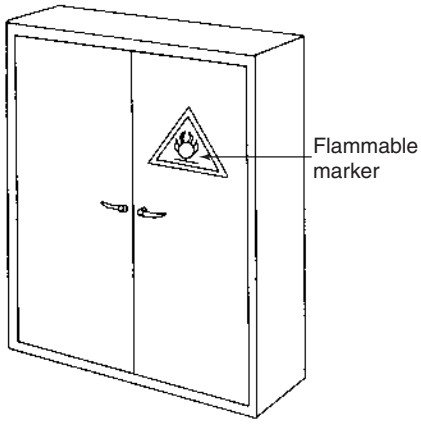

FIGURE 11.2.8 Metal Flammable Liquid Storage Cabinet

OUTDOOR HOUSEKEEPING PRACTICES

Good housekeeping practices are as essential outdoors as they are indoors. Failure to comply with good housekeeping practices outdoors can threaten the security of exposed structures and goods stored outside. The accumulation of rubbish and waste and the growth of tall grass and weeds adjacent to buildings or stored goods are probably the most common hazards. A regular program for policing the grounds is essential.

Grass and Weed Control

Tall grass, dry weeds, and bushes around buildings, along highways, on railroad properties, and along the streets of large industrial and commercial complexes present a definite fire hazard. Fires can spread from one building to another or from the vegetation to the building. To reduce this hazard, vegetation around buildings and outside storage should be controlled or destroyed through the use of common herbicides.

Outdoor Storage

Goods stored outdoors should be properly separated from buildings of combustible construction and from other combustible storage that might constitute an exposure hazard. Passageways between storage piles should also be unobstructed and clear of combustibles. These separations can become blocked by transient storage such as contractors' shacks, discarded crates, pallets, or other combustibles. The housekeeping staff must see to it that these separations are never blocked, even temporarily. Obstructed aisles and dedicated space separations not only can lead to the spread of fire from one area of storage to another but also hamper fire-fighting operations.

Proper housekeeping also requires that smoking in outdoor storage areas be prohibited. Suitable signs should be posted.

Outdoor Rubbish Disposal

Combustible waste materials stored outdoors to await subsequent disposal as rubbish should be placed not less than 10 ft (3 m), and preferably 50 ft (15 m), from buildings, and at least 50 ft (15 m), from public roadways and sources of ignition, such

as incinerators. They should also be enclosed with a secure noncombustible fence of adequate height.

The most satisfactory solution to the rubbish disposal problem is regular collection and removal from the premises. Burning rubbish is generally unsafe and is usually not permitted in developed urban and suburban areas. If burning is permitted and is conducted, it should be done in a noncombustible container or enclosure equipped with a well-maintained spark arrestor.

INSPECTIONS

Housekeeping inspections are an important part of an overall housekeeping program. This type of program should be combined with a complete safety inspection program. This type of inspection has four main objectives:

- Maintain a safe work environment
- Control unsafe actions of employees
- Maintain operations profitability (and product quality)
- Maintain operations to meet or exceed acceptable safety and government standards

Although the word *housekeeping* is never mentioned, it does not take much imagination to see good housekeeping is involved in each objective. Good housekeeping is an essential part of any successful safety program, and that includes the fire safety program.

There are several types of inspections. Some involve preventive maintenance of equipment, such as lubrication of equipment or checking the continuity of static electricity grounding systems. (Figure 11.2.9 presents a sample checklist of inspection activities.) Others involve inspection and testing of fire protection equipment. But most important is a regular inspection by the team leader and facility management. These inspections must be well defined. The program should include what areas are to be inspected, how often the inspections should be made, what is acceptable performance, and who will conduct the inspections.

One of the most time-consuming parts of an inspection is writing a report. Computers and bar coding can help. Bar coding is commonly used to identify products and equipment. However, bar codes can also be used in the identification of hazards. The facility inspector can carry a bar-code reader and recorder. Bar codes identify the department, date, and time of the inspection, as well as the inspector. Common hazards for the facility are entered on a bar-code list carried by the inspector. For each item or hazard on the list, a recommendation is also keyed into the computer program. The inspector simply scans the bar code for the desired item. At the completion of the inspection, the information is downloaded into a computer and a report is printed. This format also allows comments to be made where employees have made positive contributions to the housekeeping program. This positive reinforcement will encourage employees to continue their good work. This computer format also allows for follow-up to housekeeping recommendations. It is very important that, when recommendations are made, positive change results in the area. This change can either be the action recommended or another action that provides equal protection.

Fire-Safety Checklist

Electrical equipment

No makeshift wiring
Extension cords serviceable
Motors and tools free of dirt and grease
Lights clear of combustibles
Circuits properly fused or otherwise protected
Equipment approved for use in hazardous areas (if required)
Ground connections clean and tight and have electrical continuity

Friction

Machinery properly lubricated
Machinery properly adjusted and/or aligned

Special fire-hazard materials

Storage of special flammables isolated
Nonmetal stock free of tramp metal

Welding and cutting

Area surveyed for fire safety
Combustibles removed or covered
Permit issued

Open flames

Kept away from spray rooms and booths
Portable torches clear of flammable surfaces
No gas leaks

Portable heaters

Set up with ample horizontal and overhead clearances
Safely mounted on noncombustible surface
Secured against tipping or upset
Not used as rubbish burners
Combustibles removed or covered
Use of steel drums prohibited

Hot surfaces

Hot pipes clear of combustible materials
Ample clearance around boilers and furnaces
Soldering irons kept off combustible surfaces
Ashes in metal containers

Smoking and matches

"No smoking" and "smoking" areas clearly marked
No discarded smoking materials in prohibited areas
Butt containers available and serviceable

Spontaneous ignition

Flammable waste material in closed, metal containers
Piled material, cool, dry, and well ventilated
Flammable waste material containers emptied frequently
Trash receptacles emptied daily

Static electricity

Flammable liquid dispensing vessels grounded or bonded
Proper humidity maintained
Moving machinery grounded

Housekeeping

No accumulations of rubbish
Safe storage of flammables
Passageways clear of obstacles
Automatic sprinklers unobstructed
Premises free of unnecessary combustible materials
No leaks or dripping of flammables and floor free of spills
Fire doors unblocked and operating freely with fusible links intact

Extinguishing equipment

Proper type
In working order
In proper location
Service date current
Access unobstructed
Personnel trained in use of equipment
Clearly marked

FIGURE 11.2.9 A Sample Fire Safety Checklist

When a bar-code system does not fit the inspection program, one may find that a checklist will be a valuable aid.

To prevent inspections from taking considerable time, the inspector should:

- Have a definite schedule
- Inspect only one part of the department at a time
- Rotate inspection responsibilities among department members
- Make a point of looking for housekeeping problems as part of a daily routine

Trading inspections between departments can help increase inspection effectiveness; monotony can distort evaluation of real problem areas.

SUMMARY

Housekeeping practices are an integral part of any program to prevent or limit fire's spread. Building care and maintenance, occupancy and process housekeeping (including disposal of rubbish and control of ignition sources), appropriate outdoor housekeeping practices, and inspections are key elements.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on housekeeping practices discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 3

Building and Site Planning for Fire Safety

Albert M. Comly, Jr.

Chapter Contents

Building Interior Design Considerations
Building Design and Fire Department Operations
Building Design and Fire Suppression
Site Planning
Exposure Protection

Key Terms

building height, building separation, defend-in-place, evacuation (total), evacuation (zoned), exposure protection, fire lane, HVAC, security, site planning

Effective, fire-safe design begins with conscious analysis and decision making early in the design process. This broad overall approach includes consideration of both interior building functions and layout, as well as exterior site planning. This chapter presents some broad guidelines to be considered by building designers in analyzing fire protection measures that must be provided for a fire-safe environment for structures and their sites. Detailed information of the various aspects of fire-safe site planning and building design can be found elsewhere in this handbook, particularly in the other chapters in this section.

To effectively incorporate the building's fire defenses into the design, the fire safety objectives must first be identified. Section 1, Chapter 2, "Fundamentals of Structurally Safe Building Design," briefly discusses a systematic approach to assessment of fire safety objectives. Decisions must then be made regarding the means to achieve the objectives. The fire safety concepts tree in Section 1, Chapter 2, can be used to obtain an overall perspective of the fire safety system. Venting in conjunction with sprinkler protection continues as a subject of some controversy and is discussed in greater detail in Section 18, Chapter 4, "Venting Practices."

Concepts of egress design, an extremely important part of the design process, are discussed in Section 4, Chapter 3, "Concepts of Egress Design." That chapter, based on NFPA *101*®, *Life Safety Code*®, describes the elements that must be considered when designing adequate egress in buildings for life safety from fire.

For design issues, therefore, see Section 1, Chapter 2, "Fundamentals of Structurally Safe Building Design"; Section 4, Chapter 3, "Concepts of Egress Design"; and Section 18, Chapter 4, "Venting Practices." For other related topics see Section 13, Chapter 5, "Wildland Fire Management"; Section 15, Chapter 1, "Fixed Water Storage Supplies for Fire Protection"; Section 15, Chapter 2, "Water Supply Requirements for Public Supply Systems"; and Section 15, Chapter 6, "Water Distribution."

BUILDING INTERIOR DESIGN CONSIDERATIONS

The architectural design of a building has a significant influence on its fire safety capabilities and performance. In addition to the design of the structure and shell of the building itself, the interior layout and spatial flow, circulation patterns, interior finish materials, and building services are all important factors in the level of fire safety in a building. The design of the building and the relationship of the building to the site or lot can enhance the efficiency of fire department operations by reducing dependence on manual suppression, if the design is executed appropriately. Consequently, fire department operations should be considered in all phases of design.

The primary concept of creating fire safety in structures today involves the philosophy that the building itself must be designed to be either self-protecting or self-controlling from fire and fire spread. This is particularly important as buildings become more complex and exhibit features that

Albert M. Comly, Jr., AIA, is director of the Justice Planning and Design Program at VITETTA Architects and Engineers in Philadelphia. He is also fire marshal of Lower Gwynedd Township in Montgomery County, Pennsylvania, and is an engineer with the Wissahickon Fire Company of Ambler, Pennsylvania. He is a member of the AEBO executive board.

are contradictory to fire department operations, such as sealed environments for energy efficiency and security against intrusion. The design features that are used should consider the local fire-fighting resources that are available and be effected to reduce the reliance on the intervention of the fire service to ensure fire safety. A building should not be designed today that relies solely on the fire service to provide complete protection for the occupants of the building and property; it must include both active and passive building fire defenses to provide reasonable safety from the effects of fire.

Interior Layout

The interior layout of a building influences safety in two distinct ways: (1) The relative use of interior walls, doors, and other elements of compartmentation, combined with the approach to air handling, the use of open floor plans, and many other barrier-related choices, influence the speed and breadth of spread of fire and smoke. Because smoke and toxic gases are the cause of most deaths due to fires, it is not enough to contain the fire itself in order to protect occupants. (2) The relative complexity of the layout will either reduce or increase the time required for potentially endangered occupants to escape, the likelihood that they will find a way to safety in any reasonable space of time, and the possibility that they will move toward greater hazard rather than away from it.

The role of fire effects as a cause of fatal injury is not the only reason to focus on the role of the interior layout in separating occupants and fire effects. Long before they cause fatal injury, smoke and toxic gas reduce visibility, thereby hindering or reducing the ability to find a safe way out, and cause physical irritation and disorientation, further reducing the speed, effectiveness, and efficiency of escape.

Architectural layout and normal circulation patterns are important elements in emergency evacuation. For example, many large office buildings are a maze of offices, storage areas, and meeting rooms. Even under normal conditions, a visitor can become confused and have difficulty exiting the building. Clearly marked emergency travel routes can enhance life safety features in all buildings.

Building Height

The height of the building also has an impact on the fire safety potential of a building. Under optimum conditions, modern fire department aerial equipment only reaches the equivalent of the seventh floor of a building. Occupants on floors above that level must be evacuated by means of interior stairs. The attack at the World Trade Center Towers in 2001 demonstrated the difficulties that arise in evacuating tall buildings—including the time necessary and the impact of crowded stairs on fire fighter access. Mitigating the impact of building height requires careful attention to the layout and construction of stairs and other key building layout elements.

Building Security

Protecting buildings from unwanted intrusion and from all types of crimes has led to the installation of sophisticated and difficult-to-penetrate security hardware and systems. These systems result in the delay of access for fire fighters to an emergency in a building. Worse, they can delay the evacuation and exit of the occupants from a building. Interconnection of security and locking systems with building alarm systems can unlock doors and facilitate emergency movements. Stairs normally equipped with locks to prevent entry from the stair tower to the floor can be made accessible by the use of electrically operated locks. Another means that can be incorporated in the building design is a key lock box—providing the fire department with access to a building without waiting for someone with a key and requiring less time than forcible entry. Careful consideration must be given to the relationship between building security and emergency operations in a building.

BUILDING DESIGN AND FIRE DEPARTMENT OPERATIONS

From the beginning of the building project, the building designer should consult fire department personnel about fire suppression operations in a building. Normally the code review and planning process will serve this purpose. Such consultation is particularly important in the design phase of a building project. In this way, the designer can incorporate features into the building that will aid, rather than hinder, fire suppression and emergency operations.

Briefly, the operations may be broadly grouped as rescue, fire control, and property conservation. The first priority of any fire-fighting operation is rescue, which is defined as the removal of trapped and injured occupants and the search of all areas to ensure that all occupants are out of the building. The larger the building, the greater the number of fire-fighting personnel that must be committed to the rescue operation. In some cases, simultaneous fire suppression operations will be necessary to complete the rescue operation. Significant design features that are necessary in larger buildings include areas of refuge for the physically disabled, fire department controls for ventilation systems, and emergency communications to critical locations in the building.

Accessibility for Fire Fighting

Building design features are important factors in the spread of fire and the ease of suppression. One of the most important design features involves access to the fire. This includes access to the exterior and interior of the building by fire fighters and their equipment.

Access to the building itself requires roads and fire lanes that are designed to withstand the weight of the heaviest fire apparatus expected to respond. These access lanes must be designed to allow fire equipment to get close enough to all sides of the building for rescue and fire suppression functions. These access lanes must be of sufficient width to ensure they will not be obstructed when needed. NFPA 1, *Uniform Fire Code™,* NFPA 1141, *Standard for Fire Protection in Planned Building Groups,* and NFPA 1144, *Standard for Protection of Life and Property from Wildfire,* are consistent in requiring minimum widths of 20 ft (6.11 m) and 13.5 ft (4.11 m) vertical clearance for fire ac-

cess. Widening of paved surfaces to 26 ft (7.99 m) for the use of aerial apparatus is recommended. These widths do not include any allowance for parking. If parking is present in these areas, the space must be added to these widths. NFPA 1, 1141, and 1144 address turning radii by requiring approval by the local authority having jurisdiction. Some commonly used dimensions are a 22 ft (6.7 m) inside turning radius and 50 ft (15 m) outside turning radius. Larger equipment may need even greater radii.

Access to the interior of a building can be greatly hampered where large areas exist and where buildings have blank walls, false facades, solar screens, or signs covering a high percentage of exterior walls. Obstacles that prevent ventilation allow smoke to accumulate and obscure fire fighters' vision. Lack of adequate interior access can also delay the occupants' evacuation or prevent fire department rescue of trapped occupants or initiation of fire suppression efforts.

Windowless buildings and basements present unique fire-fighting problems, requiring careful consideration on the part of the building designer to mitigate these problems. The lack of natural ventilation facilities, such as windows, contributes to the buildup of dense smoke and intense heat, which hampers fire-fighting operations and endangers occupants trapped in these occupancies. For this reason, automatic sprinkler protection is required for windowless buildings by most building codes to extinguish or control a fire before it reaches life- and property-endangering intensity.

Any spaces in which adequate fire-fighting access and operations are restricted because of architectural, engineering, or functional barriers should be provided with automatic extinguishing systems. A complete automatic sprinkler system is generally the best solution to this problem. Other methods can be incorporated in appropriate design situations, such as access panels in interior walls and floors, fixed nozzles in floors with fire department connections, automatic smoke venting, and pressurization of certain building areas, although none of these items can take the place of, or be considered equivalent to, a complete automatic sprinkler system.

Ventilation

Ventilation is an important fire-fighting operation. It involves the removal of smoke, gases, and heat from building spaces. Ventilation of building spaces performs the following important functions:

1. Protects life by removing or diverting toxic gases and smoke from locations where building occupants must find temporary refuge.
2. Improves the environment in the vicinity of the fire by removal of smoke and heat. This enables fire fighters to advance closer to the fire and extinguish it with a minimum of time, water, and damage.
3. Controls the spread or direction of fire by setting up air currents that cause the fire to move in a desired direction. In this way, occupants or valuable property can be more readily protected.
4. Allows the release of unburned, combustible gases before they develop a flammable mixture, thus avoiding a backdraft or smoke explosion.

The building design engineer should consult NFPA 90A, *Standard for the Installation of Air-Conditioning and Ventilating Systems,* or NFPA 90B, *Standard for the Installation of Warm Air Heating and Air-Conditioning Systems,* in the design of air-conditioning, heating, and ventilating ductwork and related equipment for all buildings.

The building designer should be conscious of these important fire ventilation functions and provide effective means of facilitating venting practices whenever possible. Designers should also be conscious of system effects, including the interaction of fire-fighting ventilation with a building's HVAC system and the effects of ventilation on the effectiveness of automatic detection and suppression equipment. This may involve access panels, moveable windows, skylights, or other means of readily venting a structure in case of a fire emergency. Emergency controls on mechanical equipment may also be an effective means of accomplishing fire ventilation. Each building has unique features, and, consequently, a unique solution should be incorporated into each design. NFPA 204, *Standard for Smoke and Heat Venting,* should be consulted for additional information on venting. Training for the use and operation of these unique features should be given to fire fighters as part of a preplan for operations at the site, or staff on site should assist fire fighters in the operation of these ventilation systems.

Water Supply and Use

Water is the principal agent used to extinguish building fires. Although other agents may occasionally be employed (e.g., carbon dioxide, dry chemical, foams and surfactants, and halons), water remains the primary extinguishing agent of the fire service. Consequently, the building designer should anticipate the needs of both the fire department and automatic extinguishing systems and provide an adequate supply of water at adequate residual pressure. (See also Section 15, Chapter 1, "Fixed Water Storage Supplies for Fire Protection"; Section 15, Chapter 2, "Water Supply Requirements for Public Supply Systems"; and Section 15, Chapter 6, "Water Distribution.") The Appendices in NFPA 1 are another good source of information on water supply and flow requirements for fires.

In cities, water is normally supplied to the building site by water mains that are part of the municipal water distribution system. Cities may not be able to supply a sufficient amount of water at required pressures to every part of the city. Consequently, alternative means, including pumps and tanks, must designed as part of the building fire protection systems. These systems can then be supplemented, if necessary, by pumps on fire department apparatus.

Careful attention must be given to water supply, distribution, and pressure for emergency fire conditions. High-rise buildings are particularly sensitive because of the higher water pressures required due to the building height. Large-area buildings must also be given careful attention as to water supply needs.

Fire conditions or fire loads that require operation of a large number of sprinklers or use of a large number of hose streams can reduce pressure in sprinkler and standpipe systems to the point where residual pressures in the distribution system are adversely affected. Fire department connections for sprinkler and

standpipe systems, so the fire department can augment system pressure, are therefore important components of the building fire defenses. The building designer must carefully consider installation details of fire department connections to ensure they will be easily located, readily accessible, and properly marked. Locations for the connections should always be approved by the local fire department.

BUILDING DESIGN AND FIRE SUPPRESSION

The building designer has a significant influence on the relative ease and effectiveness of fire suppression operations. It is important not only to incorporate the needs of the fire service into the functional layout of the building and its services but also to properly plan for automatic fire detection and extinguishing capabilities.

Compartmentation

Fire-fighting efficiency decreases rapidly as the fire spreads vertically or past major horizontal barriers. Fires on two or more floors or filling a very large floor space are extremely difficult to control and extinguish by manual fire-fighting methods. Building designs that utilize unprotected vertical openings, such as open stairwells, curtain wall construction not sealed at each floor, poke-through assemblies, and air-handling ductwork (without dampers), provide avenues for vertical fire spread. It is more difficult to isolate a space completely in modern construction than it was in pre-World War II construction, yet isolation can be accomplished if attention is paid to the details of design and construction. Tested details for all components of the modern building are now documented and readily available, as well as computer modeling programs that can demonstrate what might happen within a building without exposing that building to the effects of an actual fire. These details and components of modern construction work best when they are combined with an active construction inspection program.

Detection, Alarm, and Communications

Time is the most significant factor concerning fire control. The time for fire control includes several distinct segments, including fire detection, occupant notification, fire department notification, fire department response, fire situation assessment, suppression activities, and overhaul operations. In the early development stages of a fire, a matter of minutes is a significant factor both in life safety and in manual fire extinguishment capabilities. Consequently, effective fire detection becomes a vital element in fire safety. After a fire or smoke detector is activated, appropriate action must be initiated. This may involve alarm, communications, fire suppression, or a combination of these activities. An alarm may alert building occupants to the existence of a fire, but what action should then be taken? Evacuation is the normal procedure in smaller buildings. In high-rise buildings, however, total evacuation takes much more time. Consequently, zoned evacuation and/or safe areas of refuge may be considered within the building, and instructions could be given to building occupants concerning the appropriate course of action. This "defend in place" approach is reasonable for localized or minor emergencies. Ultimately, evacuation of the public from problem areas is the most desirable strategy and is consistent with the training that the public receives beginning in elementary school.

Communications are vital in occupant safety and fire control. Communications help warn occupants, provide instructions for action, alert the fire department early about the existence and location of a fire, and can assist the fire department in manual fire suppression. Too often, fire department notification has been delayed because occupants were under the mistaken impression that a local fire alarm system notified the fire department.

Communications systems that are intended to provide emergency voice messages and to give evaluation directions must be designed to meet the survivability requirements in *NFPA 72®*, *National Fire Alarm Code®*, to ensure that they will operate in the adverse conditions found in building emergency situations.

Automatic Fire Suppression

For more than a century, automatic sprinklers have been the most important single system for automatic control of fires in buildings. Many desirable aesthetic and functional features of buildings that might offer some concern for fire safety can be protected by the installation of a properly designed sprinkler system.

Among the advantages of automatic sprinklers is that they operate directly over a fire and are not affected by smoke, toxic gases, or reduced visibility. In addition, much less water is used because only those sprinklers fused by the heat of the fire operate, particularly if the building is compartmented. Sprinkler systems must be designed and installed to provide this level of protection. (See NFPA 13, *Standard for the Installation of Sprinkler Systems*.) Other automatic extinguishing systems (carbon dioxide, dry chemical, halon agents, high-expansion foam) also provide protection in certain portions of buildings or types of occupancies for which they are particularly suited. Other advantages that sprinklered properties may offer include allowance of alternative designs, reduction of some features, and lower insurance rates.

SITE PLANNING

The architect must use a given site in designing the building and adapt the functional and engineering considerations to the particular site conditions that are present. In a similar manner, the architect should consider site features in arriving at decisions on fire protection. A particular set of site characteristics may significantly influence the type of building fire defenses incorporated by the design team. Among the more significant features are traffic and transportation conditions, fire department access, and water supply. Water supply was discussed briefly earlier in this chapter. A few additional considerations are given here.

Traffic and Transportation

Time is a vital factor in fire control. The response time of the fire department can be a major component of the overall time

for fire control. Fire apparatus must respond to a location via streets at all times of the day. Depending on traffic conditions, apparatus can be seriously delayed in responding to some locations.

It may or may not be helpful to consider limited access highways for fire department response. Highways may attract motorists, thus improving traffic conditions on other city streets. On the other hand, the limited access highway may divide a community into sections. Means of travel to locations intermediate to the access points can be delayed. This can have a significant effect on response times and must be considered by the design team in selecting the appropriate fire defenses for the building. Lengthy response times may dictate greater built-in fire protection capability.

Fire Department Access

Ideal exterior accessibility occurs where a building can be approached by fire department apparatus from all sides. This, unfortunately, is not often possible. In congested areas, only the sides of buildings facing streets may be accessible. In other areas, topography or other obstacles can prevent effective use of apparatus in combatting the fire.

Some shopping centers and buildings that are located some distance from the street make the approach of apparatus difficult. If obstructions or topography prevent apparatus from being located close enough to the building for effective use, such equipment as aerial ladders, elevating platforms, and water tower apparatus are rendered useless. Valuable manpower must be expended to carry ground ladders or hand carry hose lines long distances.

The matter of access to buildings has become far more complicated in recent years. The building designer must consider this important aspect in the planning stage. Inadequate attention to site details can place the building in an unnecessarily vulnerable position. If its fire defenses are compromised by preventing adequate fire department access, more complete internal protection in the building itself must make up the difference. If fire department access is limited or nonexistent, complete automatic sprinkler protection should be provided throughout the structure. Other features may be required.

Location of Hydrants

An adequate water supply delivered with the necessary pressure is important to control a fire. In many new developments, such as shopping centers, apartments, and housing projects, inadequate attention is given to the number and location of hydrants. There are situations that present extremely difficult fire-fighting problems where water mains are so small and hydrants are so poorly spaced that adequate water to control a fire is unavailable. The building designer must consider the importance of an adequate and accessible water supply in the planning and design of a building. NFPA 14, *Standard for the Installation of Standpipe and Hose Systems,* and NFPA 24, *Standard for the Installation of Private Fire Service Mains and Their Appurtenances,* provide good sources of information for the planning and design of site-related fire defenses.

EXPOSURE PROTECTION

A fire in one building creates an external fire hazard to neighboring structures by exposing them to heat by radiation and convection, as well as to the danger of flying brands from the fire. Any or all of these sources of heat transfer may be sufficient to cause an ignition in the exposed structure or its contents. This part of the chapter describes a method for evaluating exposure severity and suggests methods for protecting buildings from exterior fire exposures. These methods are aimed at protecting combustibles within, and on the exterior of, an exposed building. NFPA 80A, *Recommended Practice for Protection of Buildings from Exterior Fire Exposures,* is a source for further information on exposure protection.

Factors Influencing Severity of Exposure

When discussing protection from exposure fires, there are three conditions to be considered: (1) exposure to horizontal radiation, (2) exposure to flames issuing from the roof or top of a burning building in cases where the exposed building is greater in height than the burning building, and (3) airborne debris or brands that can be carried to a new building to start a fire. Radiation exposure can result from an interior fire where the radiation passes through windows and other exterior wall openings. It can also result from the flames issuing from the windows of the burning building or from flames of the burning facade itself (Figures 11.3.1, 11.3.2, and 11.3.3). In the Burlington Building in Chicago in 1922, fire in a group of brick, wood-joisted buildings spread across the 80 ft (24 m) street to ignite the upper seven floors of the 15 story office building, which was of fire-resistive construction but lacked exposure protection for street-front windows. Wind carried hot gases against the Burlington Building. Updraft due to convection made exposure most severe above the level of exposing buildings (see Figure 11.3.1). In Wellesley, Massachusetts, a fire started, igniting a building in Newton by radiated heat across the Charles River, a 100 ft (30 m) distance, against the wind. The river prevented access for fire department operations to protect the exposure (see Figure 11.3.3). Distances of 10 to 20 ft (3 to 6 m) between frame buildings, as commonly specified by building codes, do not eliminate exposure hazard but usually provide space for fire department operations (see Figure 11.3.2).

A number of factors significantly influence the danger and intensity of exposing fires to neighboring structures. Among the more important parameters is the severity of the exposing fire (total energy of the fire) itself. It involves both the temperatures developed within the exposing fire and the duration of burning. NFPA 80A describes means for protecting buildings from fire damage resulting from exposure to an exterior fire in an adjacent structure or property. In the past, NFPA 80A categorized exterior exposures into three levels of exposure severity—light, moderate, or severe. The classifications were based on (1) the average combustible load per unit of floor area and (2) the average flame spread ratings of the interior wall and ceiling finishes.

Besides the temperature and duration of the exposing fire, other variables influence the severity of exposure on buildings. Some of these variables include the following:

1. Exposing fire
   a. Type of construction of exterior walls and roofs

FIGURE 11.3.1 The Burlington Building (right), Chicago, March 15, 1922

FIGURE 11.3.2 Typical Ignition of Wood-Frame Dwelling by Heat Radiated from an Exposure Fire

b. Width of exposing fire
c. Height of exposing fire
d. Percent of openings in exposing wall area; exterior walls that are combustible or that do not have sufficient resistance to contain the fire should be treated as having 100 percent openings
e. Ventilation characteristics of the burning room
f. The fuel dispersion, or surface-to-volume ratio of the fuel
g. The size, geometry, and surface-to-volume ratio of the room involved
h. The thermal properties, conductivity, specific heat, and density of the interior finish
i. Whether or not the exposing building is fully sprinklered

FIGURE 11.3.3 Fire Starting in Wellesley, Massachusetts

2. Exposed building
   a. Type of construction of exterior walls and roofs
   b. Orientation and surface area of exposed exterior walls
   c. Percent of openings in exterior wall area
   d. Protection of openings
   e. Exposure of interior finish and combustibles to the radiation, convection, and flying brands of the exposing fire
   f. Thermal properties, conductivity, specific heat, density, and fuel dispersion of the interior finish materials and the building contents
   g. Whether or not the exposed building is fully sprinklered
3. Site and protection features
   a. Separation distance between exposing and exposed building
   b. Shielding effect of intervening noncombustible construction
   c. Wind direction and velocity
   d. Air temperature and humidity
   e. Accessibility for fire-fighting operations
   f. Extent and character of fire department operations
   g. Built-in fire protection features

Finally, it is worth noting that during construction a large building is more vulnerable to an exposing fire and thus more dangerous than it will be when it is completed. Also, buildings in the wildland/urban interface have unique exposure problems. (See Section 13, Chapter 5, "Wildland Fire Management" for additional discussion of this topic.)

Design Guidelines for Exposure Protection

When analyzing or designing a building for exposure protection, two situations are considered. The first occurs where the exposing building is equal or greater in height than the exposed building. In this case, only the thermal radiation from walls or wall openings is considered. The second case arises when the exposing building is shorter than the exposed building. This will affect the walls and wall openings for some distance above the exposing building—requirements for which are usually found in the building code.

Naturally, site conditions and economic constraints preclude the opportunity of providing most buildings with the calculated separation distance. When this occurs, the separation may be reduced by protecting the structure. NFPA 80A addresses the exposure risk by considering the following means of exposure protection, listed below without any prioritization:

1. Buildings
   - Separation between buildings
   - Total automatic sprinkler protection
2. Walls
   - Blank walls of noncombustible materials
   - Barrier walls (self-supporting) between building and exposure
   - Masonry parapet walls or horizontal extensions that extend beyond the construction
   - Automatic exposure protection sprinkler systems for combustible walls
3. Wall openings
   - Elimination of openings by filling with equivalent construction
   - Glass block panels in openings
   - Fire-rated windows and frames
   - Automatic exposure protection sprinkler systems
   - Listed automatic window sprinklers
   - Listed automatic fire shutters on openings
   - Listed automatic fire doors on door openings
   - Listed automatic fire dampers on wall openings

Additional means of protection are continually being developed, including new glazing materials and rated frames and fire-retardant coatings. As new means become available, due diligence is necessary to assure that they have been properly tested and approved. Means that require manual operation at the time of the exposure should not be used. Assuming that someone will be present to activate a device or will arrive in time is contrary to the concept of built-in protection.

These methods should be evaluated for suitability along with consideration of other potentially adverse effects and conditions including convected heat, flame impingement, and small flying brands associated with winds, as well as the beneficial effects of fire department operations. Additionally, the potential duration of the exposing fire and the fire load should be included in the final evaluation of the specific condition or detail.

Selecting the means of protection should consider the means, the appropriateness of the application, the contributing conditions, and duration of the exposure. Another step in the selection must be confirmation of the approval of the means and the specific installation for the intended use. Standards such as NFPA 80 for fire doors and windows and NFPA 13 for automatic sprinklers are basic resources for those approvals. Deviations from the approved methods of installation should be avoided.

The separation of the building to be protected from the potential exposure risk is the other key consideration in the overall protection scheme. NFPA 80A presents a series of tables that provide separation distance adjustments based on the construction of the walls (combustibility and materials), the presence of openings, and the means of protection selected for the building.

It should be noted that none of these measures is necessary, or even desirable, when both the exposing and exposed properties are provided with a complete fire sprinkler system.

SUMMARY

This chapter presented broad guidelines that building designers should follow to provide fire-safe environments for structures and their sites. The design of a building directly affects its fire safety capabilities and performance, including fire department operations, fire suppression, and exposure protection of other buildings. Site planning is equally important, in terms of traffic and transportation, fire department access, and water supply.

BIBLIOGRAPHY

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on building and site planning for fire safety. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

Chapter 4

Fire Hazards of Construction, Alteration, and Demolition of Buildings

Richard J. Davis

Chapter Contents

Planning
Construction and Alterations
General Concerns
Supervision of Fire Protection
Demolition Operations
Asbestos Removal
Underground Operations

Key Terms

construction, demolition, exposure protection, hot work, rehabilitation, renovation, temporary structure, welding blanket, welding pad

Buildings and other structures, regardless of construction type or construction method, are more vulnerable to fire when they are under construction, alteration, or demolition than when completed or when the demolition is finished. The reason for this is that when fires occur, they are likely to spread more rapidly due to the absence or impairment of fire suppression and detection systems, lack of compartmentation, and the presence of heavier concentrations of readily ignitable combustibles than would be expected during normal use. In new construction, fires can more easily cause severe damage because of incomplete structural systems, lack of applied fire-resistant materials, and the exposed condition of the structure. The use of hot work in these operations also increases the likelihood of a fire. Fires can also cause the destruction of building materials stored on site, lengthy delays in project completion, long-term business interruption, and injury or the possible loss of life.

Based on information gathered from 1995 to 2005 by a large industrial and commercial insurance carrier,[1] 46 percent of construction-related fires were caused by hot work, 14 percent were caused by incendiarism or vandalism, 8 percent were of electrical origin, 20 percent were undetermined, and most of the remaining causes were related to smoking or heating equipment. This included a total of 132 fire losses with a gross loss cost of $238 million (Table 11.4.1).

This chapter discusses the fire hazards associated with the construction, alteration, and demolition of buildings. Special situations, such as asbestos removal and underground structures, are also discussed. Practices for the prevention of fires, prefire planning, storage of combustible materials, and installation of fire protection systems are specifically addressed in the chapter.

Additional information on hazards associated with building construction, fire protection systems, and prefire planning can be found in Section 1, Chapter 2, "Fundamentals of Structurally Safe Building Design"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 7, Chapter 3, "Storage of Gases"; Section 9, Chapter 6, "Welding, Cutting, and Other Hot Work"; Section 11, Chapter 3, "Building and Site Planning for Fire Safety"; Section 12, Chapter 11, "Industrial Fire Loss Prevention"; Section 12, Chapter 17, "Pre-Incident Planning for Industrial and Municipal Emergency Response"; Section 16, Chapter 3, "Automatic Sprinkler Systems"; Section 16, Chapter 10, "Standpipe and Hose Systems"; and Section 19, Chapter 1, "Types of Building Construction."

PLANNING

Construction operations can be made reasonably safe in new construction, rehabilitation, or demolition projects with adequate planning, proper allowances in job estimates, and proper on-site supervision and control. Although new construction, rehabilitation, and demolition projects differ

Richard J. Davis, P.E., F.S.P.E., is an assistant vice-president at FM Global in Norwood, Massachusetts, and is a member and retired chair of the NFPA Technical Committee on Construction and Demolition and a member of the NFPA Technical Committee on Building Construction.

TABLE 11.4.1 Structure Fires in Properties That Are Under Construction, Major Renovation, or Demolition, 1999–2002 Annual Averages

Building Status	*Fires*	*Civilian Deaths*	*Civilian Injuries*	*Direct Property Damage (in Millions of Dollars)*
Under construction	4,800	6	97	235
Under major renovation	3,900	9	98	85
Under demolition	2,300	0	16	11
Total	11,100	15	211	331

Note: These are national estimates of fires reported to U.S. municipal fire departments and so exclude fires reported only to federal or state agencies or industrial fire brigades. National estimates are projections. Casualty and loss projections can be heavily influenced by the inclusion or exclusion of one unusually serious fire. Fires are rounded to the nearest hundred, deaths and injuries to the nearest one, and direct property damage to the nearest million dollars. Property damage has not been adjusted for inflation.

greatly in the scope of work, they have many fire safety items in common. These common items relate to establishment and maintenance of on-site fire protection, provisions for temporary fire protection, and maintenance of means of escape for workers and others in the building. NFPA 241, *Standard for Safeguarding Construction, Alteration, and Demolition Operations,* contains measures that, with prefire planning, will help prevent fire or at least minimize damage when fire occurs.

Security guard service on construction sites is recommended during nonworking hours. Patrols should be planned so that no portion of the job site is overlooked. The use of guard clock and time recording systems is recommended to ensure patrols have been made. Guards should be briefed on the fire protection measures available on the job site, on developments during the workday that affect fire hazards and fire protection capabilities, and on emergency procedures. Provision (either a telephone or a fire alarm box) should be made for notifying the fire department in the event of a fire. Provision for security service should be considered as a part of the project planning stage. NFPA 601, *Standard for Security Services in Fire Loss Prevention,* should be consulted for planning security service.

In any project, whether new construction, rehabilitation, or demolition, the fire department should be kept aware of construction progress. The fire department can thereby provide for command posts and prefire plans and be ready to deal with unusual problems encountered during the course of the project.

CONSTRUCTION AND ALTERATIONS

Site Preparation

Site preparation is the first item necessary in any new construction project. This involves the removal of brush, trees, and debris from the site prior to the start of construction. Although such land clearing provides for control of natural cover fuel fires, it mainly provides site accessibility for construction. Today's methods of site preparation differ from the "scorched earth" methods of years ago in that the preservation of as much natural vegetation as practical is desired. This should present no serious fire problem as long as temporary buildings and materials storage are properly isolated from any natural cover fuel by fire breaks of at least 30-ft (9.2-m) width.

Of prime importance for site preparation is the establishment of roadways and the installation of a water supply for fire protection. Many jurisdictions now require that permanent all-weather roads and site utilities be provided before construction begins. Construction site access by temporary or permanent all-weather roadways should be provided, as well as water service for fire protection, prior to the start of construction.

Although it is usually more economical to provide permanent water service to serve the construction fire protection needs early in the project, it is sometimes necessary to provide temporary water service in the form of aboveground water mains, tanker trucks, or ponds.

Temporary Buildings

Temporary buildings are commonly used on construction sites for the storage of tools and equipment, and serve as temporary offices for the construction management team. The use of mobile structures, such as converted manufactured homes or trailers, is common at large construction projects. The location of these temporary buildings can create a serious exposure hazard either to the building under construction or to the group of temporary buildings themselves. Often mobile structures are attached or installed adjacent to each other, creating a larger building with greater hazards than one structure alone.

It is important to consider the added exposure protection necessary if several temporary or mobile structures are on the same site. Single-story unprotected temporary buildings of combustible construction, or with combustible contents, should be located according to Table 11.4.2. When the separation distance between temporary structures is less than the minimum separation distance as specified in the table, then the exposing wall length is the sum of the individual exposing wall lengths of the temporary structures. Providing automatic sprinkler protection in the temporary buildings can be used to reduce the separation distance between temporary structures by 75 percent.

The fire hazards are much the same whether a mobile structure or a temporary structure is used. Overloaded temporary wiring, incorrectly installed portable or temporary heating equipment, and inadequate control of open-flame devices are examples of the common hazards. The high level of fuel load in the form of construction materials, construction plans, specifications, and other documents further increases the fire hazards. In

TABLE 11.4.2 Separation Distances

Temporary Structure Exposing Wall Length		Minimum Separation Distance	
m	*ft*	*m*	*ft*
6	20	9	30
9	30	11	35
12	40	12	40
15	50	14	45
18	60	15	50
>18	>60	18	60

Notes:
1. Where the separation distance between temporary structures is less than the minimum separation distance, then the exposing wall length shall be considered to be the sum of the individual exposing wall lengths of the temporary structure.
2. A 75 percent reduction in separation distances shall be permitted to be applied, provided automatic sprinkler protection is used in the exposing structure.
3. The separation distances apply to single-level structures only. This table does not apply to multilevel, unsprinklered structures. A level, where applying this table, is 3600 mm (144 in.).

Source: NFPA 241, *Standard for Safeguarding Construction, Alterations, and Demolition Operations,* Table 4.2.1, 2004, pp. 241–245.

addition, the use of space (sometimes concealed) beneath these temporary structures for miscellaneous storage can be hazardous. Such spaces and storage can be subject to vandalism and arson. Incendiary or suspicious causes are by far the number one cause accounting for nearly one half of the reported fires in these temporary buildings (what the fire incident codes call "contractors' sheds"). Vegetation growing under, or left in, these spaces can also create hazards.

The protection of these structures, especially mobile structures, is usually possible by the installation of a residential-type sprinkler system using listed plastic pipe that can be connected to the on-site water supply. The cost of this protection is low for the mobile structures, since there is only a one-time installation cost, and connection costs on the site are minimal.

Loss Prevention During Construction

Normal construction practices require considerable amounts of combustible building materials, forms, and scaffolding, which tend to accumulate in congested areas. Temporary storage of combustible materials in the yard or on the roof should be kept to a minimum and limited to 6 ft (1.8 m) in height and one or two pallet widths. Where space permits, combustible storage should be located at least 30 ft (9 m) from the structure being exposed. Those areas of a building where the fire-resistant coatings for structural steel have not been completed should not be used for the storage of combustible items. Foamed plastic materials should be stored only to a maximum height of 5 ft (1.5 m) and only in areas where automatic sprinkler protection is in service.

Water service at the site should be adequate not only for the final building construction needs, but also for fire protection during construction, in view of the amount of combustibles present. In multistory structures, either temporary or permanent standpipes should be put into service as each floor is constructed to provide fire-fighting capability. Temporary standpipe service is usually a dry standpipe with proper valves at each floor. A fire department siamese connection, easily accessible to fire department pumpers, should be provided at the street. If the siamese connection is located inside the construction site, clear access to the siamese connection via all-weather roads should be maintained. Large signs indicating the location of the fire department connection and the top level of the standpipe should be installed to assist the local fire department.

Temporary enclosure of buildings is common and should only be done with care. Only flame-resistant tarpaulins or materials of similar fire-retardant characteristics should be used (Figure 11.4.1). If temporary enclosure is required, metal or fire-retardant-treated wood forms spaced about every 4 ft (1.2 m) should be used to support the material. The enclosure materials should be securely fastened or guarded to prevent contact with heaters or other sources of ignition. Fabric or plastic film should meet the requirements of NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films.* Tarpaulins that appear weathered may have lost their fire-retardant qualities and should not be used.

Combustible formwork is a constant source of danger to concrete buildings under construction. Concrete should be poured as quickly as possible after combustible forms have been constructed and the forms removed as soon as possible after the concrete has set properly. During the time the forms are in place, storage and construction operations on that floor should be held to a minimum and ignition sources should be eliminated. Noncombustible forms should be used whenever possible

FIGURE 11.4.1 Large Sheets of Plastic Enclose Buildings Under Construction to Confine Heat

(Figure 11.4.2). Yard storage of combustible forms should be at least 30 ft (9 m) from the building.

Where fire-resistant coverings for structural members are specified, they should be applied as soon as possible to afford fire protection to beams, columns, and other structural elements early in the construction phase.

Rubbish and trash accumulations can present a serious fire hazard on the construction site. Daily cleanup of scrap lumber, cardboard, and other debris removes the fire hazard and provides a safer working environment. Trash containers should be provided on site for proper storage of debris and should be located at a safe distance from the building.

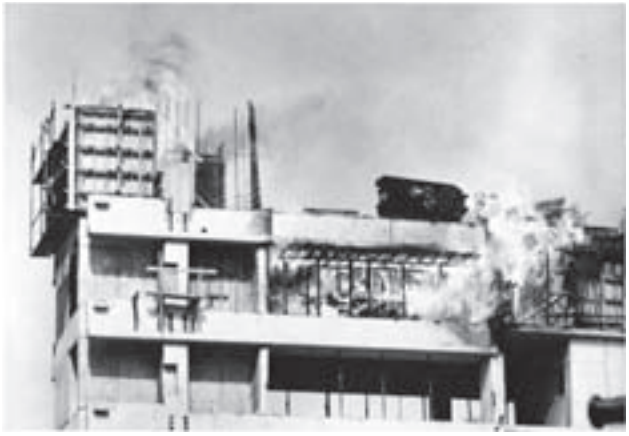

FIGURE 11.4.2 Burning Wood Formwork for Cast-in-Place Floor and Wall Panels in a Parking Garage

GENERAL CONCERNS

Hot work and trash removal are concerns with construction, alteration, and demolition. Asbestos removal is a concern during some alteration and demolition projects.

HOT WORK PERMIT

STOP!
Avoid hot work or seek an alternative/safer method, if possible.

This *Hot Work Permit* is required for any temporary operation involving open flames or producing heat and/or sparks. This includes, but is not limited to: brazing, cutting, grinding, soldering, torch-applied roofing and welding.

Part 1

Instructions

1. Fire safety supervisor:
   A. Verify precautions listed at right (or do not proceed with the work).
   B. Complete and retain Part 1.
   (Part 1A is for quality assurance documentation, if necessary.)
   C. Issue Part 2 to person performing hot work.

Hot work by
☐ Employee
☐ Contractor

Date | Job number

Location/building and floor

Nature of job

Name (print) and signature of person performing hot work

I verify the above location has been examined, the precautions checked on the Required Precautions Checklist have been taken to prevent fire, and permission is authorized for this work.

Required Precautions Checklist

☐ Available sprinklers, hose streams and extinguishers are in service/operable.
☐ Hot work equipment in good working condition.

Requirements within 35 ft. (11 m) of hot work

☐ Flammable liquid, dust, lint and oily deposits removed.
☐ Explosive atmosphere in area eliminated.
☐ Floors swept clean.
☐ Combustible floors wet down, covered with damp sand or fire resistive sheets.
☐ Remove other combustible material where possible. Otherwise, protect with FM Approved welding pads, blankets and curtains, fire resistive tarpaulins or metal sheets.
☐ All wall and floor openings covered.
☐ FM Approved welding pads, blankets and curtains installed under and around work.
☐ Protect or shut down ducts and conveyors that might carry sparks to distant combustible material.

Hot work on walls, ceilings or roofs

☐ Construction is noncombustible and without combustible covering or insulation.
☐ Combustible material on other side of walls, ceilings or roofs is moved away.

Hot work on enclosed equipment

☐ Enclosed equipment cleaned of all combustible material.
☐ Containers purged of flammable liquid/vapor.
☐ Pressurized vessels, piping and equipment removed from service, isolated and vented.

Fire watch/hot work area monitoring

☐ Fire watch will be provided during and for 60 min. after work, including any break activity.
☐ Fire watch is supplied with suitable extinguishers, and where practical, a charged small hose.
☐ Fire watch is trained in use of equipment and in sounding alarm.
☐ Fire watch may be required in adjoining areas, above and below.
☐ Monitor hot work area for an additional three (3) hours after the 60 min. fire watch.

Other precautions taken

☐

FIGURE 11.4.3 Hot Work Permit (Source: © 2006 FM Global. Reprinted with permission. All rights reserved.)

Hot Work

Hot work such as cutting and welding operations must be carefully controlled, and proper safeguards utilized. Fires started by welding, cutting, plumbing, or other torches account for one of the largest shares of construction fires. A permit system that specifies controls for safe welding should be used. Combustible materials within 35 ft (11 m) of any cutting or welding operation need to be protected by being relocated, covered with noncombustible materials, or, as a last resort, being wet down prior to and during the operation. Follow the fire protection procedures in NFPA 51B, *Standard for Fire Prevention During Welding, Cutting, and Other Hot Work.*

Listed welding blankets and welding pads are now available[2] for use in covering combustibles at or near a hot work operation. A *welding blanket* is a heat-resistant fabric designed to be placed in the vicinity of a hot work operation. It is intended for use in horizontal applications with light to moderate exposures such as that resulting from chipping, grinding, heat treating, sand blasting, and light horizontal welding. It is designed to protect machinery and prevent the ignition of combustibles such as wood that are located adjacent to the underside of the blanket. A *welding pad* is a heat-resistant fabric designed to be placed directly under a hot work operation such as welding or cutting. It is intended for use in horizontal applications with severe exposures such as those resulting from molten substances or heavy horizontal welding. It is designed to prevent the ignition of combustibles that are located adjacent to the underside of the pad.

The hot work permit serves several functions: evaluation of the fire hazards in the immediate area where hot work is to be performed, specification of requirements for fire suppression, elimination of hazardous activities, and notification of the security service of the location of the hot work. The construction manager should designate an individual, other than the operator of the heat-producing equipment, to complete the permit. Figure 11.4.3 is a sample two-part hot work permit; the second part should be posted in the hot work area.

A qualified individual should be assigned the responsibility of being the fire watch during hot work operations. It is

HOT WORK PERMIT

FIGURE 11.4.3 Continued

important that the fire watch be located in a position to observe where the falling hot materials land. This may be in a location not directly within the cutting and welding operation area.

For additional hot work guidelines, see Section 9, Chapter 6, "Welding, Cutting, and Other Hot Work."

Trash Removal

It is common practice to provide chutes for the removal of trash and debris from the upper floors. If chutes are used, they should be noncombustible and erected outside the building. By installing the chute as straight as possible, the potential for obstructions in the chute will be minimized.

Although noncombustible trash chutes are recommended, combustible plastic trash chutes are often found in use. Although NFPA 241 recommends that protection be provided for combustible trash chutes, no consensus method of protection exists. A possible method of protection is a sprinkler(s) to protect the inside of the chute. Precautions would be needed to prevent damage to the sprinkler head from debris thrown into the chute. This would include the provision of a recess in the top section of the chute and any intermediate sections where sprinklers are installed. Sprinklers should also be protected with a guard (such as used for in-rack sprinklers) and connected to any available water supply using a flexible sprinkler connector and a small hose. Tall chutes would require intermediate protection.

Dumpsters should be separated from combustible construction or unprotected windows (Figure 11.4.4).

CASE STUDY: Combustible Construction Debris. A five-story, wood-framed building was being constructed in an urban area. Sprinklers were to be installed within the next few weeks, and much of the combustible construction materials had not yet been sheathed with a thermal barrier. Scraps of combustible materials were discarded into a dumpster placed at ground level. The dumpster was immediately adjacent to the new building and a plastic trash chute was being used to feed the dumpster. The dumpster was full and trash bags were backing up into the chute. Cigarette butts were later found in some of the unburned trash bags in the dumpster. A fire started within the dumpster, ignited the plastic trash chute, and spread to the building under construction (Figure 11.4.5). The fire completely destroyed the building under construction and spread fire to many other buildings in the neighborhood (Figure 11.4.6). A total of over 20 buildings and 20 vehicles were damaged by the fire. Windows in a brick building across the street and at least 100 ft away were broken from the fire (Figure 11.4.7). This fire emphasizes the need to empty dumpsters when full, to keep dumpsters away from combustible buildings, to use noncombustible trash chutes, and to control ignition sources on the job site. It also emphasizes the importance of expediting the installation of sprinklers and the vulnerability of combustible construction materials before they are sheathed.

Temporary Heating

Salamanders and other temporary heating devices have been responsible for numerous fires that have resulted in millions of

FIGURE 11.4.4 Dumpster Separated from Building at Construction Site

FIGURE 11.4.5 Fire That Started in Combustible Waste in Dumpster, Spread via Plastic Trash Chute

FIGURE 11.4.6 Five-Story Building Under Construction Completely Involved in Fire

FIGURE 11.4.7 Damage to the Neighborhood. Windows broke in brick building 100 feet from the fire.

dollars in property losses. When salamanders are in use, they should be visually inspected every one-half hour to ensure that combustibles have not blown over or fallen near the temporary heating device. This may require the use of security guards during nonconstruction hours. During windy periods, it may be necessary to constantly attend the temporary heating devices being used. Any object that is too hot to touch should be moved or the heating device relocated. Liquefied petroleum gas (LP-gas) cylinders used to fuel temporary heating devices should be securely fastened to prevent falling. Visual inspection should also ensure that the heating appliance is operating properly. Requirements in NFPA 58, *Liquefied Petroleum Gas Code,* should be followed for LP-gas heating device operation. Permanent heating plants and temporary nonfired heat exchangers can often be used to supplant the more hazardous salamanders.

Flammable and Combustible Liquids

Flammable and combustible liquids present obvious fire protection problems. They should be stored and handled in approved metal containers or in their original shipping containers. Containers should be tightly closed when not in use. Some materials, such as contact cement, are extremely hard to pour, and should be left in their original containers. Care must be taken to ensure that these liquids are not stored in exits or stairways and that they do not block access to fire-fighting equipment. Quantities of more than 25 gal (95 L) of flammable or combustible liquids should be stored in approved flammable liquid storage cabinets or other acceptable structures. See Section 4.3 of NFPA 30, *Flammable and Combustible Liquids Code,* for maximum storage quantities for cabinets. NFPA 30 also provides information for the safe handling, dispensing, and storage of flammable and combustible liquids. Storage of more than 60 gal (227 L) of Class I and Class II liquids should be at least 50 ft (15 m) from buildings under construction. The area around the outside flammable liquid storage area should be maintained free of combustible materials, such as weeds, debris, and construction materials.

Internal combustion engines for pumps, air compressors, and so on, should be placed to avoid the discharge of the exhaust near or contacting combustibles. A minimum of a 6-in. (152-mm) clearance to combustibles should be maintained if the exhausts are piped to the exterior. The engine should be shut down and allowed to cool prior to refueling to prevent flash fires. Electric, hydraulic, or pneumatic-driven equipment should be used in underground or basement locations or windowless buildings.

Roofing Operations

Tar and asphalt kettles should be located outdoors and should not be located on a roof. Uninsulated fuel containers should be kept at least 10 ft (3 m) from the burner flame and should be secured to prevent tipping or falling over. Metal covers (at least 14 gage) should be provided to smother potential fires in asphalt and tar kettles. At least one 20-B-rated fire extinguisher should be located no less than 5 ft (1.5 m) and no greater than 25 ft (7.6 m) of horizontal travel distance of every roofing kettle at all times. If the roof is of combustible construction, at least one 2A:20-B:C-rated fire extinguisher should be available on the roof. Should a fire occur, it is important to remember that water thrown into the tar kettle may cause the tar to froth and it may overflow the container. Roofing mops should never be left indoors near ignition sources or combustible materials. Roofing mops soaked with tar can be susceptible to spontaneous ignition; however, modern roofing materials are less susceptible to this problem. To reduce this problem, mops should be spun to remove excess tar and hung or placed so that the mop head is not in contact with combustible materials or other mop heads.

During some roofing operations, it may be necessary for a fire watch to also be located under the roof. Particular attention should be paid to areas, such as around flashing, that are being heated by torches. The fire watch should have a portable fire extinguisher or water-charged hose line that can be used to extinguish small fires that start from hot slag or sparks when steel deck is being welded in place. The fire watch should not have any other duties during this time and should remain as the fire watch after the hot work has been completed. Security guard services should pay additional attention to areas where hot work was conducted during the previous shift.

Torch-applied roofing systems should be installed using extreme caution. All roofers who use a torch should be trained by someone who has passed the Certified Roofing Torch Applicator (CERTA) program implemented by the Midwest Roofing Contractors Association (MRCA) and the National Roofing Contractors Association (NRCA). Torch-applied roofing is considered hot work, and fire watches should be maintained during and after torch use. The area under the roofing operation should also be checked frequently by the fire watch. The NRCA recommends a minimum 2-hour fire watch after work is complete, including checks of the top and bottom roof surfaces for smoldering. Care must be taken so that the membrane is not overheated or excessively smoking.

The flame of the torch should not come in contact with wood nailers, cant strips, or metal flashing. Nor should the torch be used where the flame impingement cannot be fully observed. Extreme caution should be used near penetrations such as exhaust vents because flames could ignite grease and lint accumulations. Such accumulations should be cleaned before roofing work is started. Ventilation equipment should be shut down. A base ply should be used to protect wood deck, combustible insulation or cover boards (such as foam, kraft-faced glass fiber or wood fiber, oriented strand board, or OSB), small crevices, or plastic fastener plates. Small torches may be used to heat the underside of the membrane away from these areas before securing the membrane. Hot trowels should be used to feather seams at laps and flashings. For additional information, refer to FM Global Property Loss Prevention Data Sheet 1-33, *Safeguarding Torch-Applied Roof Installations.*[3]

Some types of single-ply roof covers such as polyvinyl chloride (PVC), thermoplastic polyolefin (TPO), or chlorosulfonated polyethylene (CSPE or Hypalon®) require the use of either solvent or heat welding of the laps. Other types like ethylene propylene diene monomer (EPDM) require the use of solvents to clean membrane laps prior to adhering.

Permanent Safeguards

In most construction operations, the progress of the work toward completion gradually enhances the safety of the structure. As the need for combustible formwork and scaffolding, materials storage, temporary buildings and trailers, and other inherent hazards diminishes, they should be removed from the site.

Fire fighter access to the structure is important. Installation of permanent stairways and stairway enclosures should be completed as quickly as possible. Fire barriers and other essential features that provide for the confinement of fire should be installed as early as possible. Penetrations of fire-resistant construction made for building services should be sealed with a fire-rated material immediately after the building services are installed. The fire rating of the sealant should be the same as the structural element that has been penetrated. The integrity of all fire cutoffs should be maintained.

In buildings without automatic sprinkler systems, or those in which the installation of water tanks and other fire protection equipment must wait for the completion of the structural elements, standpipe and hose systems may provide the only reliable source of water for fire fighting during the construction of the project. In buildings where automatic sprinkler protection is to be a part of the permanent protection for the building, the sprinkler system should be installed as building construction progresses. Many fires have occurred only a few days prior to the anticipated completion of a sprinkler system. Sprinkler systems should be installed, tested, and operating prior to significant combustibles being introduced into the structure and immediately following combustible construction. Blank gaskets and blind flanges used to activate sprinkler protection by sections, as construction work is completed, should be provided with lugs that are painted red, or otherwise clearly marked when installed. Doing so will help ensure that the gasket or flange is removed when the system is extended.

Permanent standpipe and hose systems should be installed as construction work progresses and should not wait for the final structural shell to be completed. Permanent wiring systems should replace temporary wiring as rapidly as possible, and certainly as soon as formwork is removed from concrete construction.

SUPERVISION OF FIRE PROTECTION

All construction, renovation, and demolition projects should have a qualified person functioning as the fire protection manager and assigned responsibility for fire prevention and protection activities. On smaller projects, this responsibility may be assumed along with other responsibilities by one individual. This person should also have full authority to enforce fire prevention procedures required for the project. In renovations of occupied buildings, a fire protection manager should be appointed by the building owner. Although responsibility for fire protection rests with the owner, steps to accomplish effective loss prevention are normally carried out by the contractor.

The fire protection manager should develop a written prefire plan in cooperation with the responding local fire department and the owner's fire brigade if present. At a minimum, the prefire plan should identify emergency access roads, fire-fighting water supplies, nature of the construction project, site-specific hazards, emergency contact lists, and on-site fire-fighting capabilities. Since construction projects are constantly changing, the prefire plan should be flexible. The prefire plan should be shared with the local fire response agency at least every six months, or more often as changes in construction warrant.

Even with a local fire department response, contractors and security guards should be trained in the use of portable fire extinguishers and standpipe hose lines. On large projects, consideration should be given to establishing a fire brigade using either contractor employees or dedicated fire brigade members. NFPA 600, *Standard on Industrial Fire Brigades,* provides additional information on the equipment and training requirements for fire brigades and employee fire fighting. The fire brigade may also be involved in other emergency response functions, such as first aid, confined space entry, or technical rescue (e.g., trench, low-angle, or high-angle rescue).

Fire prevention should be a regular topic at contractor safety meetings, which are often called "tailgate talks." All fires should be investigated by the fire protection manager and needed changes in construction-related activities or fire prevention requirements communicated to all workers.

Rehabilitation Projects

There has been a great deal of rehabilitation of older buildings in recent years. This effort is partly the result of a desire to preserve historic structures and partly a result of rising construction costs. From a fire protection standpoint, rehabilitation projects can produce fire-safe buildings if the extensive compartmentation usually present in older buildings is at least partially preserved.

Code-Related Issues. From a building code standpoint, existing buildings being rehabilitated usually must meet current code requirements for means of egress, fire protection, and light and ventilation.

In buildings with historic significance, it is sometimes undesirable to provide all of the code-required safeguards, as these changes may destroy the historic features. The use of equivalency concepts to provide the level of safety intended by a particular code is usually possible when it is impractical to meet the letter of the code. Otherwise, the safety of the occupants takes precedence, and the proper safeguards must be installed to ensure life safety. Although improvement of exits to total code compliance may not be possible, providing other compensating features in the building to control fire and smoke may result in equivalent safety. These compensating features may involve the installation of automatic sprinkler protection, smoke detection systems, and smoke-control systems. Design equivalency should be evaluated carefully to ensure that a level of life safety comparable to that required by the applicable code is being maintained.

The U.S. Department of Housing and Urban Development (HUD) has produced guidelines for the rehabilitation of buildings. An interesting feature of these guidelines is a volume that provides fire-resistance information on older methods of

building construction.[4] This information is extremely valuable when attempting to evaluate the fire resistance ratings for existing building structural systems and fire barriers. Similar literature is available from the National Institute of Building Sciences (NIBS).[5]

Life Safety. In some rehabilitation projects, the renovations must be made while the building is partially occupied. Special precautions must be taken in these cases. The most important of these is the maintenance of proper exits from the building. Not only must exits be provided for building occupants but also at least one exit must be provided for building trades workers in the construction areas. The accumulation of trash and other debris must be kept to a minimum and refuse removed daily.

If fire suppression, detection, or alarm systems are being renovated, their downtime must be kept to a minimum. Proper planning can eliminate unnecessary downtime. Isolation of parts of systems is usually possible to ensure operation in unaffected areas of the building. If it becomes necessary to shut down entire systems, a fire watch should be posted near the main control to restore service in case of fire. Some form of reliable communication should be established if the main control is remote from the work area. This precaution is especially important in sprinklered buildings. Removing the entire sprinkler system as part of a rehabilitation project can have disastrous results.

Means of egress should be readily available to building occupants during normal working hours. Therefore, alterations to means of egress should be accomplished during off-hours. In some cases, rerouting of traffic may be a practical alternative. In all cases, exit systems and fire protection systems should be restored at the end of each work day.

In cases where additions to buildings block existing exits, provision must be made for alternative means of egress or for a protected path of travel. The use of combustible materials in temporary exit construction should be avoided.

DEMOLITION OPERATIONS

If not properly controlled, demolition operations can create more serious problems than construction operations. Buildings under demolition can suffer the same lack of compartmentation and lack of built-in fire protection, but with their demolition rubble, they may have even more readily ignitable fuel load. Demolition operations should include precautions to ensure maintenance of fixed fire protection systems for as long as possible.

Fire Protection Systems

Automatic sprinkler systems should be modified to allow their removal on a floor-by-floor or area-by-area basis. The conversion of a wet system to a dry system fed only by a fire department connection is sometimes possible and provides good protection for the building as well as for fire-fighting personnel.

Standpipe and hose systems should also be removed floor by floor and should be the last fire protection feature removed. This maintains fire-fighting capability to otherwise demolished floors. A wet standpipe can be easily converted to a dry standpipe.

Trash Removal

It is common practice to provide chutes for the removal of trash and debris from the upper floors. If chutes are used, they should be noncombustible and erected outside the building. By installing the chute as straight as possible, the potential for obstructions in the chute will be minimized.

Structural Integrity

Cutting holes through floors to provide an inside chute should be avoided, since this creates a vertical opening through which fire can spread rapidly from floor to floor. Holes in floors also cause potential safety problems for fire fighters. Walls should remain intact as long as possible.

Figure 11.4.8 shows the results of a demolition operation that violated these principles. The sprinkler system had been shut down about a week before the fire instead of being shut down in stages as demolition progressed. Contrary to good practice, holes had been made in the floors to facilitate the removal of debris. The results were disastrous: not only was the building being demolished destroyed by fire, but also the fire spread to four other buildings.[6]

Utilities

Prior to the start of demolition, gas supplies should be shut off and capped outside the building. Electrical circuits should be reduced to a minimum, and those circuits that remain energized should be labeled. Discontinued lines should be physically disconnected.

FIGURE 11.4.8 Fire Originating on the Top Floor of a Partially Demolished Building and Involving Four Other Buildings

Explosives

Use of explosives requires special precautions. Explosives should be used and stored in accordance with NFPA 495, *Explosive Materials Code.*

ASBESTOS REMOVAL

Asbestos removal can be part of a demolition or alteration project. Fires during asbestos removal operations present several additional problems in addition to the issues previously discussed. The potential for exposure of fire fighters and construction workers to hazardous materials outside the containment area impacts access and fire-fighting operations. Maintenance of the containment area may reduce fire detection and will lengthen the amount of time before manual fire suppression by workers outside the containment area is possible. The widespread use of plastic film and tarping may also contribute to the fire load and fire spread.

With the exception of minor asbestos removal, the fire department and any on-site emergency responders should be notified at least 24 hours prior to the start of an asbestos removal operation. The prefire plan developed for the project should also address any asbestos removal operations. Plastic film used in the project should meet the requirements of NFPA 701, *Standard Methods of Fire Tests for Flame Propagation of Textiles and Films.* Reflective signs indicating the presence of asbestos should be posted at the entrances, exits, decontamination areas, and waste disposal areas.

UNDERGROUND OPERATIONS

Underground construction projects are common, especially those related to tunnels. Fires in these structures are particularly difficult to suppress and can cause significant damage and delays in the completion of construction. An important cause of these fires is improper precautions taken during hot work operations.

Hot Work Permits

Standard hot work precautions, including a fire watch and removing combustible materials, should always be followed. Particular attention should be paid when a combustible film membrane, such as high-density polyethylene, is used as a moisture barrier behind the rib structure of a tunnel. Cutting of rib spikes used to hold hoses and cables can transmit sufficient heat to ignite the plastic membrane.

Fire Protection

Water for fire fighting should be provided by means of a standpipe system with fire hose connections a maximum of every 300 lineal ft (92 m). Provisions for additional air supplies for fire-fighting personnel should also be made. Some tunnels use an emergency car that is equipped with wheels the same gage as the muck car tracks. This car can be used to either transport fire fighters or emergency equipment into the tunnel.

Mobile mining equipment used underground should be equipped with a fire suppression system. The system should be either automatically or manually activated. See NFPA 122, *Standard for Fire Prevention and Control in Metal/Nonmetal Mining and Metal Mineral Processing Facilities,* for further information.

Prevention

Storage of combustible materials should be limited and properly protected and arranged to prevent ignition or contribution to a fire.

Monitoring of methane is a high priority during underground operations. This is particularly important at the face of any tunnel bore or where the geology indicates the presence of organic material. All personnel, including fire fighters who enter a tunnel or underground construction site, must use the sign-in, sign-out board that is usually located adjacent to the underground entrance.

SUMMARY

Construction, alteration, and demolition operations can cause severe fires to occur. Control of combustibles, careful use of temporary electrical service and heating equipment, and control of hot work operations will reduce that probability. Proper fire protection management, prefire planning, and reasonable fire protection will help limit the extent of damage from such a fire. Precautions to reduce the risk of arson are especially important, as that is the leading cause of construction fires.

Chapter 5

Control of Electrostatic Ignition Sources

Don R. Scarbrough

Chapter Contents

Static Electricity Defined
Charge Separation
Dissipation of Static Electricity
Control of Ignitable Mixtures
Flammable Liquids
Gases
Dusts and Fibers
Static Detectors
Definitions

Key Terms

bonding, charge separation, conductor, discharge energy, grounding, ignitable mixtures, induction, nonconductor, static electricity, surface charge

Static electricity as a source of ignition is a hazard common to a wide variety of industries and processes. This chapter explains the nature of static electricity and the means and methods of eliminating or minimizing it as an ignition source.

Information on the hazards of static electricity in specific circumstances and processes can be found in the following chapters: Section 2, Chapter 8, "Explosions"; Section 6, Chapter 8, "Dusts"; Section 6, Chapter 10, "Gases"; Section 7, Chapter 2, "Storage of Flammable and Combustible Liquids"; Section 8, Chapter 13, "Electrical Systems and Appliances"; Section 9, Chapter 2, "Spray Finishing and Powder Coating"; and Section 17, Chapter 8, "Explosion Prevention and Protection."

Additional information can be found in NFPA 77, *Recommended Practice on Static Electricity,* and in the bibliography at the end of this chapter.

STATIC ELECTRICITY DEFINED

The term *static electricity* as used in this chapter refers to the electrification of materials through the physical processes described later and the effects of the positive and negative charges so formed, particularly where their release constitutes a fire or explosion hazard. Other electrical terms used in this chapter are defined at the end of the chapter.

When an electric charge is present on or in a nonconductive body and it is trapped or prevented from escaping, it is termed *static electricity.* Electricity on a conducting body that is in contact only with nonconductors or is otherwise isolated from the earth is also prevented from escaping and is therefore nonmobile or "static." In either case, the body on which this electricity is evident is said to be "charged."

Around 1890, electricity was described as a "subtle agent, without weight or form, that appears to be diffused through all nature, existing in all substances, which gives no indication of its presence in the latent state, but is capable of producing sudden and destructive effects in its active state." With the discovery of the electron, this definition now seems prophetic and the adjective "static" more meaningful. Electricity can move freely through some substances, such as metals, that are called "conductors," but can flow with difficulty or not at all through or over the surface of a class of substances called "nonconductors," "insulators," or "dielectrics." This latter group includes gases, glass, amber, resin, sulfur, paraffin, most synthetic plastics, and most petroleum oils (hydrocarbons).

The development of an electrical charge in itself might not be a potential fire or explosion hazard. There must also be a discharge or sudden recombination of separated positive and negative charges. For static electricity to be a source of ignition, four conditions must be fulfilled:

1. There must be an effective means of separating charge.
2. There must be a means of accumulating the separated charges and maintaining a suitable difference of electrical potential between them.

Don R. Scarbrough is the former safety staff consultant for the Nordson Corporation, Westlake, Ohio, and is now a consultant. He serves on NFPA's Technical Committee on Finishing Processes and Technical Committee on Static Electricity.

3. There must be a discharge (release of charge) of adequate energy.
4. The discharge must occur in an ignitable mixture.

Static electricity can be produced as the result of motions that involve the separation or pulling apart of contacting surfaces, usually of dissimilar substances, either liquid or solid, one or both of which is usually a poor conductor of electricity. Charges separated by this mechanism are usually referred to as being the result of "frictional" or "triboelectric" charging. Examples of such motion that are commonly found in industry are the following:

- Motions of all sorts that involve friction between contacting surfaces, usually of dissimilar liquids or solids
- Steam, air, or gas flowing from any opening in a pipe or hose when the steam is wet or the air or gas stream contains particulate matter
- Separation of a stream of liquid from a hose, faucet, or pouring spout
- Pulverized materials passing through chutes or pneumatic conveyors
- Nonconductive power or conveyor belts when in motion
- Moving vehicles

Accumulation of separated charges typically takes place on the surface of a nonconductive solid, within the body of a nonconductive liquid, or on a dispersed fog or mist. Appreciable charge can be accumulated within the body of a nonconductive solid that has been subjected to high-energy bombardment with electrons or ions in a particle accelerator. There will always be an electric field where such charges accumulate and these electric fields can have a profound effect on surrounding materials, particularly ungrounded conductors.

Charge can appear on the surface of a conductive object when that object is simply brought into the electric field of another object that bears a static electric charge. This is known as *induction* and results fundamentally from manipulation (through repulsion and attraction) of the inherently balanced charges within an uncharged conductive object to produce separate regions on its surface that bear balanced but opposite charges.

An initially uncharged surface can become charged through *contact* with another object or surface that is charged. For example, a pail placed to collect a falling stream of liquid or pulverized material poured from a faucet or other container (the stream therefore being charged by *separation*) will become charged by contact with the charged stream of material.

Yet another mechanism for placing charge upon a surface involves *bombardment* of the surface with charged molecules (ions) of air, which themselves have been charged by a corona from a high-voltage electrode. This mechanism is usually intentional, for example, impressing a charge on the drum of a photocopy machine.

Other processes through which charge is imparted to an object or fluid involve exposure to an electron beam or flow of a liquid around a high-voltage electrode. These techniques are commonly referred to as *charge injection.*

The separation of static electric charges cannot be prevented absolutely, because the intrinsic origins of static electricity are present at every interface. The object of most electrostatic corrective measures is to provide a means whereby charges separated by whatever cause can recombine harmlessly before sparking potentials are attained. If hazardous conditions cannot be avoided in certain operations, means must be taken to ensure that there are no ignitable mixtures at points where static electric sparks might occur.

CHARGE SEPARATION

When two bodies composed of dissimilar materials are in close physical contact, there is likely to be a transfer of free electrons between them, one giving up electrons to the other, and an attractive force is established. When the bodies are separated, work must be done in opposition to these attractive forces. The expended energy reappears as an increase in electrical tension or voltage between the two surfaces. If the bodies are insulated from their surroundings, both are said to be "charged"; the one having the excess of electrons is said to have a negative charge, whereas the other is said to have an equal positive charge. If a conductive path is available between them, the charges thus separated will reunite immediately. If no such path is available, as is the case with insulators, the charges will remain and an electric field will result.

In many cases, one of the objects has a deliberate or inherently conductive path to the earth, and its charge is immediately lost to the earth, which is considered to have an infinite capacity to absorb or give up electrons. The other (insulated) object now retains its charge and would hold this charge indefinitely, except for the fact that it must somehow be supported and no supporting insulator (even air) is a perfect nonconductor.

If one of the bodies is itself a nonconductor, the flow of electrons across its surface is inhibited, and the charge tends to remain at the points where electron transfer originally occurred. A highly charged insulating surface can be discharged with the appearance of a spark by bringing an "earthed" conductor close to it, but only a limited area will be so discharged. Sparks so produced seldom release enough energy to cause ignition. Thus, nonconductors, the bodies most directly involved in charge separation, are usually not directly responsible for fires and explosions. (There are exceptions, which are discussed later in this chapter.) However, such charges can in some cases be the agency for building up or accumulating a charge on a conductive body, which can release all of its stored energy in an incendive (ignition-capable) spark.

On a conductive body the charge is free to move. Because like charges repel each other, the charges will distribute themselves evenly over the surface. If the body is of irregular shape, charge will concentrate in areas having a small radius of curvature: the smaller the radius, the higher the concentration of charge and the higher the electric field in the area having the small radius of curvature. For a point, if the voltage is high enough, the electric field (voltage gradient) will exceed the breakdown strength of air (about 3,000,000 V/m), and the air will become ionized and a corona or brush discharge will result.

Like charges repel each other and unlike charges attract because of forces resident in the electrical fields that surround

them. These forces have a strong influence on nearby objects. If the neighboring object is a conductor, it will experience a separation of charges by induction. Its repelled charge is free to give or receive electrons as the case may be; if another conductor is brought near, the transfer might occur through the agency of a spark, very often an energetic spark. When the inducing charge is moved away from the insulated conductor, there follows a reversed sequence of events and sparks can result. Thus, in many situations, induced charges are far more dangerous than the initially separated ones on which they are dependent.

Storage

Two conductive bodies separated by an insulator constitute a capacitor (sometimes called a condenser), and where a potential difference is applied between these bodies, charge can be stored. One body receives a positive and the other an equal negative charge. In many instances involving accumulation of static electricity, one of the bodies is the earth, the insulating medium is the air, and the insulated body is some object to or from which a charge (electrons) has been transferred by one of the mechanisms previously described.

When a conducting path is made available between two conductive bodies, the energy stored on them is released, that is, the capacitor is "discharged," possibly producing a spark. The energy so stored and released is related to the charge, Q, the capacitance of the conductive body, C, and the voltage, V, in accordance with the following:

$$\text{Energy} = \tfrac{1}{2}CV^2 = \tfrac{1}{2}QV = \tfrac{1}{2}Q^2/C \quad (V = Q/C)$$

where energy is in joules; capacitance, C, is in farads; charge, Q, is in coulombs; and voltage, V, is in volts.

Discharge Energy

The ability of a discharge to produce ignition of a flammable mixture is governed largely by the energy transferred to the mixture, which will be some fraction of the total stored energy available because some energy is expended in heating the electrodes. Experiments at atmospheric pressure with plane electrodes have shown that the spark breakdown voltage has a minimum value at a critical short gap distance—about 350 V for the shortest measurable gap (about 0.01 mm). Increased gap distance requires proportionately higher voltages. At close spacing, the electrodes can be so close to the ignitable mixture that they adsorb enough heat to preclude ignition of the mixture.

Progressing from lowest to highest intensity, discharges through air can occur as corona, brush, spark, or propagating brush discharge. Corona discharge is generally thought of as not energetic enough to ignite gases and vapors. Brush discharges range from corona levels to higher energies that are capable of igniting gases and vapors but not capable of igniting common dusts. Spark discharges and propagating brush discharges are capable of igniting gases, vapors, and dusts.

At most favorable electrode spacing, tests have shown that optimum mixtures of saturated hydrocarbon vapors and gases in air require about 0.25 mJ of discharge energy to produce ignition. This level of discharge energy is typical of flammable vapors; however, there are many exceptions. The capacitance necessary to store this level of energy depends on the amount of charge (or voltage) on the capacitor. This leads to the question of how small a capacitor can be and still hold enough charge to ignite the typical hydrocarbon vapor. Experience has shown that a beverage can is big enough. In the same vein, uncomfortable discharges from the human body (usually at the fingertips) are energetic enough.

Manifestation of Static Electricity

Static electricity will be manifest only where highly insulated bodies or surfaces are found. If a body is "charged" with static electricity, there will always be an equal and opposite charge produced. If a hazard is suspected, the situation should be analyzed to determine the location of both charges and to see what conductive paths are available to both of them. Since no object can be entirely insulated from the earth, there will always be a path for charges to dissipate (discharge).

Problems arise where the rate of charge accumulation exceeds the rate of dissipation. If the resistance to ground is less than 1,000,000 Ω (1 MΩ), there are no practical systems that will accumulate charge fast enough to lead to problems of ignition with ordinary gases, vapors, or dusts. In many cases, resistance to ground will be much greater. Tests of such high-resistance paths should be made with an applied potential of 500 V or more, in order that any minor interruption (e.g., paint or grease film or air gap) will be broken down and a correct reading of the resistance obtained. Resistance as high as 1000 MΩ might provide an adequate leakage path in many cases; however, when charges are generated rapidly (e.g., pneumatic transport) a resistance as low as 1 MΩ might be required.

Ignitable Mixtures

Elimination of ignitable mixtures in the areas where sparks of static electricity can occur is the surest method of preventing static electricity-caused fires. The subject of ignitable mixtures is beyond the scope of this chapter but is discussed in other NFPA literature, for example, NFPA 30, *Flammable and Combustible Liquids Code*; NFPA 77, *Recommended Practice on Static Electricity;* NFPA 497, *Recommended Practice for the Classification of Flammable Liquids, Gases, or Vapors and of Hazardous (Classified) Locations for Electrical Installations in Chemical Process Areas*; and NFPA 921, *Guide for Fire and Explosion Investigations.*

DISSIPATION OF STATIC ELECTRICITY

A static charge that already exists can be removed or allowed to dissipate itself. One obvious way to accomplish this is to reduce the resistance between where the charge resides and ground. Another way is to neutralize the charge by adding an equal charge of opposite polarity.

Humidification

A static charge cannot persist except on a body insulated from its surroundings. Most commonly encountered materials that

are not usually thought of as conductors, such as fabrics, paper, wood, concrete or masonry foundations, and so on, have a certain amount of moisture on their surface in equilibrium with that in the surrounding atmosphere. This moisture content varies, depending on the weather, and it controls to a large measure the surface conductivity of the material and, thus, its ability to allow the escape of static electricity. In an analogous manner, under some conditions water vapor will condense on the surface of some nominally insulating materials, notably glass and porcelain, to render the surface conductive enough to allow static charges to dissipate.

The surface conductivity of the materials under discussion (wood, paper, etc.) is controlled by the water content of the air. Under conditions of high humidity, the materials in question will reach equilibrium conditions containing enough moisture to make the surface conductive enough to prevent accumulations of static electricity. The generating mechanism might still be present, but the rate of charge dissipation exceeds the rate of charge generation and the charge leaks away so fast that no observable accumulation results.

At the opposite extreme, that is, with low humidity, these same materials might dry out, become good insulators, and manifestations of static electricity become noticeable. There is no definite boundary line between these two conditions.

Where static electricity has introduced operational problems, such as the adhesion or repulsion of sheets of paper, layers of cloth, fibers, and the like, humidifying the atmosphere has proved to be a solution. It is usually stated that a relative humidity of about 50 percent or higher at normal room temperature will avoid such difficulties.

Unfortunately, it is not practical to humidify all occupancies in which static electricity might be a hazard. Some operations must be conducted in an atmosphere having a low humidity to avoid deleterious effects on the materials handled. High humidity can also cause intolerable comfort conditions in operations where the dry bulb temperature is high. On the other hand, a high humidity might advantageously affect the handling properties of some materials, thus providing an additional advantage. In some cases, localized humidification produced by directing a steam jet onto critical areas can provide satisfactory results without the need for increasing the humidity in the whole room. However, it must be remembered that steam that contains droplets of water can itself generate static electricity. This situation can sometimes be overcome by using a low-velocity jet of humidified air.

Humidification is not a cure for all static electricity problems. In particular, it must be remembered that the conductivity of the air is not appreciably increased by the presence of water in the form of a gas. If static electricity accumulates on some surface that is heated above normal atmospheric temperature (e.g., cloth passing over heated rollers), increasing the relative humidity in the surrounding air might do no good whatsoever.

Another situation where the control of atmospheric humidity appears to accomplish little is in controlling the charge of static electricity that appears as a space charge in the body of oils. In order to dissipate, such a charge must move through the body of the liquid; therefore, altering the surface conductivity of the oil does little, if anything, to help in the dissipation process.

Therefore, increasing the relative humidity of the atmosphere to 50 percent or higher at ordinary room temperatures might eliminate static electricity problems where the surfaces on which the charge accumulates can reach equilibrium with the atmosphere, such as paper or wood. For heated surfaces and for electrostatic charges in oils and other liquid and solid insulating materials, high humidity will not provide a means for draining off charges and some other solution must be sought.

Bonding and Grounding

Where natural conditions, including humidity, do not ensure a conductive path to prevent accumulation of static electricity, artificial conducting paths (bonding, grounding) might be necessary. *Bonding* is the process of connecting two or more conductive objects together by means of a conductor. *Grounding* (earthing) is the process of connecting one or more conductive objects to the earth and is a specific form of bonding. A conductive object can also be grounded by bonding it to another conductive object that is already connected to the ground. Some objects are inherently bonded or inherently grounded by their contact with the earth. Examples are underground piping or large storage tanks resting on the ground. Bonding eliminates the potential difference between conductive objects. Grounding eliminates potential differences between objects and the earth.

When grounding and bonding wires are used to dissipate static electric charges, the currents are quite small and even the smallest of wires are usually adequate to carry the current. The currents encountered in the bond connections used in the protection against accumulations of static electricity are on the order of microamperes (one millionth of an ampere). However, the wires used for bonding and grounding must be able to withstand the rigors of the workplace. The acceptable resistance in a ground connection depends on the type of hazard for which it is intended to give protection. To prevent the accumulation of static electricity, the resistance need not be less than 1 MΩ and in most cases may be even higher. To protect electrical power circuits, the resistance must be low enough to ensure operation of the fuse or circuit breaker under fault conditions. Any ground that is adequate for power circuits or lightning protection is more than adequate for protection against static electricity.

A bond or ground is composed of suitable conductive materials having adequate mechanical strength, corrosion resistance, and flexibility for the service intended. Since the bond or ground does not need to have low resistance, nearly any conductor size will be satisfactory from an electrical standpoint. Solid conductors are satisfactory for fixed connections. Flexible conductors are used for bonds that are to be connected and disconnected frequently. Conductors can be insulated, although this is not necessary, or uninsulated. Some prefer uninsulated conductors so that defects can be easily spotted by visual inspection. If insulated for mechanical protection, the concealed conductor should be checked for continuity at regular intervals, depending on the inspector's experience. Connections can be made with pressure-type ground clamps, brazing, or welding. Battery clamps, or magnetic or other special clamps, ensure good metal-to-metal contact. A special situation requiring substantial conductors might arise if there is a possibility that a ground wire might be

called upon to carry current from power circuits or lightning protection systems.

Ionization

Were it not for cosmic radiation, air would be nonconductive in its normal state. But, under certain circumstances, air can become sufficiently conductive to bleed off electrostatic charges. For instance, cosmic radiation creates ion pairs in the air. An electric field from an accumulated charge will attract its opposite counterpart ion and repel its like counterpart ion such that the accumulated charge will slowly dissipate. This process is usually too slow to be of much commercial value, but similar mechanisms can be employed.

Static Comb. A static electric charge on a conducting body is free to flow and, on a spherical body in space, it will distribute itself uniformly over the surface. If the body is not spherical, self-repulsion will cause the charges to concentrate on the surfaces having the least radius of curvature.

If the body is surrounded by air (or other gas) and the radius of curvature is reduced to almost zero, as with a sharp needle point, the charge concentration on the point can produce ionization of the air, rendering the air "conductive." As a result, whereas a surface of large diameter can receive and hold a high voltage, the same surface equipped with a sharp needle point can reach only a small voltage before the leakage rate through the self-ionized air equals the rate of generation.

A *static comb* is a metal bar equipped with a series of such needle points. A variation uses a metal wire surrounded with metallic tinsel. If a grounded static comb is brought close to an insulated charged body (or a charged insulating surface), ionization of the air at the points will provide enough conductivity to make the charge speedily leak away or be "neutralized." This principle is frequently employed to remove the charge from fabrics, power belts, paper, and plastic webs.

Electrical Neutralization. The electrical neutralizer is a line-powered high-voltage device that is an effective means for removing electrostatic charges from materials, such as cotton, wool, silk, or paper in process, manufacturing, or printing. It produces a conducting ionized atmosphere in the vicinity of the charged surfaces, enabling the charges to leak away to an adjacent grounded conducting body. Electrical neutralizers should not be used where flammable vapors, gases, or dust might be present, unless approved specifically for such locations.

Radioactive Neutralizer. Another method for dissipating static electricity involves ionization of the air by radioactive material. Such installations require no redesign of existing equipment, but engineering problems are involved, such as elimination of health hazards, dust accumulations, determination of radiation required, and proper positioning in relation to the stock, machine parts, and personnel. These considerations are best worked out in consultation with radiation specialists.

Open Flame. Ionization of the air can also be obtained by an open flame. This method is frequently used in the printing industry to remove static from paper sheets as they come off the press, thus avoiding the mechanical problems involving one sheet of paper adhering to another, but obviously avoiding ignition.

CONTROL OF IGNITABLE MIXTURES

Despite efforts to prevent accumulation of static electric charges, which should be the primary aim of good design, there are many operations involving the handling of nonconductive materials or nonconductive equipment that do not lend themselves to this built-in solution. In these cases it becomes necessary to provide other measures to supplement or supplant static electricity dissipation. For example, where a normally ignitable mixture is contained within a small enclosure, such as a processing tank, an inert gas can be used to render the vapor space safe from ignition. When operations are normally conducted in an atmosphere above the upper flammable limit, it might be practical to apply the inert gas only during the periods when the mixture passes through its flammable range.

Mechanical ventilation can be used in many instances to dilute an ignitable mixture to a point below its normal flammable range, that is, below the lower flammable limit. Also, by directing the air movement, it might even be practical to prevent the flammable liquids or dusts from approaching an operation where an otherwise uncontrollable electrostatic hazard exists. To be considered reliable, mechanical ventilation should be interlocked with the equipment it protects to ensure proper operation. Where a static electricity-accumulating piece of equipment is unnecessarily located in a hazardous area, it should be relocated to a safe location.

FLAMMABLE LIQUIDS

Charge Generation in Liquids

Static electric charge can be generated when liquids having a low conductivity move in contact with other materials. This occurs commonly in operations in which liquid flows through pipes and in which liquid is mixed, poured, pumped, filtered, or agitated. Under certain conditions, particularly with liquid hydrocarbons, with high-velocity flow and with filtration through nonconducting, resin-bonded media, static electricity can accumulate on the body of the liquid. If the accumulation is sufficient, a static electric spark can occur even though all conductive equipment is properly grounded. If the spark occurs in the presence of an ignitable vapor-air mixture, ignition is likely. Therefore, steps must be taken to prevent the simultaneous occurrence of these three conditions: low conductivity, energetic manipulation, and ignitable mixture.

Before transfer is started, contact should be made between the filling nozzle and the container, and the contact should be maintained throughout the filling operation. With this procedure, any difference in potential between the container and nozzle will be dissipated before the filling operation is started and differences in potential between the nozzle and container are prevented from forming during the filling operation. See

Figure 11.5.1 for methods of bonding containers and nozzles during container filling.

The relative static electricity-accumulating tendencies of a number of petroleum products have been measured in laboratory tests.[1,2] In general, aliphatic solvents and lower boiling point hydrocarbons exhibited lower charging tendencies than did higher boiling products. However, the charging tendency of any given product was found to vary widely from one sample to the next.

The conductivity of a liquid is a measure of its ability to hold a charge. The lower the conductivity, the greater the ability of the liquid to hold a charge. If the conductivity of a hydrocarbon liquid is greater than 50 pS/m (picosiemens per meter), any charges that are generated will dissipate without accumulating to a hazardous potential as long as all of the associated conductive equipment is properly grounded.

Free Charges on Surface of Liquid

If an electrically charged liquid is poured, pumped, or otherwise transferred into a tank or container, the unit charges of similar sign (i.e., + or –) within the liquid will be repelled from each other toward the outer surfaces of the liquid, including not only the surfaces in contact with the container walls but also the top surface adjacent to the air space. It is this latter charge, often called the *surface charge,* that is of most concern in many situations.

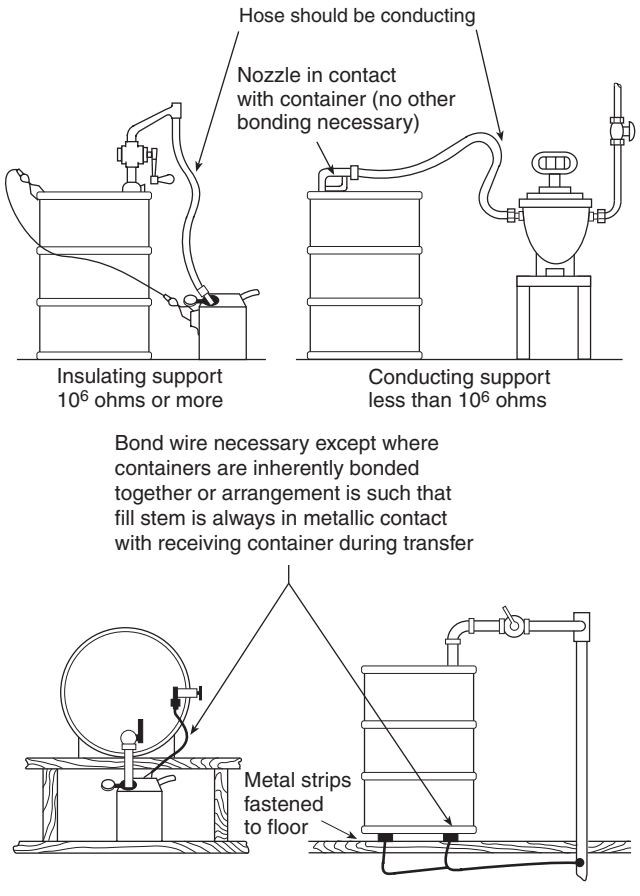

FIGURE 11.5.1 Recommended Methods of Bonding Flammable Liquid Containers During Container Filling

In most cases, the container is made of metal and is conductive. Two situations can occur, somewhat different with respect to protective measures, depending on whether the container is in contact with the earth or is insulated from it. Examples of these two situations are (1) an ordinary storage tank resting on earth, concrete, or another slightly conducting foundation, and (2) a metal can resting on a plastic surface.

In the first situation, the metal vessel is connected to ground. The charges that reach the surfaces in contact with the vessel will reunite with charges of opposite sign that have been attracted there. During this process, the tank and its contents, considered as a unit, are electrically neutral; that is, the total charge in the liquid and on its surface is exactly equal and opposite to the charge on the interior of the tank shell. This charge on the tank shell is "bound" there, but gradually disappears as it reunites with the charge migrating through the liquid. The time required for this to occur is called "relaxation time." The relaxation time depends primarily on the conductivity of the liquid. It might be a fraction of a second or several minutes.

During this process, the tank shell is at ground potential. Externally, as already mentioned, the container is electrically neutral. But internally, there could be differences of potential between the container wall and the fluid, lasting until charges on the fluid have gradually leaked off and reunited with the unlike charges on the tank walls.

If the potential difference between any part of the liquid surface and the metal tank shell should become high enough to cause ionization of the air, electrical breakdown can occur and a spark might jump to the shell. A spark across the liquid surface is an ignition hazard where flammable vapor-air mixtures are present. No bonding or grounding of the tank or container can remove this internal surface charge.

In the second situation, where the can is highly insulated from the earth, the charge on the liquid attracts an equal and opposite charge to the inside of the container. This leaves a "free" charge on the outside of the can, of the same sign as that in the liquid and of the same magnitude. This charge can escape from the can to the ground in the form of a spark. In filling a gasoline can resting on a plastic bedliner of a pickup truck, it is this source of sparking that is suspected of creating an ignition potential in some situations; in this case, the spark jumps from the edge of the fill opening to the fill pipe, which is at ground potential. This hazard can be easily controlled by removing the can from the vehicle and placing it on the ground, where any accumulated charge can leak to the earth.

The foregoing discusses the distribution of charges delivered into a container with a flowing stream. Further generation or separation can occur inside the container in several ways to produce a space or surface charge: (1) flow with splashing or spraying of the incoming stream, (2) disturbance of "water bottoms" by the incoming stream, (3) bubbling of air or gas through a liquid, (4) jet or propeller blending within the tank, or (5) the settling out of a water layer from a hydrocarbon.

These charges on the surface of a body of liquid cannot be prevented by bonding or grounding, but can be rendered harm-

less by inerting, that is, displacing part of the oxygen with a suitable inert gas, or by increasing the concentration of flammable gas in the vapor space to a point above the upper flammable limit. In some cases, additives can be used to increase the conductivity of the liquid such that the charge will rapidly relax and prevent a hazardous condition from developing.

It must be recognized that mists and foams of flammable and combustible liquids can be ignited by static electric sparks in much the same way as dusts can be ignited. Ignition is possible even though the liquid in the mist is below its flashpoint.

GASES

Gases not contaminated with solid or liquid particles will not generate any electrification in their flow. When flowing gas is contaminated with dust, metallic oxides, scale particles, or with liquid particles or spray, however, electrification is possible. A stream of such particle-containing gas directed against a conductive body will charge the latter unless it is grounded or bonded. Compressed air or steam containing particles of condensed water vapor often manifests strong static electric charges when escaping.

Carbon dioxide, discharged as a liquid from orifices under high pressure (where it immediately changes to a gas and "snow"), can result in electrostatic accumulations on the discharge device and the receiving container. This condition is not unlike the effect from contaminated compressed air or from steam flow where the contact effects at the orifice play a part in the accumulation of static electricity. High-pressure carbon dioxide should not be discharged into flammable atmospheres because it presents a high risk of ignition due to static electric spark.

Hydrogen-air and acetylene-air mixtures can be ignited by a spark energy of as little as 0.017 mJ. In the pure state, no static electric charges are generated by the flow of hydrogen. However, as gaseous hydrogen is commercially handled in industry, such as flowing through pipelines, discharging through valves at filling racks into pressure containers, or flowing out of containers through nozzles, the hydrogen will often be found to contain particles of oxide carried off from the inside of the pipes or containers. In this contaminated state, hydrogen can accumulate a static electric charge.

DUSTS AND FIBERS

Charge Generation in Dust

As previously pointed out, the flow of a stream of gas containing small particles can result in a separation of electrons and the accumulation of a static electric charge on any insulated conductive body with which it comes in contact. Also, dust displaced from a surface on which it rests can develop a considerable charge. The ultimate charge depends on the inherent properties of the substance, size of particle, amount of surface contact, surface conductivity, gaseous breakdown, external field, and resistance to leakage in a system. Greater charges develop from smooth rather than from rough surfaces, probably because of greater initial surface contact. Electrification develops during the first phase of separation.

Charge separation seldom occurs if both materials are good electrical conductors, but it is likely to occur with a conductor and a nonconductor or two nonconductors. When like materials are separated, as in dispersing quartz dust from a quartz surface, positive and negative charges are developed in the dispersed dust in about equal amounts to give a net zero charge. With materials differing in composition, a charge of one polarity might predominate in the dust. Each of the materials becomes equally charged but with opposite polarity.

Charge generation in moving dust normally cannot be prevented. The method of dispersion of the dust, the amount of energy expended in dispersal, the degree of turbulence, and the composition of the atmosphere usually affect the magnitude and distribution of the charges in the dust.

Not only can dust participate in the generation of static electricity, it can also be the material ignited by a discharge spark. A suspension of finely divided combustible particles in air has much the same properties as a flammable gas-air mixture, except for a generally higher ignition energy. (With some metallic dust, ignition energy is comparable to gas-air mixtures.) It can burn to produce explosive effects. Dusts have a lower flammable limit, usually referred to as the "minimum explosible concentration," but no strictly definable upper limit.

Ignition of Dust by Static Electric Discharge

Clouds and layers of many combustible dusts (with or without a volatile constituent) have been ignited experimentally by static electric discharge. With dust clouds, it has been shown that a minimum ignitable dust concentration exists below which ignition cannot take place regardless of the energy of the spark. At the minimum ignitable dust concentration, a relatively high energy is required for ignition. At higher dust concentrations, less energy is required for ignition.

A layer of combustible dust can be ignited by static electric discharge and will burn with a bright flash, glow, or, for some metallic dusts, with flame. Apparently, there is little correlation in the minimum energy required for ignition of dust layers and clouds. Layers of some metallic dusts, such as aluminum, magnesium, titanium, and zirconium, require less energy for ignition than carbonaceous materials.

Primary explosives, such as mercury fulminate, are readily initiated by static electric discharge. Steps necessary to prevent accidents caused by static electricity in explosives manufacturing operations and storage areas vary considerably with the ignition sensitivity of the material being handled.

In most instances in which static electricity was authentically established as the cause of ignition of a dust, the spark occurred between an insulated conductor and ground. Propagating brush discharges from insulators, however, have been shown to be incendive to dust clouds and to the dust within a pneumatic transport system when thin wall insulative hose is used. The dust within a metallic dust collector duct has been shown to be ignited when an insulative coating was formed inside a wye where thermoplastic dust has impact fused. It has not been verified experimentally that a dust cloud can be ignited by

discharge within itself, that is, in a manner analogous to lightning, in experiments conducted within silos having a radius up to 16 ft (5 m).

STATIC DETECTORS

The following devices have an application in the measurement and determination of static electricity within the limitations of each device as described.

Electroscopes

The leaf electroscope is a simple but sensitive device that indicates the presence or absence of electric charge by the repulsion of its leaves when the device is charged. Only units intended as portable dosimeters for ionizing radiation and one or two classroom demonstration models are available.

Neon Lamps

A small neon lamp or fluorescent tube will light up feebly when one terminal is grounded (or held in the hand) and the other makes contact with any sizeable conductor that carries a charge potential of 70 V or more. Like the electroscope, it gives but little quantitative information; however, when it passes current, it might give a rough idea of the rate at which charges are being produced in certain operations. Adjustable series-parallel groupings of such lamps and small capacitors can be arranged to give a semblance of quantitative information.

Electrostatic Voltmeters

These meters operate by electrostatic attraction between movable and stationary metal vanes. A small current is required to deflect the needle, but no current is passed to maintain the deflection because one set of vanes (usually the stationary one) is very highly insulated. Small, portable, accurately calibrated instruments are available in several ranges from 100 to 10,000 V. This type of meter can be used for quantitative electrostatic analysis.

Electrometers

Electrometers are frequently used for laboratory and field investigations of static electricity. These instruments employ special input stages designed for high input resistance and low grid current and can be used in several ways. With a small antenna mounted on the grid terminal, they are very suited for detecting transient electrostatic charge effects; in the presence of a constant field, the charge induced on the grid will leak off and the meter pointer will return to zero. However, as the rate of leakage is not high, the electrometer finds considerable use for "on-the-spot" checks. Often electrometers are equipped with high-resistance terminal shunts to convert them to current meters in the nanoampere range. They can thus be used in many applications to indicate the rate of charge development. A simple adaptation converts the instrument into a megohm meter, as explained in the manufacturer's instruction manual. Electrometers can be rather expensive and require a user of some sophistication.

Field Mills

A field mill is a device that overcomes the serious limitations of the electrometer in that it provides a continuous indication of charge by providing its own transients in the form of continuous grid modulation. It can therefore "look" at a distant charge and determine its sign and potential. The electrical field extending from the charge is "chopped" by a motor-driven variable condenser or window. The resulting pulsations are transformed, amplified, and rectified to give a dc meter deflection proportional to the strength of the field. A similar instrument of suitable design can be immersed in a liquid, as in a pipeline, to measure charge density. Since a field mill senses an electric field, it likewise senses the presence of an accumulated charge. Thus, field mills are handy devices for qualitatively determining the presence of an accumulated charge; with some modest experience, they can even be quantitative.

DEFINITIONS

Some terms used in this chapter are defined as follows.

Brush Discharge. A form of corona discharge in which brighter "fingers" or "streamers" can be seen. Brush discharges are capable of igniting flammable gases and vapors, but not dusts.

Capacitance. The ability to store an electric charge. Electrons received by an electrically neutral body of conductive material, such as a person, a car, or an aircraft, raise the voltage at a rate determined by the surface area and shape of the body. The voltage is determined by the surface characteristics (capacitance) of the body and the number of electrons on this surface. The larger the body, the more electrons are needed to raise the voltage a specific amount; hence, the higher the capacitance of the body.

Capacitance is measured in "farads" or millionths of a farad (i.e., microfarads). Millionths of one millionth of a farad are called picofarads.

Charge. Measured in coulombs or fractions thereof, the quantity of separated electrons on the body (negative charge) or the quantity of separated electrons not on the body (positive charge). Electrons cannot be destroyed, short of an encounter with antimatter (a positron); so when an electron is removed from one body, it must go to another body. Thus there are always equal and opposite charges produced. Since it would be awkward to say there are 6,240,000,000,000,000,000 electrons on a body, the body is said to have a charge of one coulomb. A coulomb is simply a name for this specific quantity of electrons. In electrostatics an even more practical unit is a microcoulomb, representing a charge of electrons.

Corona. A type of air discharge that can occur between flat electrodes or as a single-point discharge at an electrode that has a very small radius or a point. The discharge has a faint blue glow and can make a hissing sound. Corona discharge is usually not capable of causing ignition of ordinary gases and vapors; however, acetylene, carbon disulfide, and hydrogen are among the exceptions.

Current. A measure of the flow of electricity. Just as waterflow is measured in terms of the amount of water that passes a certain point in a specific period of time (liters per min), so too is the flow of electrons past a certain point measured by time. The flow of electrons is called current. Current is measured in terms of electrons per second, coulombs per second, or amperes. When dealing with static electricity, current is commonly limited to the microampere range.

Energy. The ability to do work. Energy is measured in joules or fractions thereof. A spark is energy being expended. The measure of energy takes several forms. Often it is physical energy, which is measured in joules. If it is heat energy, it is measured in calories (cal), and if it is electrical energy it is measured in watt-seconds or in joules. A joule is the energy expended in one second by an electric current of one ampere in a resistance of one ohm (approximately 0.738 foot-pound). Static electric discharge energy is usually measured in thousandths of a joule (millijoules or mJ). A static spark must contain a minimum amount of energy to ignite flammable or combustible materials.

Incendive. Capable of causing ignition. A discharge that has enough energy to ignite an ignitible mixture is said to be incendive. Thus an incendive spark can ignite an ignitible mixture and cause a fire or explosion. A nonincendive discharge does not possess the energy required to cause ignition even if it occurs within an ignitible mixture.

Incendivity. The ability of a discharge to ignite an ignitible mixture. The energy level required for incendivity varies as described in the text.

Potential. Stored energy is able to do work. In electricity, this ability is expressed in terms of the potential of doing work. Potential in electricity is measured in terms of volts, kilovolts, or millivolts. Potential, or voltage, is measured from a base point. This point can be any voltage but is usually "ground," which is theoretically zero voltage. When one point with a potential of x volts to ground is compared with another point with a potential of y volts to ground, then it is said that a potential difference of x–y volts exists between the two. Then, when a point with a potential of 2500 volts to ground is compared with a point with a potential of 1500 volts to ground, the potential difference is 4000 volts.

Propagating Brush Discharge. An energetic discharge from an insulative surface on which an intense charge has been stored. To store adequate charge, the insulator must be thin (less than 6 mm) and be backed by a conductive surface that is either grounded or at opposite polarity. The discharge is branched, occurs over an area of several square centimeters, and produces a loud popping sound.

Resistance. Electrical current encounters difficulty in passing through an electrical circuit or conductor. This difficulty can be measured and is called resistance. Resistance can be measured in terms of voltage drop over a part of the circuit but is usually measured in terms of ohms or megohms. The resistance of a circuit in ohms is equal to the ratio of voltage in volts to current in amperes.

Spark. An energetic discharge, usually accompanied by a popping sound, that occurs when air or gas between two charged conductors becomes highly ionized, enough to break down conducting current through a distinct, luminous channel.

SUMMARY

Ignition caused by static electricity is a potential fire hazard in many operations and processes. Static electricity is produced by motions involving the separation or pulling apart of contacting, usually dissimilar, surfaces, one or both of which is usually a poor conductor of electricity. Whenever possible, ignitable mixtures should be removed from areas where sparks of static electricity can occur. Another way to reduce the hazard is to dissipate the static electricity through a variety of means, including humidification (50 percent or higher at normal room temperature), artificial conducting paths (bonding or grounding), or ionization of the air. In cases where dissipation is not possible, measures must be taken to reduce the flammability of ignitable mixtures, for example, by inert gas or mechanical ventilation. Certain operations are especially hazardous with regard to static electricity and require precautionary measures. Such operations include flammable liquid flowing through pipes or being mixed, poured, pumped, filtered, or agitated and gaseous hydrogen flowing through pipelines or discharging through valves at filling racks into pressure containers or flowing out of containers through nozzles. Dust presents a particular hazard as it can both generate static electricity and be ignited by it. Several devices can be used to detect and measure the presence of static electricity, including electroscopes, neon lamps, electrostatic voltmeters, electrometers, and field mills.

Property Protection
Protection of Persons

Key Terms

bonding, conductors, grounding, infrastructure, lightning protection, pilot streamer, resistivity, striking distance, surge protection devices

From 1994 to 1998, lightning caused an estimated 35,000 fires per year as reported to U.S. municipal fire departments, with associated annual losses of 12 civilian fire deaths and $223 million in direct property damage. From 1995 to 2004, lightning was also cited for 489 deaths.

Unlike many other causes of death and injury that one can run away from, lightning strikes before the warning thunder. The principles of protection and personal safety are well known and spelled out in NFPA 780, *Standard for the Installation of Lightning Protection Systems.* It must be remembered, nevertheless, that lightning involves many uncertainties and that, although a given pattern of lightning behavior might be probable, there is no guarantee that a lightning discharge will not deviate from that pattern.

For related information on lightning protection, see Section 9, Chapter 11, "Protection of Wastewater Treatment Plants"; and Section 21, Chapter 10, "Marine Vessels."

FACTORS IN THE NEED FOR LIGHTNING PROTECTION

Frequency and Severity of Thunderstorms

The frequency of thunderstorms varies throughout the world. The severity of thunderstorms, as distinguished from their frequency of occurrence, is much greater in some locations than in others. Hence, the need for protection varies geographically, although not necessarily in direct proportion to thunderstorm frequency. A few severe thunderstorms a season can, in fact, make the need for protection greater than a relatively large number of storms of lesser intensity. Figure 11.6.1 shows statistical data on the yearly number of flashes to ground per km^2 due to thunderstorms in the United States. Note that the highest flash density is encountered in south-central Florida. The data show the average number of lightning flashes per year for the United States. Eleven years of lightning data were collected to make the flash density map in Figure 11.6.1. Measured lightning flash density has been corrected for NLDN detection efficiency.

Since 1894, the recording of thunderstorms has been defined as the local calendar day during which thunder was heard. A day with thunderstorms is recorded as such, regardless of the number occurring on that day. The occurrence of lightning without thunder is not recorded as a thunderstorm. Figure 11.6.2 illustrates statistical data on the frequency of thunderstorms in Canada, and Figure 11.6.3 shows the data for the world.

Earth Resistivity

Figure 11.6.4 illustrates the estimated average resistivity of the earth, measured at various locations in the United States, in ohm-meters. Resistivity is measured in ohm-centimeters and is defined as the resistance in ohms of a cube of material measured in centimeters. In Figure 11.6.4, however, it is measured in ohm-meters. The highest resistivity is located in the northeastern segment of the country, with 2000 ohm-meters measured in Long Island, New York, northern New Hampshire, and Vermont. Structures in these areas are susceptible to more frequent lightning strikes.

John M. Caloggero retired from NFPA as principal electrical specialist and NFPA staff liaison to NFPA's Technical Committee on Lighting Protection. He is an electrical code consultant.

FIGURE 11.6.1 Statistics for Continental United States Showing the Average U.S. Lightning Flash Density in Flashes/km^2/Year (Source: Global Atmospherics, Inc.)

Value and Nature of Building and Contents

Buildings and structures that are essential to life safety or are considered critical infrastructure, such as hospitals, fire stations, police stations, military facilities, emergency management and power plants, and water treatment facilities, should have a lightning protection system installed if they are located in areas where lightning commonly occurs. Some buildings have an uninsurable historical or cultural value. The type of building construction also influences the degree of protection to be considered. Some buildings require no supplemental lightning protection due to their construction. The real or intangible value of the building's contents must also be considered, and, in some cases, attention must be given to the nature of the contents and its susceptibility to damage by induced lightning currents, for example, storage of explosives.

Appendix L of NFPA 780 contains a risk assessment guide that provides guidelines for assessing the need for lightning protection. Not part of the requirements of NFPA 780, the appendix is included there for informational purposes only. NFPA does not mandate that lightning protection systems be installed in specific buildings or structures; however, Appendix L of NFPA 780 does provide a method for determining the need for lightning protection based on a risk assessment of computed values.

Personnel Hazards

The lightning hazard is a major concern not only to personnel in buildings or structures, but also to persons involved in outdoor activities at golf courses, football stadiums, and the like. Early warning systems can be installed to warn of approaching

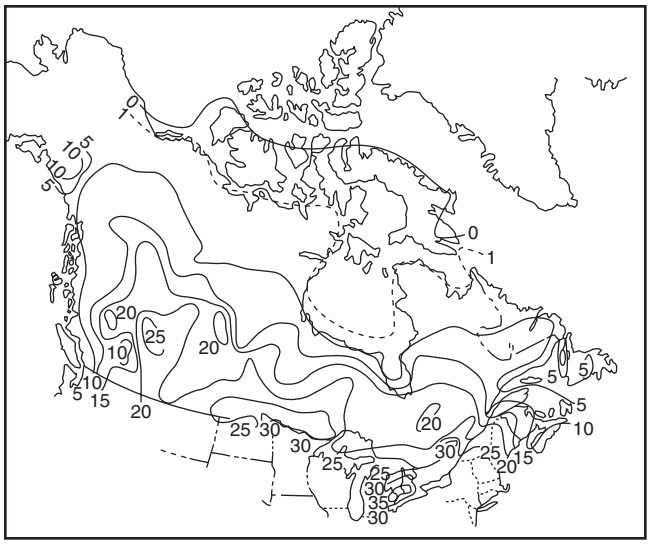

FIGURE 11.6.2 Canadian Statistics Showing Annual Average of Days with Thunderstorms in the Period 1957 to 1972 (Source: Meteorological Division, Department of Transportation, Canada)

storm cells. Because a lightning strike may lead to considerable discomfort, if not injury or death, lightning protection may be necessary to eliminate possible personnel hazards in buildings of any type (other than those constructed of structural steel framing).

Relative Exposure

Lightning will nearly always strike the highest point in its area of impact. In closely built-up towns and cities, this means the hazard is not as great to one-story buildings or individuals outside as it is in open country. In rural areas, however, a one-story barn is likely to be the tallest object in its area. In hilly or mountainous areas, a building located on high ground is usually subject to greater hazard than is one in a valley or in an otherwise sheltered area.

Indirect Losses

In addition to direct losses (e.g., damage to buildings or their contents by lightning, fire resulting from lightning, death of livestock, etc.), there could be indirect losses. Interruption of business, computer, or farming operations, especially at certain times of the year, can involve losses quite distinct from and in addition to those arising from direct property damage. In some cases, whole communities depend on the integrity of a single structure for a measure of safety and comfort, for example, the brick chimney of a water pumping plant or a hospital smokestack. A stroke of lightning to the unprotected chimney of a plant of that sort might have serious consequences, resulting in lack of sanitary drinking water, irrigating water, water for fire protection, or lack of medical services when most needed during stormy weather, or some similar effect.

NATURE OF LIGHTNING

The planet and its atmosphere can be viewed as a large spherical capacitor, with the earth at about 300,000 volts negative,

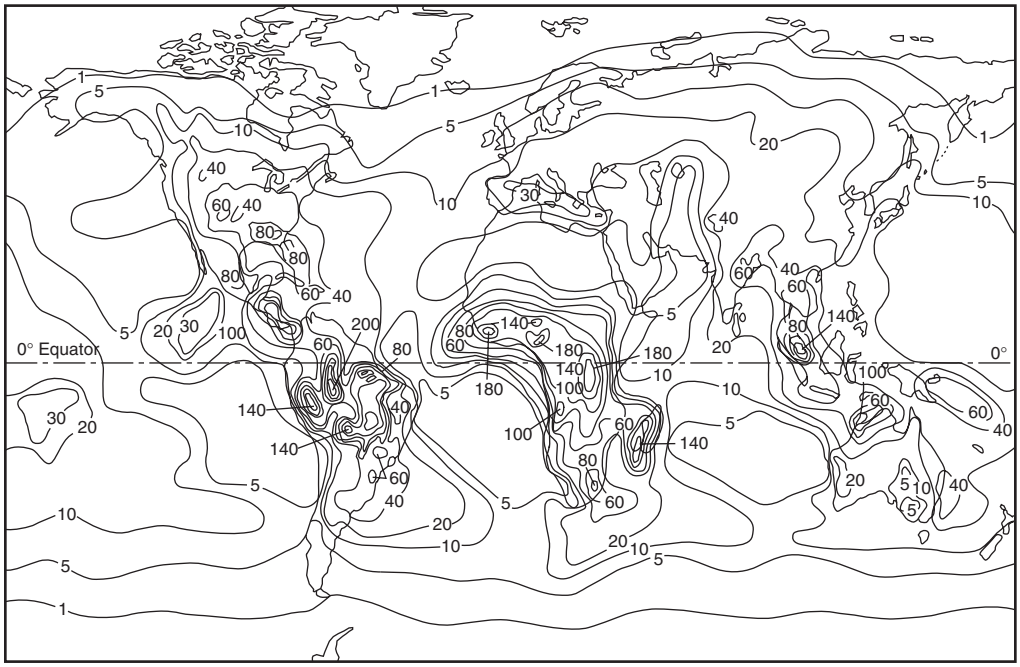

FIGURE 11.6.3 Annual Frequency of Thunderstorm Days as Compiled by the World Meteorological Organization, 1956 (Source: World Meteorological Organization)

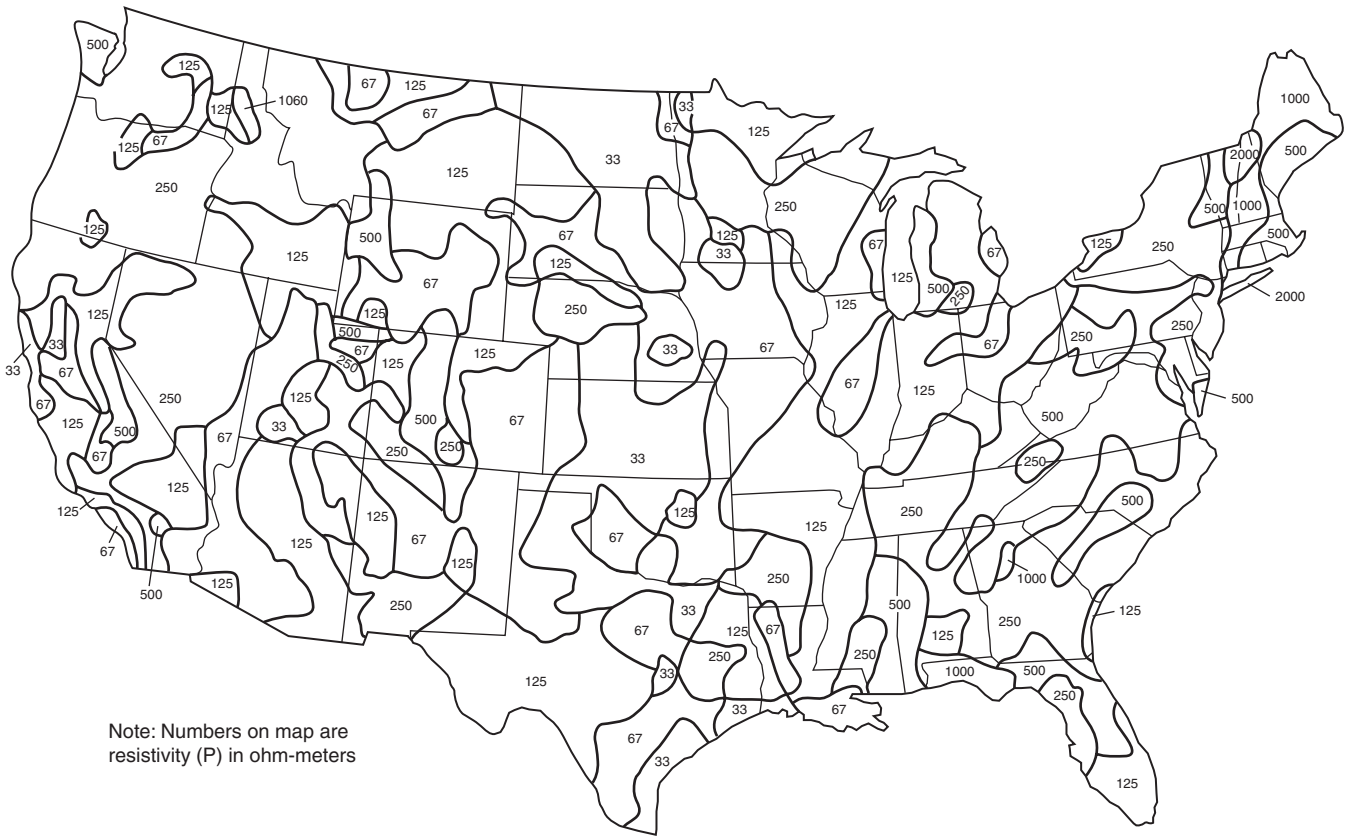

FIGURE 11.6.4 Estimated Average Earth Resistivity in Continental United States

with respect to the upper ionosphere. This potential difference powers a flow of electricity from the earth to the atmosphere. The rate of current flow, calculated at approximately 1400 to 1800 A, is spread out over the earth's entire surface. Therefore, this amounts to about 0.00009 A/mi^2 (0.000035A/km^2). Under clear, normal conditions, the electrostatic field intensity at the earth's surface is 150 to 200 volts per meter (V/m) of elevation. As a thunderstorm approaches, the potential difference rises to 10,000 to 30,000 V/m of elevation.

Air currents pick up moisture as they pass over large bodies of water, such as lakes, rivers, and oceans. This air mass is heated when it passes over warmer land masses, causing it to rise. As the moist air mass passes through the 14,000 ft (4200 m) elevation, the moisture condenses and forms ice crystals. The ice crystals in an active cloud become positively charged, whereas the water droplets usually have negative charges. Due to these conditions, a thundercloud normally develops a positive charge at the upper level and negative charge at the lower level. An electric field now exists within the cloud as well as above and below it. This negative charge in the lower level of the cloud induces a positive charge in grounded objects below it. Sharp pointed objects, such as flagpoles, steeples, corners of buildings, and trees, develop concentrated fields at these locations, resulting in a point-discharge current of a few amperes that moves upward in the electric field.

As the voltage between the earth and the cloud increases, the lightning discharge to earth starts at the cloud, progressing in incremental steps with a faintly luminous discharge, called a leader stroke in lengths of about 65 ft (20 m). The current in these leaders is estimated at about 200 amperes. When the faint lightning leader reaches an upward leader, an intense flash can be seen traveling upward to the cloud. This is called the return stroke and is a direct short circuit between the negative portion of the cloud and the electrostatically induced positive charge of the earth.

The development of a stepped leader is diagrammed in Figure 11.6.5. When sufficient charge has built up on a cloud, a "pilot streamer" will develop in a generally downward direction. This streamer ionizes a path in the air. The current associated with it is small, on the order of only a few amperes. The streamer initially extends on the order of 150 ft (45.7 m) below the cloud. After a pause of about 50 microseconds, the streamer will proceed for a second step, again generally downward but usually in a somewhat different direction from the initial step. Subsequent steps occur at intervals of about 50 microseconds. The path of each step is essentially straight, but each new step generally takes a different direction. The change in direction at each junction results in the zigzag path characteristic of lightning. Branches can (and often do) occur but, for simplification, these are not shown in Figure 11.6.5.

As the leader progresses downward, it creates a highly conductive ionized path in the air. Thus, the tip of the leader essentially remains at cloud potential, and the voltage gradient between the tip and the earth increases as the tip progresses

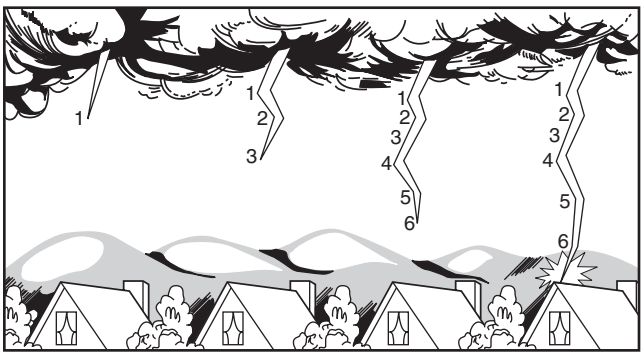

FIGURE 11.6.5 Development of a Stepped Leader

downward. At some critical point (point 6 in Figure 11.6.5), the voltage gradient becomes high enough to break down the remaining air gap, and the initial stroke to ground is completed. The point from which the final breakdown occurs is called the point of discrimination; the distance over which this breakdown occurs is defined as the striking distance.

As many as 40 component strokes have been observed in a single flash. Speeds range from 100 mi/sec (161 km/sec) for the first pilot leader stroke to 20,000 mi/sec (32,190 km/sec) for the main stroke. Currents average about 24,000 A but range up to 270,000 A in extreme cases, lasting for a few millionths of a second, but lesser currents are present for a longer period. Potentials have been estimated as high as 15 million volts.

Because of the high voltage and rapid changes in current flow, induced charges are produced that can be hazardous. Thus, NFPA 780 requires the interconnection (bonding) of metallic masses as a part of any lightning protection system, which will keep all electrically conductive components at the same potential. Bonding minimizes the likelihood of arcing between the electrically conductive components of the building and equipment in the building.

Lightning causes fire when sufficient heat is produced to ignite combustible materials in the vicinity of the lightning strike. Substantial damage, however, can be produced without resulting in fire. Dry wood beams in houses struck by lightning can be severely splintered and windows can be blown outward due to pressure wave produced from the implosion. Such damage primarily results from pressure generated by the expanding lightning channel. Because some effects of lightning can be indirect, it is not necessary for lightning to strike a building to cause damage. Lightning striking an overhead wire can be conducted over the wire to a building, where severe damage to the building wiring concealed within walls and ceiling is not visible without opening the walls. Conductor insulation and cable sheathing can be melted and decrease the dielectric strength of the insulation. This occurrence can result in a delayed reaction that could further result in arcing and a fire within the walls at a later date. Therefore, lightning arresters (surge arresters) should be provided to minimize such damage. Although there are several types of surge arresters, all permit the free flow of lightning charges to ground, while preventing the flow of ordinary electric current over the same path. The surge arrester should be backed up with a surge protective device (SPD). SPDs are required to be installed on electrical or electronic system conductors that leave a building or structure to supply electric power, signal, data, and communications systems in another structure, where the conductors are run in excess of 100 ft (30 m) and are not buried or installed in a grounded metallic conduit or tubing.

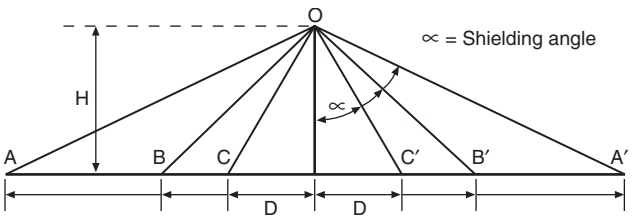
TRADITIONAL THEORY OF LIGHTNING PROTECTION

The theory of lightning protection is simple—to provide means by which a lightning discharge can enter or leave the earth without damaging the protected property. There is no evidence that any form of protection can prevent the occurrence of a lightning discharge. A lightning protection system has two functions: (1) to intercept a lightning discharge before it can strike the object protected and (2) to discharge the lightning current harmlessly to earth.

Conventional Concept

The zone protected by a grounded rod or mast is conventionally taken as the space enclosed by a cone that has its apex at the top of the mast. Similarly, the zone protected by a grounded horizontal overhead wire is conventionally taken as a triangular prism, with the upper edge along the wire. In either case, the degree of protection is generally assumed to be a function of the shielding angle, that is, the angle between an element of the cone and a vertical line through the apex, or between the side of the prism and the vertical plane through the horizontal wire. This is sometimes expressed as the ratio of the horizontal distance protected to the height of the mast or wire.

Figure 11.6.6 illustrates this concept and tabulates some generally accepted zones of protection. NFPA 780 states that, for structures not greater than 50 ft (15 m) in height, a horizontal distance equal to the height of the rod or mast has been found to be substantially immune to direct strokes. This horizontal distance extends to twice the height of the rod or mast if the structure does not exceed 25 ft (7.6 m) in height. The *British Standard Code of Practice,* "The Protection of Structures



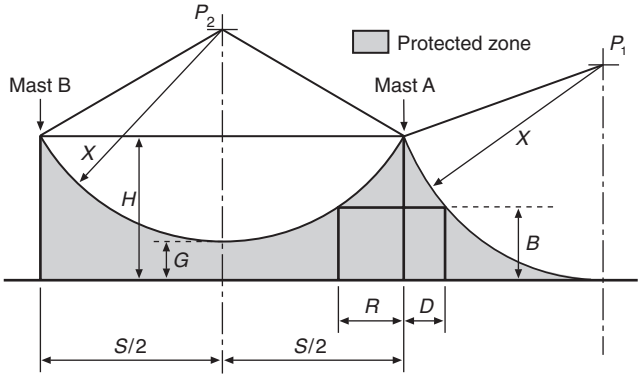
Zone	D/H	∝	Authority	Recommended for
AOA′	2/1	63°	NFPA	Ordinary cases
BOB′	1/1	45°	NFPA	Important cases
COC′	0.58/1	30°	British code	Ordinary structures
			British code	Danger structures

FIGURE 11.6.6 Conventional Concept of Protected Zones

Against Lightning,"[1] states that a shielding angle of 45 degrees provides an acceptable level of protection for ordinary structures, but for structures with explosives or highly flammable contents, the shielding angle should not exceed 30 degrees. Both codes indicate that complete protection cannot be guaranteed in any case. It is assumed, however, that the criteria presented reduce the probability of lightning strikes to a practical minimum. Although these criteria provide essentially complete protection in most cases, theoretical consideration indicates that even the 30° shielding angle is not always adequate.

Geometric Concept of Lightning Protection

The geometry of lightning protection is illustrated in Figure 11.6.7, which shows a hypothetical cross section of an area protected by two vertical masts (or horizontal overhead wires). Consider first a downward leader descending to the right of Mast A. Final breakdown will occur when the leader tip approaches within a specified distance, *X* (the striking distance), of any grounded object or surface. If the point of discrimination, *P* (the point at which final breakdown will occur), is equidistant from the tip of the mast and the ground, either the mast or the ground can be struck. If *P* is close to the mast, it will intercept the stroke; if *P* is farther from the mast, the ground will be struck. If any structure to the right of the mast extends aboveground to within a distance less than *X* of point *P,* the structure will be struck.



P_1, P_2 = Point of discrimination
X = Striking distance
R, D = Horizontal distances for protected height B
G = Minimum elevation completely protected

$$D = H\sqrt{\frac{2X}{H}} - 1 - B\sqrt{\frac{2X}{B}} - 1 \qquad (H \le X)$$

$$R = (H-G)\sqrt{\frac{2X}{(H-G)}} - 1 - (B-G)\sqrt{\frac{2X}{(B-G)}} - 1$$

$$G = H - X + \sqrt{X^2 - \left(\frac{S^2}{2}\right)} \qquad (S \le 2X)$$

For $H > X$,

$$D = X - B\sqrt{\frac{2X}{B}} - 1$$

FIGURE 11.6.7 Geometric Concept of Lightning Protection

It can be seen that the zone protected by a single mast or by an outside mast of a multimast system, in a direction away from the other masts, is bounded by the arc of a circle of radius *X,* passing through the tip of the mast and tangent to the ground. Geometrically, it can be shown that the protected distance *D,* at an elevation *B* aboveground, is given by the expression shown, where *H* is the height of the mast aboveground and *X* is the striking distance.

Similarly, for a leader extending downward between the two masts, the protected zone is bounded by the arc of a circle of radius *X* passing through the tips of the two masts. If the masts are close enough together, the space between them is completely protected for an elevation above ground, which is a function of mast height *H* and spacing *S.* In this case, the protected distance *R* at elevation *B* and the minimum elevation *G,* which is completely in the protected zone, are given by the two expressions shown.

These equations hold only if *H* is less than or equal to *X* and *S* is less than or equal to 2*X*. Furthermore, *G* must be positive. If *G* is negative, complete protection does not exist between the two masts, and the equation for *D* holds.

The geometric concept shows that the protected zone is not a cone or prism but is bounded by surfaces generated by concave arcs. This fact is not generally appreciated, although it is at least partially recognized in transmission line shielding. Furthermore, the protected distance is seen to be a function of:

1. Striking distance
2. Height of mast or overhead wire above ground
3. Distance between two or more masts or overhead wires

Figure 11.6.7 shows why the protected zone between two masts is greater than the total of the zones of the two masts considered individually. Previous NFPA lightning protection codes recognized this qualitatively but not quantitatively. The figure also shows why the shielding angle required on transmission lines decreases as tower (and overhead ground wire) height increases.

Striking Distance

The striking distance is related to the potential of the lightning stroke, which is directly related to the charge on the cloud. Because the peak stroke current is also related to the charge on the cloud, it can be shown that the striking distance is directly related to the peak stroke current. For a given mast or ground wire height, the protected distance increases with increasing striking distance. Thus, an adequately designed lightning protection system provides maximum protection against what could be the most damaging strokes. Because minimum protection exists for a minimum striking distance (and minimum stroke current), the lightning protection system should be designed to protect against minimum anticipated striking distances.

The peak stroke current is usually at least 10,000 A. This corresponds to a striking distance of slightly over 100 ft (30.5 m). It is, therefore, believed that a protective system based on this minimum striking distance will essentially provide complete protection. This scenario is considered to be a reasonable design basis.

Design Curves

Using the derived equations and an assumed striking distance, the protection provided by a single mast (or horizontal overhead wire) can be readily calculated. Similarly, the configuration of masts or overhead wires required to protect a given structure can be investigated. However, the calculations are tedious, and it is not convenient to determine directly by simple algebra the mast or overhead wire height required to protect a structure of given dimensions. Hence, curves showing the relationship between protected zones and various mast or horizontal overhead wire configurations are useful. Such curves can be readily constructed graphically (Figures 11.6.8 and 11.6.9). In Figure 11.6.8, the solid curves are the geometric concept, with a striking distance of 100 ft (30.5 m). The dashed lines are the conventional concept, with a shielding angle of 45 degrees. H equals the height of the mast or horizontal wire. In Figure 11.6.9, the striking distance is 100 ft (30.5 m). H equals the height of the horizontal wire, S is the spacing between masts or wires, and B is the height protected above ground.

PROPERTY PROTECTION

Components

Air Terminals. According to current United States practice, as indicated in NFPA 780, conditions required for protection of ordinary buildings are met by placing metal air terminals on the uppermost parts of the building or its projections, with conductors connecting the air terminals with each other and to the ground. By this means, a relatively small amount of metal, properly proportioned and distributed, affords a satisfactory degree of protection and can be installed in a way that interferes only minimally with the contour and appearance of the building. In the current *British Standard Code of Practice*,[1] the use of pointed air terminals (vertical finials) is not considered essential, except where dictated by practical considerations.

One theory states that a protective system based on a minimum striking distance of 100 ft (30.5 m) for structures containing flammable liquids and gases will provide 99.9 percent protection, and a minimum striking distance of 150 ft (45.7 m) will provide 99.5 percent protection for ordinary structures that are generally capable of withstanding minor direct strikes.[2–4] This theory supports the use of 10 in. (254 mm) minimum height air terminals above the object to be protected at 20 ft (6.1 m) maximum intervals. A convenient geometric equation

$$Y = \sqrt{R^2 - (R - h)^2}$$

where

Y = Radius of horizontal protected zone

R = Striking distance

h = Height of air terminal

illustrates that a striking distance of 100 ft (30.5 m) will provide a 12.9 ft (3.9 m) radius of horizontal protected zone or 25.8 ft (7.9 m) horizontal protected zone between air terminals, and a striking distance of 150 ft (45.7 m) will provide a 15.8 ft (4.8 m) radius of horizontal protected zone or 31.6 ft (9.6 m) horizontal protected zone between air terminals.

The subject of sharply pointed versus blunt air terminals is under study by the NFPA Lightning Protection Committee. According to Moore et al.,[5] pointed air terminals have a built-in defense against lightning strikes. The strength of the electric field

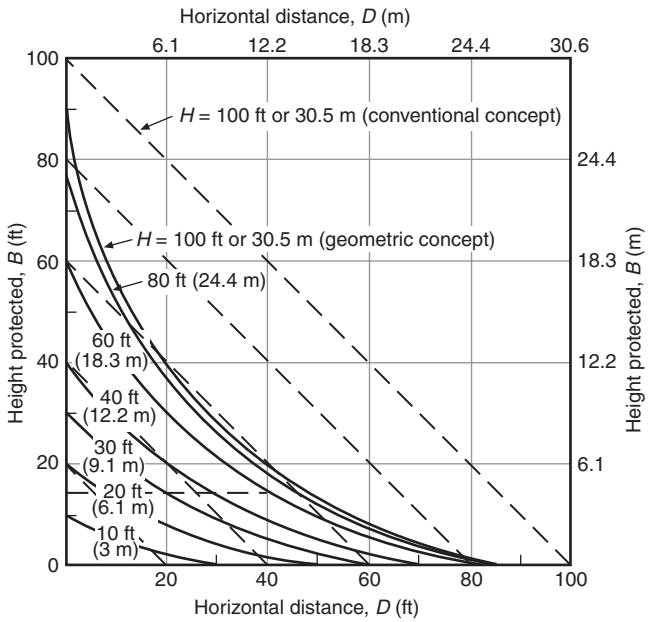


FIGURE 11.6.8 Zone Protected by a Single Mast, Horizontal Wire, or Air Terminal

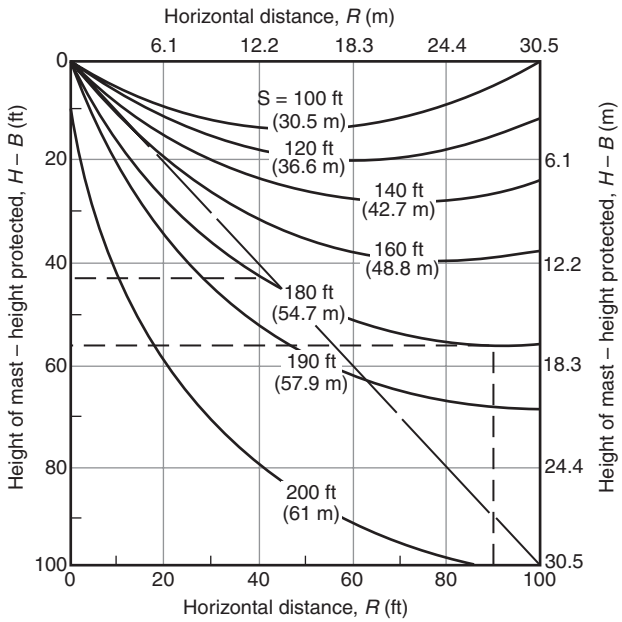

FIGURE 11.6.9 Zone Protected by Two Masts, Two Horizontal Wires, or Two Air Terminals

around the tip of an air terminal is limited by a phenomenon called "point discharge." When the electric field reaches a certain strength but before lightning strikes, the stepped leader current flows from the air through the air terminal to the ground. The effect is called point discharge because the point is letting the surrounding air lose charge or discharge electricity. A pointed air terminal will presumably discharge sooner than a blunt one. Accordingly, Moore et al.[5] concluded that a blunt air terminal is more likely to intercept a lightning strike and complete a circuit.

Conductors. NFPA 780 specifies the use of copper or aluminum metals for lightning conductors. When copper and aluminum are used together, special precautions must be taken against electrolytic corrosion. Conductors are coursed along ridges of sloping roofs, around the edges of flat roofs, and vertically from these and from the air terminals to ground. Vertical runs are designated as "down conductors," and there are never fewer than two on any kind of structure, except for flagpoles, masts, spires, and similar structures. The down conductors are normally placed at diagonally opposite corners of square or rectangular structures, but other factors, such as direct coursing, security against displacement, location of metallic elements in the structure, location of water pipes, and favorable ground conditions, need to be considered in determining optimum placement. For detailed instructions about the installation of conductors, their form and size, and about the installation of air terminals, refer to the latest edition of NFPA 780.

The down conductors to ground must be substantial and must provide a reasonably direct path. The blocking effect (choke) of electrical induction must be avoided. For example, a lightning conductor that is installed within a piece of iron pipe for mechanical protection must be bonded to the pipe at both ends to reduce the choke effect on the conductor, which increases the impedance of the conductor.[6]

Grounding. Ground connections are essential if a lightning protection system is to be effective; every effort should be made to provide ample contact with the earth (Figure 11.6.10). Resistance of the protective system to ground is not critical. However, resistance and surge impedance must be low enough to prevent side flashes between the down conductor and other grounded objects. The resistance also must be low enough to prevent

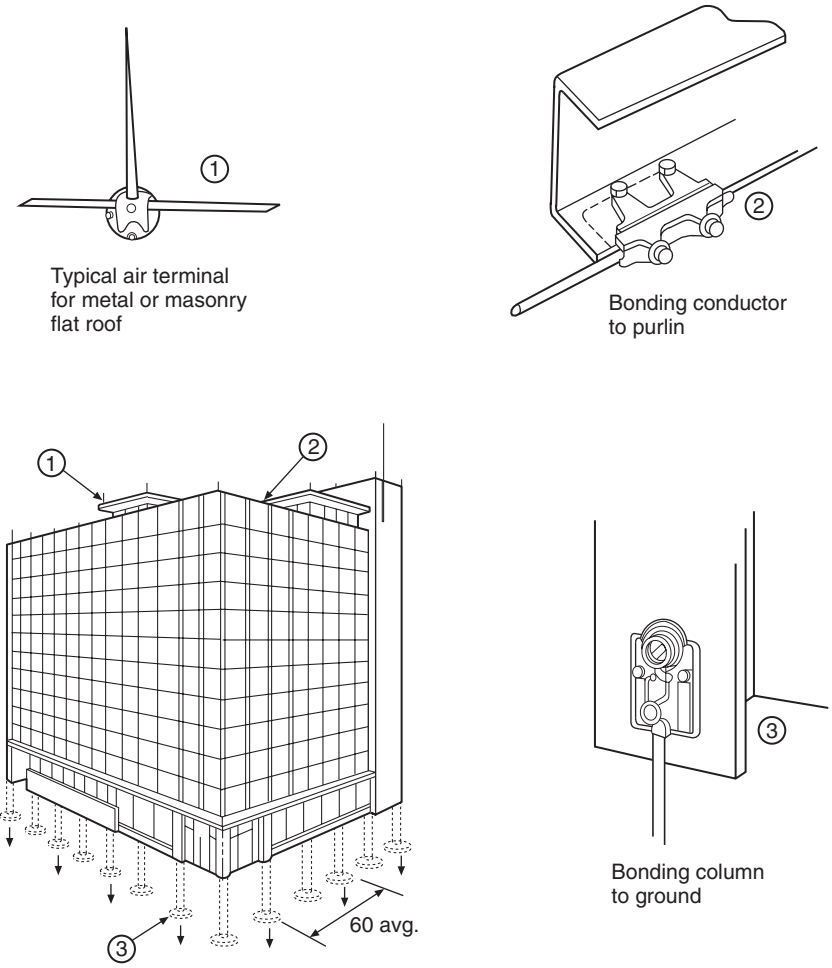

FIGURE 11.6.10 Grounding and Bonding of Lightning Down Conductors. Water pipe ground (if pipes are metallic) can be made at 1, 2, or 3.

excessive voltage gradients in the soil surrounding the ground electrode. Excessive voltage gradients can be dangerous or fatal to people or animals that might be standing or walking in the vicinity when a lightning stroke occurs. If the down conductor is remote from other grounded objects and people or animals are not likely to be near the ground electrode during a lightning storm, a relatively high ground resistance can be tolerated. Otherwise, an extensive wire network will need to be laid on the surface.

NFPA 780 does not specify any maximum recommended ground resistance. The *British Standard Code of Practice*[1] recommends a maximum resistance of 10 Ω for a lightning protection system that will normally include two or more ground electrodes. Also 10 Ω is generally considered a reasonably good ground resistance for transmission towers. In this case, a high ground resistance might result in flashover to the line conductors, even though the overhead ground wire intercepts the direct lightning stroke. The U.S. Department of Agriculture recommends a ground resistance not greater than 50 Ω as acceptable for protection of farm structures.

The ground resistance of a ground electrode is directly proportional to soil resistivity. Soil resistivity varies over wide limits, as shown in Figure 11.6.4; nevertheless, 10,000 Ω/cm is a reasonable order of magnitude average for many areas. Figure 11.6.11, which is based on derived equations,[7] has been prepared to show the variation in resistance to earth of vertical rods or pipes as a function of length in 10,000 Ω/cm soil. For other soil resistivities, the resistance to ground can be obtained by multiplying the indicated resistance by the known soil resistivity divided by 10,000. Vertical rods driven into the ground are commonly used as grounding electrodes. In addition, where buried metallic water pipes are nearby, it is required to connect the lightning protection ground system to the piping system.

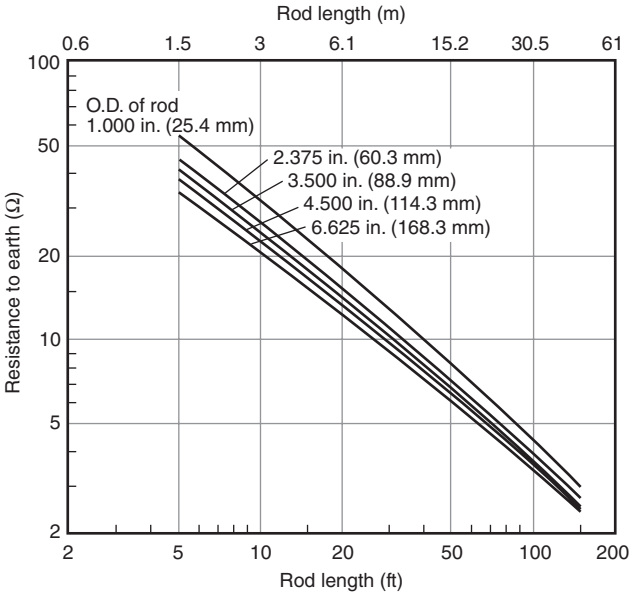

FIGURE 11.6.11 Resistance of Vertical Ground Rods in 10,000 Ω/cm Soil

If bedrock is on or near the surface, it would be impossible to make a ground connection in the ordinary sense of the term because most kinds of rock are insulating or at least of high resistivity and, in order to obtain effective grounding, other and more elaborate means are necessary. An effective method to achieve grounding is to use an extensive wire network (grid) laid on the surface of the rock surrounding the building, to which the down conductors are connected. Another method is to install a ground ring interconnecting the down conductors, with metal straps running outward in a radial formation on the surface of the rock from each of the down conductors. One ground ring should be installed at the bottom of the foundation to which the down conductors or structural steelwork are connected, with a second ring conductor provided by blasting a circular trench around the periphery and placing in it a strip conductor. The blasted area should be thoroughly compacted with backfill, and the two ground ring conductors should be electrically interconnected. Using one of these methods would make the distribution of the electrical potential around the protected building substantially the same as if it were resting on conducting soil; the resulting protective effect would be equal.

For sandy soil or any dirt covering the foundation, a concrete-encased electrode (commonly called a Ufer ground, after the inventor Herb Ufer) should be installed for new construction. This electrode consists of steel reinforcing bars or rods tied together in the footing of the foundation that is in direct contact with the earth.

In general, the extent of the grounding arrangements will depend on the character of the soil, ranging from simple extension of the conductor into the ground where the soil is deep and of high conductivity, to an elaborate buried network where the soil is very dry or of very poor conductivity. Where a network is required, it should be buried if there is soil enough to permit it, as doing so adds to its effectiveness. Its extent will be determined largely by the judgment of the person planning the installation, following the minimum requirements of NFPA 780, and keeping in mind that, as a rule, the more extensive the underground metal available, the more effective the protection.

Protection of Structures (Traditional Systems)

Underwriters Laboratories Inc. "Master Label Service" for Lightning Protection Systems. Underwriters Laboratories Inc. (UL) has had a "Master Label Service" for lightning protection systems since 1923. It provides for both factory inspection and labeling of lightning protection materials (components), as well as field inspections of a substantial number of installations for which Master Labels have been issued. The service covers the installation of labeled lightning protection materials (components) on all types of structures, with the exception of those used for the production, handling, or storage of ammunition, explosives, flammable liquids or gases, and explosive ingredients. Protection of electrical transmission lines and equipment is not within the scope of the "Master Label Service."

Structural Steel Buildings. Buildings constructed of structural steel framing can be protected by the installation of air terminals at the high parts of the building, connecting such air terminals to

the metal framing, and grounding the framing at the bottom end. This construction assumes that the structural steel framework is inherently electrically continuous or is made electrically continuous by bonding. Grounding is required from approximately every other steel column around the perimeter and is arranged so that grounds average not more than 100 ft (30.5 m) apart, except as noted in the following.

Air terminals are not required if the steel columns extend at least 10 in. (254 mm) above the object to be protected. Air terminals are not required on metal roofs where the metal is not less than 3⁄16 in. (4.8 mm) thick.

Additional grounding is not required if the steel column extends 10 ft (3.05 m) or more into the earth or is connected to a concrete-encased electrode.

Reinforced Concrete Structures. Reinforced concrete buildings in which the reinforcing rods are electrically bonded together and grounded are similar to structural steel buildings in regard to lightning protection. In usual building practice, as successive reinforcing bars are fitted, they are made to overlap lengthwise with bars already installed and are then tied together with metal binding wire. With thousands of such connections in a completed framework, the electrical resistance is fully acceptable for the purpose of lightning protection. However, if the reinforcing rods are electrically discontinuous, the building should be treated the same as a building of nonconducting materials. Lightning strokes to reinforced concrete buildings where there are insulating gaps between reinforcing rods can cause cracks at places where beams and floor slabs are connected to their supports. Prestressed concrete buildings are a particular problem. If the wires in precast units are not interconnected (as they frequently are not), individual units are isolated and when a lightning charge is induced, serious damage can result.

Metal-Roofed and Metal-Clad Buildings. Metal roofing and siding must not be substituted for the main conductors and air terminals of a lightning protection system, unless constructed of 3⁄16 in. (4.8 mm) minimum sheet metal that has been made electrically continuous by bonding or an approved interlocking contact. This requirement is because there is a likelihood that lightning will puncture thinner sheet metals and ignite wood framing.

Tanks Containing Flammable and Combustible Liquids and Gases. Tanks containing flammable and combustible liquids or flammable gases stored at atmospheric pressures have been ignited by lightning. Fires can be started by direct hits, which ignite vapors escaping from metal floating roof tanks. Roofs of wooden tanks can ignite from a direct strike. A lightning stroke in the vicinity can, by induction, produce sparks that might ignite such vapors. If there are openings in the roof, either intentional or unintentional, externally ignited vapors might carry flame inside the tank, resulting in an explosion or fire if it contains a flammable or combustible vapor-air mixture.

Aboveground tanks storing flammable or combustible liquids or flammable gases at atmospheric pressures are considered to be reasonably well protected against lightning if constructed entirely of steel, and if (1) all joints between steel plates are riveted, bolted, or welded; (2) all pipes entering the tanks are metallically connected to the tank at point of entrance; (3) all vapor openings are closed or are provided with flame arresters (for Class I liquids as defined by NFPA 30, *Flammable and Combustible Liquids Code*); (4) the tank and roof are constructed of 3⁄16 in. (4.8 mm) minimum thick sheet metal so holes will not be burned through by lightning strokes; and (5) the roof is continuously welded, bolted, or riveted and caulked to the shell to provide a vapor-tight seam and electrical continuity. Where additional protection is desired, the internal supporting members of the roof can be bonded to the roof at 10 ft (3.05 m) intervals or an overhead ground-wire system or mast protection can be installed in accordance with NFPA 780 (Figure 11.6.12).

Steel tanks in direct contact with the ground or aboveground steel tanks connected to extensive properly grounded metallic piping systems are considered to be inherently grounded. Steel tanks with wood or other nonmetallic roofs are not considered self-protecting, even if the roofs are essentially vapor-tight or sheathed with thin metal. Such tanks should be protected by an overhead catenary ground-wire system or mast protection (see Figure 11.6.12).

Floating roof tanks with hangers located within the vapor space can be protected by bonding the roof to the shoes of the seal at 10 ft (3.05 m) intervals around the circumference of the tank and by providing insulated joints or installing jumper bonds around each pinned joint of the hanger mechanism. Floating roof tanks without vapor spaces do not appear to need lightning protective measures.

Aboveground storage tanks or containers of flammable liquids or liquefied petroleum gas under pressure are considered to be safe from lightning-caused explosions because the vapor-air mixture is "too rich" to burn and the vapor is contained within the tank.

Tall Structures. Spires, masts, and flagpoles of materials other than metal and other slender structures require one air terminal extending 10 in. (254 mm) or more above the uppermost point, a down conductor, and a ground terminal in compliance with NFPA 780. Church steeples will require one air terminal with a two-way path to ground at the extremities and additional air terminals on the lower-level portion that is outside of the steeple's zone of protection.

In Great Britain, brick chimneys, church spires, and so on are protected by two down conductors connected at the top to an existing metal cap or to a circular conductor with no air terminals (Figure 11.6.13[1]). Note the absence of air terminals on the lower-level portion; protection is provided by an elevated conductor above the ridge. Metal smokestacks need no protection against lightning other than that provided by their construction if they are grounded.

Trees, Other Specialized Structures, and Facilities. Trees are sometimes provided with lightning protection if they are especially valuable, are of historical significance, overhang buildings, or provide a shelter for livestock. Guidance on the installation of lightning protection is given in the appendices of NFPA 780, such as for (1) parked aircraft; (2) livestock in fields;

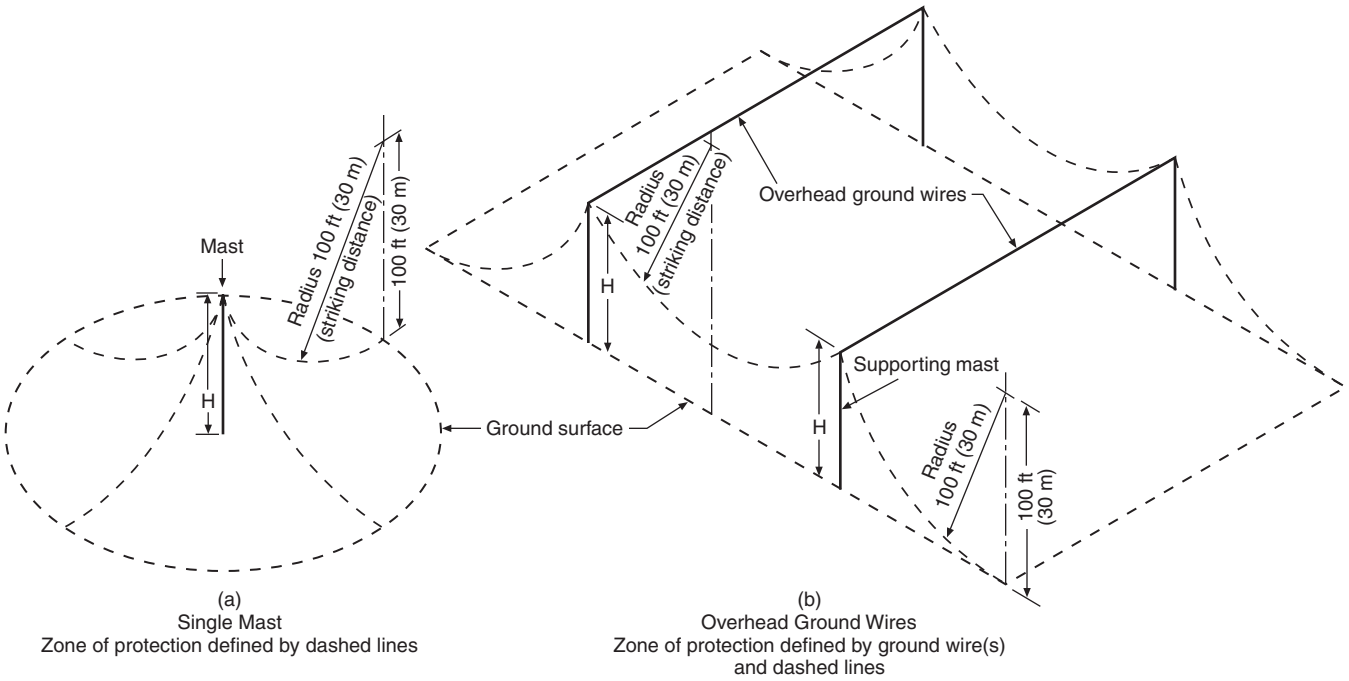

FIGURE 11.6.12 Zone of Protection for Mast Height H

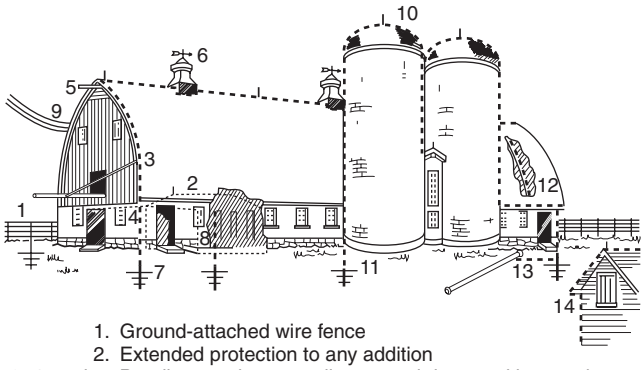

FIGURE 11.6.14 Lightning Protection System on a Typical Large Barn

and (3) picnic grounds, playgrounds, ballparks, and other open places (Figure 11.6.14).

Grounding Metal Masses (Bonding). Extensive masses of metal that form part of a building or its appurtenances, such as metal ventilators and television or radio antennas, must be bonded to the lightning protection system. Nevertheless, the grounding of metal windowsills could be a hazard to human life in the event of a direct lightning strike. Details are given in NFPA 780, under "Metal Bodies," "Potential Equalization," and "Bonding of Metal Bodies," which determine the need for bonding and require loop conductors around a structure at various levels to be bonded to

all down conductors. This standard provides an equipotential ground grid that causes the different metal components in the structure to be at the same voltage, thereby minimizing the shock and arcing hazard and also decreasing the amount of current that could affect computers and other electronic equipment.

Maintenance

Proper maintenance of lightning protection systems is essential. Particular attention should be given to air terminals and connections in the vicinity of water gutters and ground rod connections, as rods might be broken or corroded at ground level or just below, where the damage is not apparent. Materials (components) might be missing because of storm damage or stolen because of their value.

Surge Arresters and Suppressors on Electrical Apparatus and Circuits

The installation of surge arresters on power and communications lines where they enter structures and at power utility plants is covered in Article 280 of NFPA 70, *National Electrical Code*®. The use of secondary service arresters on electric services is required for buildings equipped with a UL Master-Labeled Lightning Protection System. Such arresters can be installed at the yard pole, at the outside electric service entrance, or at the interior service entrance equipment, depending on local regulations. Home lightning protectors are available that are designed for installation at the dwelling weatherhead or indoors at the service entrance equipment. These protectors (arresters) drain lightning surge-induced charges harmlessly to ground and then open to restore electrical service to normal. Before a secondary service arrester is installed, it should be determined that the neutral wire is grounded.

With the installation of sophisticated electronic equipment in many homes and in industry, it is imperative that surge arresters and transient voltage surge suppressors be incorporated to complete the lightning protection system. The surge arrester should be coupled with a transient voltage surge suppressor on branch circuits that serve computers and electronic appliances. These devices are constructed as portable (plug-in) or permanently wired units.

In the United States, except on the Pacific Coast where lightning storms are infrequent, most electric utilities install lightning arresters on the primaries of important transformers on systems of 44,000 V or less.

PROTECTION OF PERSONS

The risk of direct lightning strike is greatest among persons whose occupations keep them outdoors. Prevention of injuries due to lightning or lightning-induced fire involves a combination of protection of the structure from fire due to lightning and the usual steps to protect occupants of a building from injury due to fire.

Guide for Personal Safety During Thunderstorms

Persons should not go out of doors or remain outside during thunderstorms, unless it is necessary. They should seek shelter inside buildings, vehicles, or other structures or locations that offer protection from lightning, such as the following places:

- Dwellings or other buildings that are protected against lightning
- Underground shelters, such as subways, tunnels, and caves
- Large metal or metal-framed buildings
- Large unprotected buildings
- Enclosed automobiles, buses, and other vehicles with metal tops and bodies
- Enclosed trains and streetcars
- Enclosed metal boats or ships
- Boats that are protected against lightning
- City streets that are shielded by nearby buildings

If possible, they should avoid the following places that offer little or no protection from lightning:

- Small unprotected buildings, structures, barns, sheds, and so on
- Tents and temporary shelters (not lightning protected)
- Automobiles (nonmetal top or open tops)
- Recreational vehicles (nonmetal or open)

They should also avoid use of or contact with electrical appliances, telephones, and plumbing fixtures. Certain locations are extremely hazardous during thunderstorms and should be avoided if at all possible. Approaching thunderstorms should be anticipated and the following locations avoided when storms are in the immediate vicinity:

- Open fields, athletic fields, hilltops, and golf courses
- Parking lots and tennis courts
- Swimming pools, lakes, and seashores
- Areas near wire fences, clotheslines, overhead wires, and railroad tracks
- Areas under isolated trees

In the preceding locations, it is especially hazardous to be riding in or on any of the following during lightning storms:

- Open tractors and other farm machinery operated in open fields
- Golf carts, scooters, bicycles, and motorcycles
- Open boats (without masts) and hovercraft
- Automobiles (nonmetal top or open)

It might not always be possible to choose an outdoor location that offers good protection from lightning. Persons should follow these rules when there is a choice in selecting locations:

- Seek low-lying areas; avoid hilltops and other high places.
- Seek dense woods; avoid isolated trees.
- Seek buildings, tents, and shelters in low areas; avoid unprotected buildings and shelters in high areas.
- If you are isolated in an exposed area, believe a lightning strike is imminent, and cannot reach shelter, crouch as low as possible, with your feet close together to minimize the area of the body in contact with the ground. Do not lie flat on the ground or place your hands on the ground.

SUMMARY

Lightning or lightning-caused fire results in dozens of deaths a year. The need for lightning protection depends in part on geography, because the frequency and severity of thunderstorms vary throughout the world. The degree of lightning protection installed should take into account the nature of the building. For instance, certain types of buildings that are essential to life safety, such as hospitals, police and fire stations, and military installations, or historically important buildings should have lightning protection systems installed if they are in vulnerable areas. However, some buildings do not require supplemental protection because of their construction. Although no lightning protection system can prevent the occurrence of a lightning discharge, protection is achieved by intercepting the current, which is then discharged harmlessly into the earth. A lightning protection system usually consists of a grounded metal mast or multimast system, overhead wires, or air terminals. The type of lightning protection system needed is determined by the physical characteristics of the building and the properties of its contents.

For personal protection against lightning, certain areas such as golf courses, swimming pools, areas near railroad tracks, and areas under isolated trees should be avoided during thunderstorms. Vulnerable vehicles such as open cars, tractors, or boats and electrical appliances and plumbing fixtures should also be avoided. People who find themselves out of doors should seek shelter in a lightning-protected building or, if this is not possible, seek low areas or dense woods. An individual who is isolated in an exposed area should crouch down with feet close together and with hands off the ground.

NFPA Codes, Standards, and Recommended Practices

Reference to the following NFPA codes, standards, and recommended practices will provide further information on lightning protection systems discussed in this chapter. (See the latest version of The NFPA Catalog *for availability of current editions of the following documents.)*

NFPA 30, *Flammable and Combustible Liquids Code*
NFPA 70, *National Electrical Code®*
NFPA 302, *Fire Protection Standard for Pleasure and Commercial Motor Craft*
NFPA 780, *Standard for the Installation of Lightning Protection Systems*

ANSI Standards, Surge Arresters

ANSI/IEEE C62.1–1989, *Gapped Silicon-Carbide Surge Arresters for Alternating-Current Power Circuits*
ANSI/IEEE C62.11–1993, *Standard for Metal-Oxide Surge Arrestor for AC Power Circuits*
ANSI/IEEE C62.31–1987, *Specifications for Gas Tube Surge-Protective Devices, Test*
ANSI/IEEE C62.32–81, *Standard Test Specifications for Low-Voltage Air Gap Surge-Protective Devices (Excluding Valve and Expulsion Devices)* (R1994)

air-inflated, 20-222
air-supported, 20-222, Fig. 20.20.3
cable-supported, 20-222, Fig. 20.20.4
defined, 20-222
membrane combustibility, 20-222–20-223
as special structures, 20-222–20-223
Memorial Tunnel Fire Ventilation Test Program, 21-206, 21-207–21-210, Tables 21.11.10–21.11.14
Mercantile occupancies
bulk merchandising retail stores, 20-98
classifications
accessory occupancies, 20-98
large occupancies, 20-98
medium occupancies, 20-98
small occupancies, 20-97–20-98
fire load, 20-99
life safety factors, 20-102–20-103
mall buildings
defined, 20-99
design, 20-99–20-100
exit access, 20-101–20-102
exiting concept, 20-100
means of egress, 20-102
occupant allowance requirements, 20-100, Fig. 20.10.2
separation of tenant stores, 20-102
single-level/multilevel design, 20-99, 20-100–20-102, Fig. 20.10.1, Figs. 20.10.3–20.10.4
smoke management, 20-102
sprinkler protection, 20-102
systems approach, 20-100–20-102
occupant load, 20-99
Mercy Hospital fire (1950), 3-23
Meridian Plaza fire (1991), 1-165, 12-138, 16-44, 19-67
MERV filters. *See* Minimum efficiency reporting value (MERV) filters
Mesa (Ariz.) Fire Department, performance management, 12-26
Metal(s). *See also* specific metals
alkali as water reactive, 6-153, 6-159, 6-160
combustibility, 6-153
factors, 6-154–6-155
dusts (*see also* Dust(s))
combustibility/explosivity, 6-154–6-155
precipitation, Figs. 6.9.2–6.9.4
explosivity, 6-153, 6-154–6-155, Fig. 6.9.1
fire/life safety requirements, 6-153
fire prevention/protection, 6-155
ignition temperatures, Table 6.9.1
water reactivity, 6-153, 6-154, 6-155
